FIGURE 21-4 Dermatomes (cutaneous innervation of spinal nerves). Stimulation of the skin in the depicted area for each nerve causes reflex activity. C, Cervical spinal nerves; L, lumbar spinal nerves; S, sacral spinal nerves; T, thoracic spinal nerves. (From Ignatavicius DD, Workman ML: *Medical-surgical nursing: Critical thinking for collaborative care*, ed. 6, Philadelphia, 2010, Saunders.)

- There are 12 pairs of cranial nerves, some of which are sensory nerves and others of which are motor nerves (Table 21-2).

Table 21-2
The Cranial Nerves and Their Functions

TYPE AND FUNCTION	
Olfactory (CN I)	Sensory: smell
Optic (CN II)	Sensory: visual acuity, field of vision, pupillary response (afferent impulse)
Oculomotor (CN III)	Motor: eyelid elevation, extraocular eye movement, pupil size, convergence, pupillary constriction (efferent impulse)
Trochlear (CN IV)	Motor: extraocular eye movement (inferior and lateral)
Trigeminal (CN V)	Sensory: corneal reflex Motor: facial sensation; chewing, biting, lateral jaw movement
Abducens (CN VI)	Motor: extraocular eye movement (lateral)
Facial (CN VII)	Sensory: taste Motor: facial muscle movement, including muscles of expression; lacrimal gland and salivary gland control
Acoustic (CN VIII)	Sensory: hearing, sense of balance
Glossopharyngeal (CN IX)	Sensory: sensations of the throat, taste (posterior tongue) Motor: gagging and swallowing movements
Vagus (CN X)	Sensory: sensations of posterior tongue, throat, larynx; impulses from heart, lungs, bronchi, and gastrointestinal tract
Spinal accessory (CN XI)	Motor: shoulder movement and head rotation
Hypoglossal (CN XII)	Motor: tongue movement, articulation of speech

- The spinal cord extends from the medulla to the level of the first lumbar vertebra.
- The spinal cord is a conduction pathway for impulses going to and from the brain and also serves as a reflex center for nerve impulse transmission. Sensory impulses travel to the brain on ascending conduction pathway tracts; motor impulses travel on descending tracts.
- Pyramidal tracts are conduction pathways that begin in the cerebral cortex and end in the spinal cord. These tracts control skeletal muscle movement. All other conduction pathways are

extrapyramidal tracts, and they control muscle movements associated with posture and balance.

Nerves Conduction of Impulses

- The axons of many neurons, bundled together and wrapped in connective tissue, make up a nerve. Ganglia are collections of nerve cell bodies outside the CNS.
- When in a state of polarization, neurons have the capacity to become excited (stimulated). They also have the ability to conduct that stimulus along the nerve pathways.
- A stimulus is a physical, chemical, or electrical event that changes the cell membrane and initiates conduction of the stimulus as an electrical impulse along the nerve pathway.
- The stimulus travels from one neuron to another across a **synapse** (the space between two neurons).
- A neurotransmitter secreted by the neuron is necessary for transmission of an impulse across the synapse ([Table 21-3](#)). Acetylcholine, dopamine, and norepinephrine are the major neurotransmitters.

Table 21-3

Neurotransmitters That Affect Transmission of Nerve Impulses

NEUROTRANSMITTER	LOCATION	FUNCTION	COMMENTS
Acetylcholine	CNS and PNS	Generally excitatory but is inhibitory to some visceral effectors	Found in skeletal neuromuscular junctions and in many ANS synapses
Norepinephrine	CNS and PNS	May be excitatory or inhibitory depending on the receptors	Found in visceral and cardiac muscle neuromuscular junctions; cocaine and amphetamines exaggerate the effects
Epinephrine	CNS and PNS	May be excitatory or inhibitory depending on the receptors	Found in pathways concerned with behavior and mood
Dopamine	CNS and PNS	Generally excitatory	Found in pathways that regulate emotional responses; decreased levels in Parkinson disease
Serotonin	CNS	Generally inhibitory	Found in pathways that regulate temperature, sensory perception, mood, onset of sleep
Gamma-aminobutyric acid (GABA)	CNS	Generally inhibitory	Inhibits excessive discharge of neurons
Endorphins and enkephalins	CNS	Generally inhibitory	Inhibit release of sensory pain neurotransmitters; opiates mimic the effects of these peptides

ANS, Autonomic nervous system; CNS, central nervous system; PNS, peripheral nervous system.

From Applegate E: *The anatomy and physiology learning system*, ed. 4, Philadelphia, 2010, Elsevier Saunders.

- Neurotransmitter substances are secreted at the synapse, and these diffuse across the synapse to stimulate the postsynaptic membrane on the next neuron. **When the neurotransmitter is absent or decreased at the synaptic junction, the stimulus cannot travel along the nerve pathways normally.**
- Impulses either travel in a reflex arc, going to the spinal cord and traveling back to an effector site, or they travel along nerve pathways to the brain to be interpreted.
- After impulse interpretation, a message may be sent out from the brain through the spinal cord or cranial nerves (PNS) for appropriate action to be taken. In other words, a stimulus produces a response.
- Many axons are surrounded by a myelin sheath that is a white, fatty covering. The myelin sheath is an excellent electrical insulator and it speeds the conduction of nerve impulses. **When myelin is destroyed, as in multiple sclerosis, impulse transmission is slowed or stopped.**

Interaction of the Peripheral Nervous System With the Central Nervous System

- The PNS is subdivided into an afferent division and an efferent division. The afferent division carries impulses to the CNS; the efferent division carries impulses away from the CNS.
- The reflex arc is a simple conduction pathway that uses a receptor (a sensory neuron centered in the spinal cord) and a motor neuron located in an effector (skeletal muscle). A stimulus travels from the sensory receptor through the spinal cord and back to the effector, causing action ([Figure 21-5](#)).

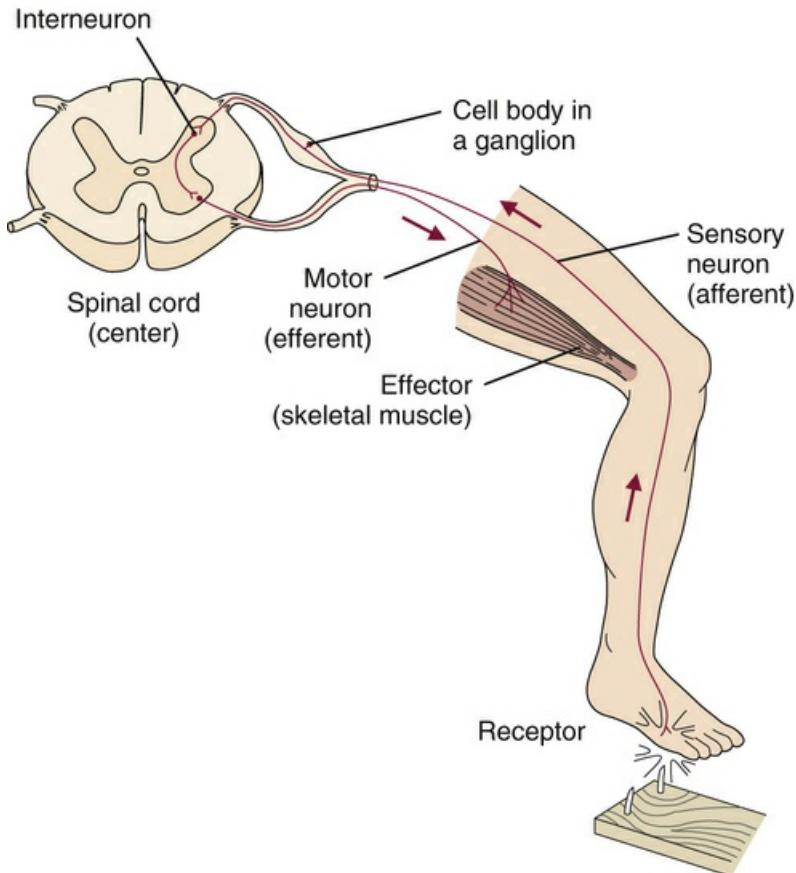

FIGURE 21-5 Components of a generalized reflex arc.

- Reflex arcs are important to most functions of the body, including maintaining an upright position.
- The cranial and spinal nerves are part of the somatic subsystem and respond to changes in the outside world. Because these nerves initiate voluntary action, the somatic system often is called the *voluntary system*.
- The autonomic system of the PNS is active in maintaining internal body balance (**homeostasis**) and is automatic (involuntary) in its actions.
- The autonomic system is divided into the sympathetic nerves, which mobilize energy to initiate changes aimed at maintaining or restoring homeostasis, and the parasympathetic nerves, which conserve and restore energy that has been used to maintain homeostasis.
- **Sympathetic and parasympathetic nerves have opposite effects on many organs** (Table 21-4).

Table 21-4
Autonomic Effects on Various Organs of the Body

ORGAN	EFFECT OF SYMPATHETIC STIMULATION	EFFECT OF PARASYMPATHETIC STIMULATION
Eye		
Pupil	Dilated	Constricted
Ciliary muscle	Slight relaxation (far vision)	Constricted (near vision)
Glands: nasal, lacrimal, parotid, submandibular, gastric, pancreatic	Vasoconstriction and slight secretion	Stimulation of copious secretion (containing many enzymes for enzyme-secreting glands)
Sweat glands	Copious sweating (cholinergic)	Sweating on palms of hands
Apocrine glands	Thick, odoriferous secretion	None
Blood vessels	Most often constricted	Most often little or no effect
Heart		
Muscle	Increased rate Increased force of contraction	Slowed rate Decreased force of contraction (especially of atria)
Coronary arteries	Dilated (beta ₂); constricted (alpha)	Dilated
Lungs		
Bronchi	Dilated	Constricted
Blood vessels	Mildly constricted	Dilated
Gut		
Lumen	Decreased peristalsis and tone	Increased peristalsis and tone
Sphincter	Increased tone (most times)	Relaxed (most times)
Liver	Glucose released	Slight glucose synthesis
Gallbladder and bile ducts	Relaxed	Contracted

Kidney	Decreased output and renin secretion	None
Bladder		
Detrusor	Relaxed (slight)	Contracted
Trigone	Contracted	Relaxed
Penis	Ejaculation	Erection
Systemic arterioles		
Abdominal viscera	Constricted	None
Muscle	Constricted (alpha-adrenergic) Dilated (beta-adrenergic) Dilated (cholinergic)	None
Skin	Constricted	None
Blood		
Coagulation	Increased	None
Glucose	Increased	None
Lipids	Increased	None
Basal metabolism	Increased up to 100%	None
Adrenal medullary secretion	Increased	None
Mental activity	Increased	None
Piloerector muscles	Contracted	None
Skeletal muscle	Increased glycogenolysis Increased strength	None
Fat cells	Lipolysis	None

From Guyton AC, Hall JE: *Textbook of medical physiology with student consult access*, ed. 12, Philadelphia, 2010, Elsevier Saunders.

Protection of the Central Nervous System

- The bones of the skull and the vertebral column form the outer layer of protection for the brain and the spinal cord.
- The meninges are protective membranes that cover the brain and are continuous with the membranes covering the spinal cord. The meninges consist of the pia mater, which covers the brain; the arachnoid, which encases the entire CNS; and the dura mater, which is a tough membrane protecting the brain and spinal cord.
- The subarachnoid space is located between the pia mater and the arachnoid membrane and is where the cerebrospinal fluid (CSF) circulates ([Figure 21-6](#)).

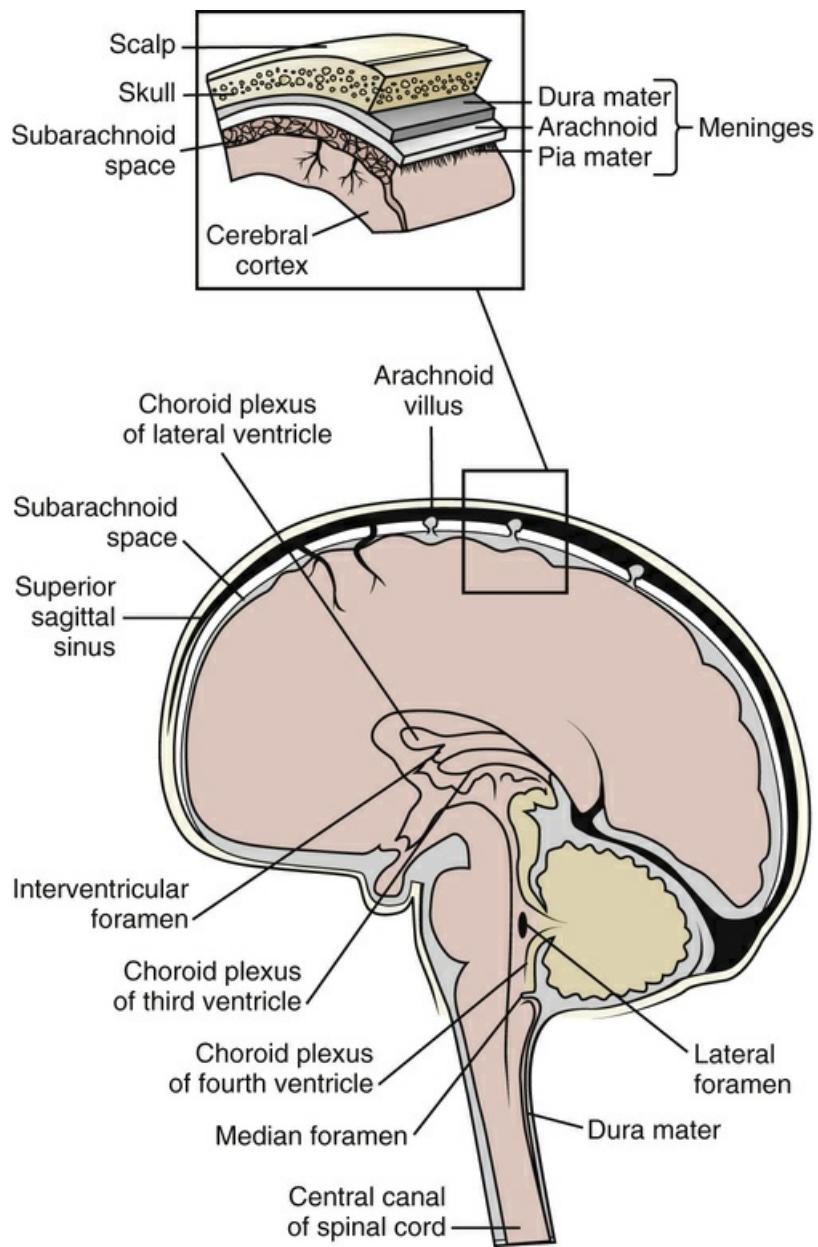

FIGURE 21-6 Flow of the cerebrospinal fluid. *Inset, Meninges covering the brain.*

- CSF serves to cushion and protect the brain and spinal cord. It is formed continuously as a filtrate from the blood in specialized capillary networks in the choroid plexus, located in the ventricles of the brain. It is reabsorbed by the arachnoid villi of the arachnoid membrane at the same rate at which it is formed. The volume of CSF normally stays constant (see Figure 21-6).
- **Normal CSF pressure is 70 to 125 cm water pressure (cm H₂O).** When there is an excess of fluid in the subarachnoid space, the CSF pressure rises above normal.

Special Characteristics of the Nervous System

- Although some cells in the PNS have an outer membrane called the *neurolemma* that may regenerate after damage, cells of the CNS do not have this capability. **Once destroyed, cells in the brain cannot be replaced,** but other brain cells may pick up their function.
- In the PNS, the Schwann cells can regenerate. The Schwann cells form myelin sheaths that wrap around the axons in the PNS.
- Neurons are very sensitive to oxygen and die quickly when deprived of oxygen. **The brain's neurons cannot survive anoxia for more than 4 to 6 minutes.**

Aging-Related Changes in the Nervous System

- There is a loss of neurons with aging, and brain weight may drop considerably after age 70 years; there is no loss of intellectual function attributable to this loss of neurons.
- The number of functioning dendrites decreases with aging. This decrease causes slower impulse transmission and resultant slower reaction time in older adults.
- Blood flow to the brain is decreased with advanced age; this makes older adults more susceptible to permanent damage if blood flow to the brain is further compromised.
- Loss of neurons and slower nerve conduction cause a decrease in efficiency of the autonomic nervous system with advanced age.
- In late adulthood, changes can cause slower movement, slower response time, and decreased sensation. Tremors may occur without rigidity, and tendon reflexes may be hypoactive.
- Body homeostasis is more difficult for older adults to maintain or regain. Exposure to prolonged cold or to excessive heat may cause death. Adaptation to physiologic stress takes much longer, and recovery often is incomplete.
- The aging process affects recent, short-term memory, but long-term, distant memory is often not affected. The ability to learn is not affected by aging, but the learning process is slower. It takes longer to process new information. Abstract reasoning ability slowly diminishes with advancing age, and perception may become impaired.
- Decreases in secretion of the neurotransmitters norepinephrine and dopamine occur with advanced age, and there is an increase in monoamine oxidase, which can affect cognitive function, gait, and balance.
- The number of posterior root nerve fibers and sympathetic nerve fibers of the autonomic nervous system declines with aging of the spinal cord. In the PNS, the motor nerve fibers and the myelin sheath degenerate with advancing age, and reflexes may become diminished or absent.
- Pupils decrease in size with advanced age, and more light is needed for reading.
- Older adults may need more time to process questions, solve problems, or learn new information.
- Using the brain and keeping it active promotes continued intellectual function in healthy older adults.

Causative Factors Involved in Neurologic Disorders

Many factors can affect neurologic function, including genetic and acquired developmental disorders. Infections and inflammation, benign and malignant tumors, vascular or neuromuscular degeneration, and metabolic and endocrine disorders can all cause damage to or interfere with normal function of the nervous system. Chemical or physical trauma often causes permanent damage to the brain or spinal cord. **Box 21-1** lists by category the most common neurologic disorders in adults.

Box 21-1

Classification of Common Neurologic Disorders

Genetic/Developmental Disorders

- Cerebral palsy
- Muscular dystrophy
- Huntington disease (chorea)

Trauma

- Head injury
- Penetrating brain injury
- Spinal cord injury
- Ruptured intervertebral disk

Cerebrovascular

- Cerebrovascular accident
- Ruptured aneurysm
- Arteriovenous malformation
- Migraine, cluster headache

Tumor

- Brain tumor
- Spinal cord tumor

Infection

- Meningitis
- Encephalitis
- Brain abscess
- Poliomyelitis
- Guillain-Barré syndrome

Neuromuscular Disorders

- Multiple sclerosis
- Myasthenia gravis
- Amyotrophic lateral sclerosis

Degenerative Disorders

- Parkinson disease
- Alzheimer disease

Cranial Nerve Disorders

- Bell palsy
- Trigeminal neuralgia

Prevention of Neurologic Disorders

The nervous system coordinates all sensory and motor activities by receiving, interpreting, and relaying messages that are vital to the proper performance of all the body's activities. Respiratory, circulatory, digestive, and endocrine functions all depend on an intact and normally functioning autonomic nervous system.

Nurses can help prevent neurologic problems in many ways. The goals for *Healthy People 2020* encourage health protection through education about safety and responsible self-care.

Health Promotion

Protecting the Nervous System

- Encourage people to wear helmets when biking, in-line skating, skateboarding, or riding motorcycles, and when involved in other sports activities that may lead to head injury.
- Remind people that wearing safety hats or helmets when in a workplace where head injury is a danger reduces the number of injuries.
- Review safety precautions when diving and swimming. To help prevent spinal cord injury, never dive into water of unknown depth.
- Encourage people to fasten their seat belts before putting the car into gear.
- Be certain that children are fastened into appropriate restraints.
- Wear mask, gloves, long pants, and long-sleeved shirt when spraying with insecticide; wash up immediately afterward and change clothes.
- Refrain from using recreational drugs, because they can affect the cardiovascular system and can cause a stroke.

Teaching about the dangers of recreational drug use, such as the possibility of stroke from the use of "crack" cocaine and the potential for accidents while under the influence of some drugs, are other areas for public education. Informing the public about the damaging effect of too much alcohol on brain cells, as well as the increased incidence of alcohol-induced accidents, is another area for education.

Promoting immunizations to protect from tetanus, measles, poliomyelitis, and infectious diseases that may cause high fever and resultant brain damage is an area in which nurses can be effective. **Control of hypertension and cholesterol can reduce the number of strokes and the damage they cause.** Teaching people to recognize the symptoms of stroke and to seek early treatment may prevent permanent disability.

Pesticides and various chemicals in household and work environments can cause neurologic toxicity and damage. Parkinson disease is particularly more prevalent in farm workers and others who handle pesticides or work where pesticides are frequently used (Seaman, 2013). Read information on containers of pesticides carefully. Wear long-sleeved clothing and gloves when spraying pesticides in the garden. Spray in quiet, nonwindy conditions. Wash hands and exposed skin with soap and water afterward. Change clothes and launder the clothing worn after pesticide spraying.

Evaluation of Neurologic Status

The complete neurologic examination performed by the health care provider systematically measures the ability of the body to perform its myriad motor and sensory functions. Mental acuity, memory, and emotional stability also are assessed. A complete neurologic examination is a very long procedure and may be performed in stages over several days. However, gross assessment of the cranial nerves, coordination and balance, muscle strength, and reflexes is standard for every patient with a neurologic complaint. Nurses sometimes do all or part of the examination.

Cranial Nerves

The 12 cranial nerves (CNs; designated as CN I through CN XII) control both sensory and motor activities within various parts of the body (see [Table 21-2](#)). [Table 21-5](#) explains how to perform a basic assessment of cranial nerve function.

Clinical Cues

A mnemonic for remembering the CN names is as follows:

"On Old Olympus's Towering Top A Finn Very Gladly Viewed A Hop" (Olfactory, Optic, Oculomotor, Trochlear, Trigeminal, Abducens, Facial, Vestibulocochlear, Glossopharyngeal, Vagus, Accessory, Hypoglossal).

Table 21-5
Quick Gross Assessment of Major Cranial Nerves

CRANIAL NERVE TESTED	QUICK METHOD OF TESTING*
Olfactory	Have patient smell a sample of ground coffee, perfume, and pickle juice.
Optic	Test visual acuity with a Snellen eye chart. Test visual fields by asking patient to hold the head still and identify items on various areas of a chart.
Oculomotor, trochlear, and abducens	Assess pupil size, direct and consensual constriction, and accommodation. Assess the cardinal fields/directions of gaze.
Trigeminal	Ask patient to clamp jaw shut, open the mouth against resistance, open the mouth widely, move the jaw from side to side, and make chewing motions. Test sensation by placing a warm and then a cold item on various portions of the face. Ask whether item is warm or cold.
Facial	Observe the face for symmetry; ask patient to smile, frown, raise the eyebrows, tightly close the eyes, whistle, show the teeth, and puff out the cheeks.
Vestibulocochlear (or acoustic)	Whisper from varying distances and locations behind the patient and ask patient what was said. Test equilibrium with Romberg test: ask patient to stand with feet only slightly apart and eyes closed. Observe for swaying of the body.
Glossopharyngeal and vagus	Ask patient to open mouth wide and say "Ah." Place tongue depressor on first third of tongue to flatten it and observe movement of the uvula and palate; they should rise symmetrically with the uvula at midline. Assess gag reflex by touching each side of the pharynx; there should be a brisk response. Have patient swallow a bit of water.
Spinal accessory	Ask patient to elevate the shoulders with and without resistance, turn the head to each side, resist attempts to pull the chin back toward the midline, and push the head forward against resistance.
Hypoglossal	Ask patient to open mouth wide, stick out tongue, and rapidly move it from side to side and in and out. Watch for deviation from midline. Apply pressure to cheek and ask patient to push tongue against hand to check for strength.

*These maneuvers do not check for every function of these cranial nerves, but will provide data indicating whether a more thorough assessment is needed.

Coordination and Balance

This portion of the neurologic examination evaluates functions controlled by the higher centers of the brain, the cerebrum and cerebellum. The patient is asked to stand with her feet together and to close her eyes (Romberg test). If the sense of balance is normal, a steady posture will be maintained and there will not be swaying from side to side. Next ask the patient to walk across the room, and assess the gait. Then stand in front of the patient, hold up a finger, and ask the patient to touch your finger and then her own nose; move your finger to different locations in front of the patient. This tests both the ability to follow directions and coordination.

Neuromuscular Function Testing

Groups of large muscles are tested for strength and coordination. Evaluate the patient's gait while walking, hand grip strength, and arm and leg strength as the patient pushes against resistance. More sophisticated tests include electromyography ([Table 21-6](#)).

Table 21-6
Diagnostic Tests for Neurologic Disorders

PURPOSE	DESCRIPTION	NURSING IMPLICATIONS
Skull and Spine Radiographs		
To detect fractures, bone loss, and other bony abnormalities	Radiographs are taken of the desired area from various angles.	Explain that the test is noninvasive. Advise that the patient will have to move into various positions.
Lumbar Puncture (Spinal Tap) (see Figure 21-11)		
To determine whether CSF pressure is elevated; to determine whether there is a blockage to the flow of CSF; to inject medications; to obtain fluid for chemical analysis and culture	Provider performs a sterile puncture into the arachnoid space, using local anesthetic, between L3 and L4 or L4 and L5; opening pressure is obtained; fluid is aspirated and placed in sterile test tubes labeled 1, 2, and 3. Fluid is analyzed for color, pH, cell count, protein, chloride, and glucose; a culture is usually done. Local anesthetic is used.	Procedure requires a signed consent form. Obtain sterile lumbar puncture tray, local anesthetic, sterile gloves, and tape. Assist patient into position with back bowed, head flexed on chest, and knees drawn up to the abdomen. Patient may be lying or sitting. Assist patient to maintain position and to hold still during procedure. Reassure patient and provide emotional support. Personnel must wear a mask during procedure. <i>Postprocedure:</i> Appropriately label tubes with patient data and transport them to the laboratory immediately. Keep patient flat in bed to reduce headache for 1 hr or longer after procedure and encourage fluid intake unless contraindicated. Observe the site for signs of drainage and inflammation.
Electroencephalography (EEG) (Figure 21-12)		
To detect abnormal brain wave patterns that are indicative of specific diseases, such as seizure disorder, brain tumor, CVA, head trauma, and infection; to determine cerebral death	May be performed while patient is asleep, drowsy, or undergoing stimulation such as hyperventilation or rhythmic bright light. Test may be done at the bedside or in the EEG laboratory. Tracing is taken with patient in reclining chair or lying down. Electrodes are applied to the scalp with an electrode paste. Test takes 45 min-2 hr.	Explain purpose of test to the patient; assure her she will not receive an electrical shock, the test is not painful, and that the machine does not determine intelligence or read her mind. Hair should be clean and dry. No sleeping pills or sedatives the night before test; check with provider regarding other drugs to be held; restrict coffee, tea, caffeine, and alcohol for 24-48 hr. If a sleep EEG is ordered, patient may need to be kept up most or all of the night before the test; do not keep NPO, as hypoglycemia can affect the test. <i>Postprocedure:</i> Wash hair to remove the electrode paste. <i>Nothing touches the patient during the procedure.</i>
Magneto-Encephalography (MEG)		
To pinpoint the area of the brain damaged by a stroke, where seizure activity is originating, or location of other injury or disorder	A biomagnetometer machine detects the small magnetic fields generated by neurons.	<i>Postprocedure:</i> Care is the same as for electroencephalography.
Electromyography (EMG)		
To measure electrical activity of skeletal muscle at rest and during voluntary activity to determine abnormalities in muscular contraction; helpful in diagnosing neuromuscular, peripheral nerve, and muscular disorders	With the patient sitting in a chair or lying on a table, needle electrodes are inserted in selected muscles. Tracings of electrical activity are taken with the muscles at rest, then with various voluntary activities that produce muscle contraction. The test takes 1-2 hr depending on how many muscles are tested.	Procedure requires a signed consent form. Explain the procedure to the patient; tell her that there is discomfort when the electrodes are placed. Check with provider regarding medications to be withheld; muscle relaxants, cholinergics, and anticholinergics can influence test result. There is no food or fluid restriction. If serum enzymes are ordered, they should be drawn before the EMG.
Myelography		
To detect spinal lesions, intervertebral disk problems, tumors, or cysts	Contrast medium is injected into the spinal canal, and fluoroscopic examination and radiographs are made. The study is contraindicated if the patient has increased ICP. The patient is placed prone and strapped to the x-ray table for the spinal puncture; as the contrast medium is injected, the table is tilted. After the test, if oil-based medium was used, it is withdrawn. The patient is kept in bed with head of bed elevated 60 degrees or flat depending on the contrast medium used. Procedure takes 1 hr. Rarely performed.	Procedure requires a signed consent form. Explain what to expect. Patient may feel a warm flush when contrast medium is injected. Bowel evacuation regimen may be ordered the night before. Keep NPO for 4-8 hr before procedure. Check for medications to be withheld before and for 48 hr after test. Assess for allergy to iodine or shellfish. Dress in myelogram pajamas; administer preoperative sedative or analgesic if ordered. <i>Postprocedure:</i> Monitor VS q30min × 2 hr, then hourly × 4 hr. Assess pulses and sensation in extremities; monitor urinary output; catheterize as ordered if patient cannot void in 8 hr; encourage increased fluid intake. Observe for signs of meningitis.
Computed Axial Tomography (CAT or CT Scan); Xenon CT; Intrathecal Contrast-Enhanced CT		
To examine the brain from many different angles, obtaining a series of cross-sectional images that provide views from three dimensions To identify hematomas, tumors, cysts, hydrocephalus, cerebral atrophy, obstruction to CSF flow, and cerebral edema	May be done with or without contrast dye enhancement. Patient lies on a narrow table with her head cradled and is moved so that her head is inside the circular opening of the machine. A security strap is wrapped snugly around her. CT scanner produces a narrow x-ray beam. Various clicking and whirring noises are heard as the machine rotates the scanner for different views. The test takes 45 min-1½ hr. A lumbar puncture is needed for an intrathecal contrast-enhanced CT.	Procedure requires a signed consent form. Explain the procedure and what patient will see, hear, and feel. If contrast dye is used, the patient will feel a warm flush and have a metallic taste in her mouth as it is injected. If contrast dye is used, patient should be NPO for 3-4 hr before test to prevent vomiting. Assess for allergy to iodine or shellfish. Remove all hairpins, jewelry, and metal from the head and neck. Patient may need to be sedated if she is prone to claustrophobia; the table can be uncomfortable for those with arthritis or back problems. She will be able to communicate with the machine's operator. <i>Postprocedure:</i> Care is the same as for lumbar puncture.
Cerebral Angiography		
To visualize the structure of the cerebral arteries to determine the presence of stricture, tumor, aneurysm, thrombus, or hematoma	Radioopaque liquid is injected through a catheter inserted into the common carotid artery, and a series of radiographs is taken. Fluoroscopy is used during the procedure. Digital subtraction angiography (DSA) is done by using a computer along with the angiography procedure. Test takes 1-2 hr.	Procedure requires a signed consent form. Assess for allergy to iodine and shellfish. Explain procedure; patient will be supine on x-ray table; local anesthetic will be used to introduce the catheter; an IV line will be started in case of need for emergency drugs; patient will feel a flush as the dye is injected. Patient should be NPO 8-12 hr before test; anticoagulants are discontinued beforehand. May be given preprocedure sedative, antihistamine, or steroid to decrease possibility of allergic reaction to dye. <i>Postprocedure:</i> Assess for bleeding at catheter site; assess distal pulses; perform neurologic checks; monitor VS q15min × 2 hr, then hourly × 4 hr or until stable. Assess for dysphagia and respiratory distress that could indicate internal bleeding in the neck. Activities are restricted for 24 hr.
Radionuclide Imaging (Brain Scan)		
To detect an intracranial mass: tumor, abscess, hematoma, or aneurysm	A radioisotope is administered IV. Abnormal tissue usually absorbs more of the isotope than normal tissue. After a 1- to 3-hr waiting period for absorption, a scintillation scanner is used to image the brain. The test takes 30 min-1 hr.	Explain the procedure; patient will sit or lie on a table; the scanner makes clicking noises; the amount of radioactivity is very low and is not dangerous to the patient or others. Patient will need to lie or sit still during the scanning. A drug may be given the night before to block uptake of the radioactive element by the thyroid and salivary glands. There is no food or fluid restriction; no special aftercare.
Magnetic Resonance Imaging (MRI)		
To visualize soft tissue without the use of contrast media or ionizing radiation; provides excellent images of soft tissue, eliminating bone; can visualize lesions undetected by CT scan To detect white matter areas in nervous system that represent demyelination, as in multiple sclerosis	An electromagnet is used to detect radiofrequency pulses produced by alignment of hydrogen protons in the magnetic field. Computer produces tomographic images with high contrast of area studied. Cannot be used in the presence of metal. Is quite expensive. A contrast agent often is used for better visualization and definition of specific structures.	Inform patient that the test is painless; no dietary restrictions. Remove all metal objects before test. Screen the patient for hidden sources of metal, such as bullet fragments, iron filings, aneurysm clips. MRI is contraindicated for patients with pacemakers. Patient must be still during test. Explain that body part to be imaged is moved inside large machine; some patients become claustrophobic. Patient will be able to communicate with the machine operator. Requires a signed consent for use of contrast media.
Magnetic Resonance Angiography (MRA)		
To evaluate intracranial and extracranial blood vessels and for diagnosing cerebrovascular disease; is rapidly replacing cerebral angiography	Similar to MRI. Uses differing signals of flowing blood to collect data. May be enhanced with use of contrast media.	Explain the need for lying completely still for 1 hr. May require sedation. Screen patient for any metal on body before test. Requires a signed consent for use of contrast media.
Magnetic Resonance Spectroscopy (MRS)		
To determine loss of neurons with markers of neuronal integrity (e.g., N-acetyl	Uses MRI to gather information about chemical composition of brain tissue.	Same as for MRI.

aspartate) and to study brain diseases		
Positron Emission Tomography (PET)		
To assess for cell death, damage in brain tissue	Radioactive material is given and provides differing color in areas of cellular activity.	Procedure requires a signed consent form. Explain that two IV lines will be inserted. Patient is to avoid sedatives or tranquilizers before test. Ask to empty bladder before test. Patient may be asked to perform various activities during the test.
Single-Photon Emission Computed Tomography (SPECT)		
To visualize glucose or oxygen metabolism in the brain and to visualize blood flow	Radiolabeled compounds are injected, and their single-photon emissions are scanned. Images are made of the accumulated radiolabeled compounds.	Same as for PET.
Ultrasound Arteriography (Doppler Flow Studies)		
To study flow and determine areas of constriction or obstruction in cerebral arteries To detect arterial spasm	Noninvasive test. Doppler image scanning device is used with computer to visualize anatomy of major cerebral arteries.	Tell patient that the test is noninvasive and painless. A small Doppler wand is positioned over particular "window" areas on the skull (temples), and with the computer, sound waves are directed so as to produce an image of the interior arteries and their blood flow. No special preparation or aftercare.
Carotid Duplex Doppler Studies		
To determine whether blood flow in carotid arteries is decreased or blocked	Sound waves graph a picture of blood flow in the carotid arteries.	Explain that the test is noninvasive and painless. Patient will lie flat with head turned to one side and then the other as metal wand passes along the artery.
Evoked Potential Studies		
To measure response of the CNS to visual, auditory, or sensory stimulus and helpful in detecting tumor of CN VIII, blindness in infants, or brainstem lesions; also useful in diagnosing multiple sclerosis	May be done in conjunction with EEG. Electrodes are used to pick up and transmit impulses to a computer while a stimulus is delivered to the patient. Signals are displayed on an oscilloscope, and data are stored for later interpretation.	Explain the procedure to the patient. Visual-evoked potentials: stimulus may be a bright flashing light or checkerboard patterns. Somatosensory-evoked potentials require stimulation of a peripheral sensory nerve with a mild electric shock. Auditory brainstem-evoked potentials use various noises or tone bursts through earphones. Discomfort is minimal. Test takes 30-60 min.
Cerebrospinal Fluid Analysis and Culture		
To detect abnormalities that are indicative of specific neurologic problems and determine which organism is responsible for infection	CSF is obtained by lumbar puncture. It is analyzed for color, cell count, protein, chloride, and glucose. The fluid is cultured to detect the presence of organisms; if present, an antibiotic sensitivity test is done to determine which drug will best kill the organism. CSF pressure also is measured. Normal CSF values for the adult are: Color: clear Cell count (WBCs): 0-8 mm ³ Protein: 14-45 mg/dL Chloride: 118-132 mEq/L Glucose: 40-80 mg/dL Pressure: 70-150 cm H ₂ O or <20 mm Hg	Follow lumbar puncture procedure. Label the test tubes as 1, 2, and 3 and be certain they are filled with at least 3 mL of CSF in this order. Do not refrigerate the tubes; transport to the laboratory immediately. Maintain Standard Precautions (see Appendix B).
PLAC (Lipoprotein-Associated Phospholipase A₂/Lp-PLA₂)		
To detect enzyme marker for increased ischemic stroke risk	This substance is thought to be partly responsible for atherosclerosis formation.	Explain that this is a simple blood test. Results take 7-10 days.

CN, Cranial nerve; CNS, central nervous system; CSF, cerebrospinal fluid; CVA, cerebrovascular accident; ICP, intracranial pressure; IV, intravenous; NPO, nothing by mouth; VS, vital signs; WBCs, white blood cells.

Reflexes

A **reflex** is an action or movement that is built into the nervous system and does not need the intervention of conscious thought to take place. In other words, it is an automatic response. The knee jerk is an example of the simplest type of reflex. When the knee is tapped, the nerve that receives this stimulus sends an impulse to the spinal cord, where it is relayed to a motor nerve. This causes the quadriceps muscle at the front of the thigh to contract and to move the leg upward. This reflex, or simple reflex arc, involves only two nerves and one synapse. The leg begins to jerk up while the brain is just becoming aware of the tap on the knee (see [Figure 21-5](#)).

The knee jerk, or patellar reflex, tests nerve pathways to and from the spinal cord at the level of the second through fourth lumbar nerves. In addition to testing the patellar reflex, a neurologic examination might include testing the biceps reflex (pathways for the fifth and sixth cervical nerves), triceps reflex (seventh and eighth cervical nerves), brachioradialis reflex (fifth and sixth cervical nerves), and Achilles tendon reflex (first and second sacral nerves). Reflexes are graded as follows: 0/5 = absent; 1/5 = weak response; 2/5 = normal; 3/5 = exaggerated response; and 4/5 = hyperreflexia with clonus. **Clonus** is a continued rhythmic contraction of the muscle while there is continuous application of the stimulus.

Another reflex action widely used as a diagnostic aid in CNS disorders is the **Babinski reflex**, which is elicited by scraping an object such as a key along the sole of the foot. In a normal response to this stimulus, the toes will bend downward. In a *positive* Babinski reflex, the great toe bends backward (upward) and the smaller toes fan outward. A positive Babinski reflex in an adult who is not under the influence of chemical substances indicates an abnormality in the motor control pathways leading from the cerebral cortex ([Figure 21-7](#)).

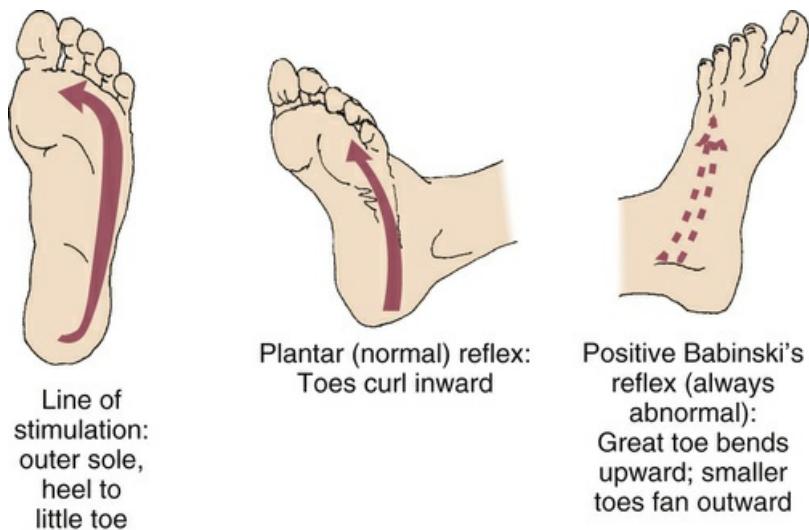

FIGURE 21-7 Normal and Babinski reflexes.

For an unconscious person, tests are performed to determine brainstem function. After ruling out spinal cord injury, the oculocephalic ("doll's eye") and oculovestibular reflexes are assessed. For the doll's eye reflex, the examiner places a hand on each side of the patient's head, using the thumbs to gently hold open the eyelids. While watching the patient's eyes, the head is rotated briskly to one side and eye movement is observed in relation to head movement. If the brainstem pathways are intact, the eyes appear to move in a direction opposite to that of the head movement; that is, if the head is rotated to the right, the eyes appear to move to the left. This finding is a "positive" doll's eye reflex and indicates an intact brainstem. If the eyes remain stationary and do not appear to move, then the result is a "negative" doll's eye reflex and is abnormal. After ensuring that the tympanic membrane is intact, the oculovestibular reflex is assessed by **caloric testing**. With the patient's head elevated at least 30 degrees, 20 to 200 mL of cold or ice water is instilled into the ear with a catheter-tipped syringe. While the external ear canal is irrigated, the patient's eye movements are observed. Normally the eyes will show nystagmus, darting away from the irrigated ear. Absence of eye movement may indicate a brainstem lesion.

❖Nursing Management

■ Assessment (Data Collection)

Neurologic nursing requires special training and experience in observation, critical judgment, and specific skills to help patients cope with myriad problems. You not only must be aware of subtle changes in the patient's condition but also must recognize the significance of these changes and act promptly when medical attention is needed. LPNs/LVNs assist RNs with the gathering of data for the neurologic assessment.

Assignment Considerations

Reporting Observations

If a patient with a neurologic problem that may affect the level of consciousness is assigned to a CNA for bathing and morning care, remember to remind the assistant to report to you any change in wakefulness, irritability, speech, eye appearance, gait, or balance. It is best not to assign a patient who has already shown some signs of deteriorating level of consciousness to a CNA.

Patient History

Because neurologic disorders can be present in conjunction with or in addition to disorders of other body systems, include questions about neurologic status in the initial and ongoing assessments of all patients. For example, a surgical patient could have had a previous stroke, or could have a history of seizures or an existing neuromuscular disease such as multiple sclerosis. Although these

may not be the primary reason for admission to a hospital, they will certainly influence the course of the illness or injury for which admission occurred.

Focused Assessment

Data Collection for the Neurologic System

When gathering a history for a patient who may have a neurologic problem, ask the following questions:

- Do you or does any member of your family have any genetic disorder of the nervous system?
- Have you ever had a seizure or been told you have epilepsy?
- Have you ever had difficulty in speaking, concentrating, remembering, or expressing thoughts? Have you noticed any changes in these functions?
- Have you had any changes in muscle strength or coordination?
- Have you ever injured your head?
- Have you ever had a really high fever?
- Have you had any severe sinus, ear, tooth, or facial skin infection?
- Do you recall any episodes of tremors, muscle spasms, fainting, dizziness, ringing in the ears, or blurred vision?
- Have you had any “blackout” spells?
- Have you noticed any changes in taste or smell?
- Do you have any numbness or tingling in the extremities?

Physical Assessment

A basic nursing assessment of neurologic function is performed on any patient who is suspected of experiencing a neurologic problem. Nurses often need to assess for the occurrence of cerebrovascular accident (CVA, or stroke) or of a neurologic deficit after a surgical procedure. Basic neurologic assessment includes assessment of the following areas.

Vital signs. Assessing and recording temperature, pulse, respirations, and blood pressure are essential. The patient's temperature is important and may be elevated for a number of reasons. Infection or damage to the temperature control mechanisms within the brain from increasing intracranial pressure (ICP) may be present.

Changes in blood pressure, particularly a rise in systolic pressure and a widening pulse pressure, may indicate an ICP increase. The pulse may become slow and bounding, and breathing may become irregular and labored as ICP rises. Changes in breathing pattern often indicate a problem with neurologic control of respiration. Any identified change must be reported to the provider promptly.

Clinical Cues

When the systolic and diastolic pressure readings are farther apart, a widening pulse pressure has occurred. For example, if the blood pressure was 128/78 mm Hg earlier and is now 136/64 mm Hg, there is a widened pulse pressure. Notify the provider when the pulse pressure widens.

Current vital signs should be compared with those from the previous several days to determine any changes or trends. Look for changes in blood pressure, pulse rate and quality, and respiratory pattern and for rising temperature.

Mental function and level of consciousness. Patients experience varying levels of consciousness and ability to respond. It is necessary to determine where the patient is in relation to level of consciousness (LOC), the extremes being alert wakefulness and deep coma (no responsiveness at all).

When observing a patient to determine LOC, the best assessment is based on established criteria or standards that are understood by the observer as well as by others who will be reading the results of the observations. The Glasgow Coma Scale (GCS) is a tool that is universally used in one form or another for this purpose ([Table 21-7](#)). The patient's LOC is scored in three different categories. The first category is eye opening, the second is best motor response, and the third is best verbal response. A number is assigned for each category depending on what the assessment reveals. Assessment in the first and last categories determines whether the patient can respond to voice commands or to pain or does not respond at all. Verbal responses are evaluated according to whether the patient is oriented and "making sense," confused, making inappropriate remarks, incomprehensible, or silent. **The score in each area is added together, with the optimal score being 15, which indicates a fully alert patient. A score of 3 indicates a totally comatose patient.** A score of 8 or less indicates coma level. Some of the criteria for assessing LOC include: Does the patient awaken easily? Is she oriented to person (herself as well as others), place, and time? Is she able to follow commands? Does she fail to respond to any stimulus, even physically painful ones? Is she restless? Combative? Does she respond to pain with abnormal posturing?

Table 21-7
Glasgow Coma Scale

	SCORE
Eye Opening	
Spontaneous	4
To sound	3
To pain	2
Never	1
Motor Response	
Obey commands	6
Localizes pain	5
Normal flexion (withdrawal)	4
Abnormal flexion posturing	3
Extension posturing	2
None	1
Verbal Response	
Oriented	5
Confused conversation	4
Inappropriate words	3
Incomprehensible sounds	2
None	1

*A score of 8 or less indicates coma. The highest possible score is 15.

The FOUR (Full Outline of UnResponsiveness) score developed by Eelco Wijdicks, a neurologist at the Mayo Clinic, is becoming the preferred scale to assess comatose or intubated patients who cannot speak. A score of 0 to 4 is assigned in each of four categories: eye, motor, brainstem, and respiratory function. A score of 0 indicates no function and a score of 4 indicates normal function ([Wijdicks et al, 2011](#)).

Think Critically

If your patient's blood pressure was 138/84 mm Hg and is now 146/76, what is happening? Is the ICP probably increasing or decreasing?

For an alert patient, note changes in mental function by asking questions to determine orientation to person, place, and time: "What day is today? What month is it? Where are you now?" Memory lapses may be assessed by asking when the patient was born, what state she resides in, what the last major holiday was, and so on. Thinking can be evaluated by asking the patient to add three numbers together; to count by sixes; or to solve a simple puzzle, such as "If a man goes to the store and purchases four oranges at 40 cents each, two apples at 60 cents each, and two bananas for 46 cents, how much did he spend?" (Allow pencil and paper to be used.) If the patient can read English, hand her a card with a command written on it, such as "walk to the sink" or "turn on your right side" (assuming she is physically capable of performing such a task).

Judgment can be grossly tested by assessing whether the patient has been making rational choices in her day-to-day life and by asking her what she would do in a particular situation. Asking

specifically what she would do should there be a fire in the trash can will provide information about her judgment.

Neurologic and neuromuscular status. While watching the patient perform morning activities of daily living (ADLs), basic assessment of cranial nerves and motor function can be performed. Assess the following: Does the face move symmetrically when she smiles? Is speech clear when she answers questions? Does she move left and right extremities without noticeable problems? Is there anything abnormal about her gait as she moves across the room or down the hall? Does she have difficulty eating or swallowing? Observe the pupils of the eye for size and equality. Pupils should be equal size and should constrict and dilate readily when the environmental light changes ([Figure 21-8](#)). Can the patient hear you if you speak to her when her back is turned? Does she seem as alert as usual? Is she having any trouble with balance?

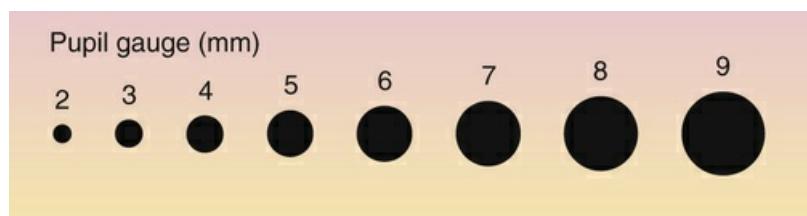

FIGURE 21-8 Pupil gauge (mm). (From deWit SC, O'Neill P: *Fundamental concepts and skills for nursing*, ed. 4, St. Louis, 2014, Saunders.)

Evaluate the extraocular muscle movements. Ask the patient to follow your finger while you move it through the cardinal positions of gaze ([Figure 21-9](#)). Note whether both eyes move together (conjugate) or one deviates. If there is deviation, it is important to note the direction of the deviation. Note any quick back-and-forth oscillation (**nystagmus**) of the eye at the end points of each direction. Nystagmus can indicate abnormality, such as multiple sclerosis, or can be a side effect of medication, such as phenytoin (Dilantin).

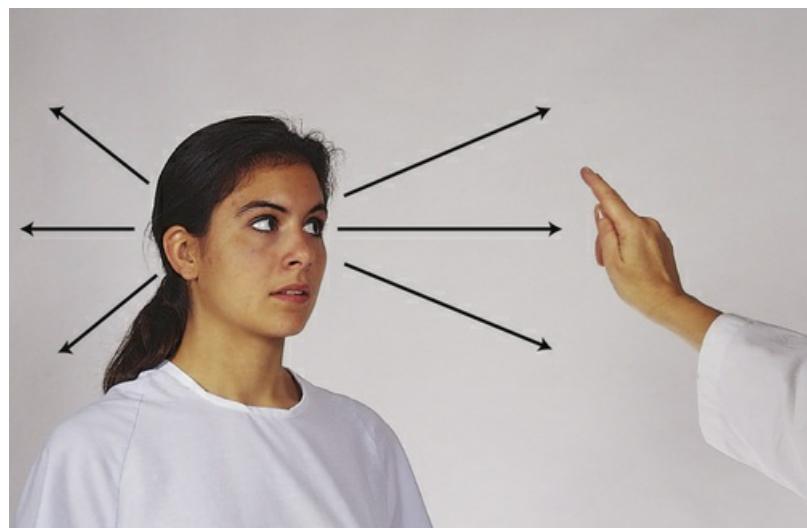

FIGURE 21-9 Checking the cardinal positions of eye movement. (From Jarvis C. *Physical examination and health assessment*, ed. 6, Philadelphia, 2011, Saunders.)

Neuromuscular assessment is concerned with the function of the motor pathways. Test each of the upper and lower extremities. Ask the patient to follow verbal commands such as "raise your left leg," "bend your right knee," "touch your left elbow with your right hand," and "touch your face with your left hand." Have her push against the palms of your hands first with one foot and then the other to test the strength of the leg muscles. To test muscle strength, have the patient extend her arms in front of her, and press down on each arm one at a time, while asking her to try to raise her arm. If the patient has an extremity that is not responding, another stimulus may be necessary to

test it. If the patient does not respond to voice commands at all, and deafness is not an issue, test the degree of unconsciousness. First use a louder voice to try to arouse the patient; then, if she does not respond, gently shake her as you would to awaken a child. If that is not successful, painful stimuli are applied for 20 to 30 seconds. First try applying pressure above the eye by placing a thumb under the orbital rim beneath the middle of the eyebrow and pushing upward. If there is no response, pinch the trapezius muscle at the angle of the shoulder and neck; twist the fingers slightly. If there is no response, apply pressure to the angle of the mandible with the index and middle fingers. If there is still no response, the sternum is rubbed with the knuckles in the form of a fist; a twisting motion is used. **The sternal rub is performed on subsequent assessments only if there is good reason to believe that the patient's comatose status is changing, as it causes bruising.**

The levels of response are:

- Purposefully withdrawing from the stimulus or an attempt to push it away
- Nonpurposeful response, in which the patient may frown or move her arm or leg in a random fashion
- Failure to respond at all

Nonpurposeful responses to pain occur in two ways. **Decorticate (flexor) posturing**, which is the extension of the legs and internal rotation and adduction of the arms with the elbows bent upward, occurs with damage to the cortex. In **decerebrate (extensor) posturing**, the arms are stiffly extended and held close to the body, and the wrists are flexed outward. This response means there is damage to the midbrain or brainstem, which indicates a very serious injury ([Figure 21-10](#)). The response may be “lateralization,” wherein one side of the body shows typical decorticate or decerebrate posturing. An important aspect of neurologic assessment is to look for changes in the patient from each day to the next. Bilateral flaccidity is usually present when there is no response at all.

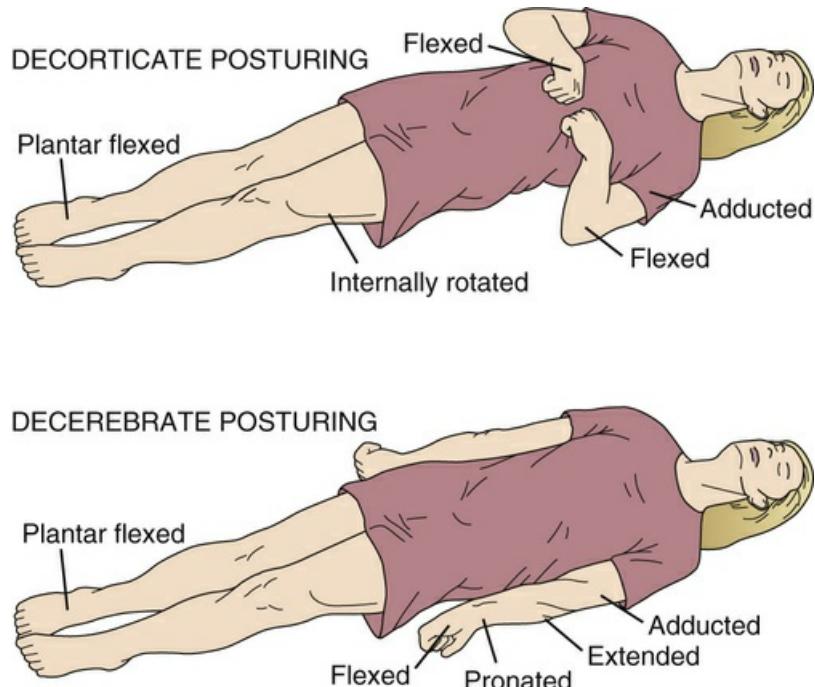

FIGURE 21-10 Decorticate and decerebrate posturing indicating brainstem injury.

Pupillary reactions. Changes in pupil size in response to a bright light are commonly used to determine whether the areas of the brainstem that help control consciousness are functioning normally. Cranial nerves II and III control pupil movement. When ICP rises beyond a certain point, pressure on these nerves causes changes in the pupils. If at all possible, find out the normal pupil size for the patient. Although pupils of equal size are considered normal, some people have pupils that are unequal in size. The size of the pupils also may vary from person to person (see [Figure 21-8](#)). It is best to measure pupil size rather than estimate it.

Examine the pupils in a room with low light, when the pupils would usually be dilated. Direct a

bright light into each eye from the side while the other eye is covered. Observe whether the pupil into which the light shines constricts and whether it does so briskly or sluggishly (**direct reflex**). Finally, shine the light into each eye while watching to see if the pupil constricts in the other eye (**consensual reflex**) (Table 21-8). When pupils have been previously reactive, changes in pupil size or reactivity may signal an emergency, and the provider must be notified immediately. To test for **accommodation** (eyes able to focus on both near and far objects), ask the patient to look at an object across the room away from the light source, and then to look at your fingers held about 6 inches from the eyes. The lenses should change shape and the pupils constrict. If a flow sheet is not being used for charting, normal pupil responses often are charted as "PERRLA," meaning "pupils equal, round, and reactive to light with accommodation."

Table 21-8
Pupillary Abnormalities and Possible Causes

ASSESSMENT DATA	APPEARANCE	POSSIBLE CAUSES
Unilateral, fixed, dilated pupil. Unreactive to light. May be accompanied by ptosis and deviation to side and downward.		Damage to oculomotor nerve related to increased intraocular pressure; compression of oculomotor nerve; head trauma with epidural or subdural hematoma
Bilateral dilated and fixed pupils that do not react to light.		Hypoxia associated with cardiopulmonary arrest Pressure on midbrain Severe CNS disorder Anticholinergic drug overdose
Bilateral small, fixed pupils that do not react to light. Accompanied by motor deficits, drowsiness, confusion, headache, vomiting, incontinence when caused by damage to diencephalon.		Side effect of opiates such as morphine Miotic eyedrops Hemorrhage into the pons Damage to the diencephalon
Unequal pupil size; both pupils react to light unless there is underlying pathology.		Ocular inflammation Congenital aberration Adhesion, as of iris to cornea or lens Disturbance of neural pathways

CNS, Central nervous system.

Pupils that remain dilated and fixed in the presence of a bright light indicate brain damage if there are no drugs in the system that affect the pupils. One pupil that remains fixed and dilated indicates increased ICP. If both pupils remain constricted, there probably is damage to the pons.

Safety Alert

Report Changes Immediately

If changes in data indicate a rise in ICP or a decrease in LOC, it is important to alert the charge nurse and provider. This is even more important when possible intracranial bleeding is suspected, because it may indicate an emergency situation.

Although changes in the pupils, such as unequal constriction or decreased rate of constriction, indicate increased ICP, sometimes changes in pupils can be caused by medications. For example, atropine and scopolamine can produce dilated pupils, and opiates, miotics, and street drugs can cause constriction (see [Table 21-8](#)).

The “neuro” check. Monitoring the neurologic status of a patient with a known neurologic disorder includes a “neuro” check on a set schedule. It is performed to determine whether increased ICP is present or ICP is rising. For example, monitoring is necessary after a traumatic head injury, after ingestion of an overdose of a drug or other chemical, when a stroke has occurred or is suspected, or for any other condition in which the patient has lost or may lose consciousness. A  neurologic assessment flow sheet is used to chart assessment data so that the trend in function of each area can be quickly identified. Four areas are monitored: vital signs, LOC, pupil reaction, and motor function. Neuro checks may be ordered as frequently as every 15 minutes or at intervals from 2 to 8 hours.

Assignment Considerations

The Neuro Check

Although the measuring of vital signs can be assigned to assistive personnel, the gathering of data for the neuro check should not be delegated. It is important to compare current data with previous data and to carefully assess neuromuscular and pupillary response.

Think Critically

You arrive at the home of an older adult woman who has severe heart disease and atherosclerosis and is very weak. Her spouse says she is confused and lethargic and that she would not eat breakfast. He is worried. As her nurse, what specific assessments would you perform in an attempt to determine whether she has suffered a CVA?

Diagnostic tests. The major diagnostic tests most commonly used to evaluate the neurologic system are presented in [Table 21-6](#). Basic physiologic testing is also performed to rule out disease in some other system that might be affecting the nervous system. A nerve or muscle biopsy may be performed to determine pathologic changes in these tissues. [Figure 21-11](#) shows the technique used for lumbar puncture.

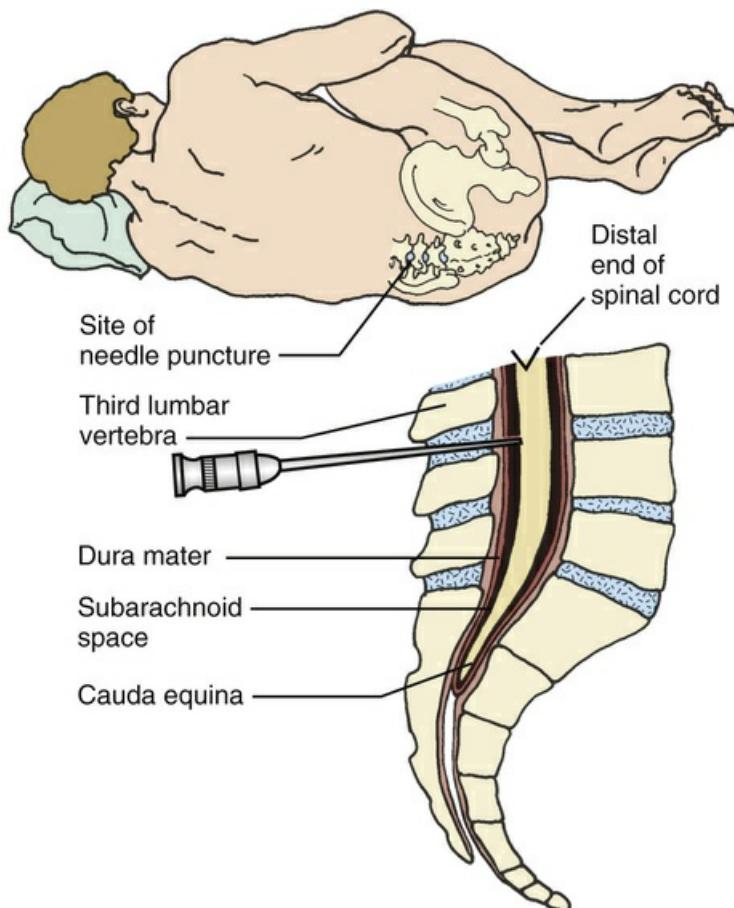

FIGURE 21-11 Lumbar puncture technique.

Nursing Diagnosis

The most common problem statements for patients with neurologic disorders are listed in **Table 21-9**. Specific NANDA-I diagnoses can be chosen from the NANDA-I list (see inside back cover). Each problem statement/nursing diagnosis chosen for the patient should be individualized to fit the situation. Problems included in a care plan vary according to whether the patient is in the acute stage, recovery stage, or rehabilitative stage of the disorder. General expected outcomes for each problem statement are presented in **Table 21-9** along with appropriate interventions.

Table 21-9

Common Problem Statements, Goals/Expected Outcomes, and Nursing Interventions for Patients With Neurologic Disorders

Problem Statement	GOALS/EXPECTED OUTCOMES	NURSING INTERVENTIONS
Potential for injury due to decreased level of consciousness, paralysis, or decreased sensation	Patient will have no evidence of injury or trauma.	Side rails up at all times patient is unattended. Bed in low position when patient is unattended. Pad side rails if seizure activity or restlessness indicates need. Provide eye care for unconscious patient and if corneal (blink) reflex is absent; lubrication and eye patch or shield as needed. Position carefully; protecting extremities from contact with side rails. Maintain correct body alignment. Administer anticonvulsants as ordered to prevent seizure activity. Protect from thermal injury. Use hand mitts to prevent injury from dislodging tubes.
Altered breathing pattern to neurologic disruption of respiration	Maintain a patent airway.	Assess respiratory status q2-8h depending on patient condition.
	Maintain a PO ₂ of 80-100 mm Hg.	Position to maximize open airway and to promote chest expansion.
	Patient will have no evidence of pulmonary infection.	Insert oropharyngeal airway as ordered. Suction secretions PRN as ordered. For controlled ventilatory support: auscultate to verify that both lungs are inflating. Check ventilator settings with those ordered. Keep alarm set to "on" at all times. Remove excess water gathering in ventilator tubing as needed. Suction patient using sterile technique as ordered PRN. Monitor blood gas values for changes. Provide frequent mouth care (i.e., q2-4h). Monitor hydration status.
Altered physical mobility due to CNS deficit, weakness, paralysis, or fatigue	Patient will maintain mobility of all joints.	Perform passive ROM or supervise active ROM qid.
	Patient will have no	Teach ROM exercises to patient and family.

	evidence of contractures.	
	Patient will regain optimal physical mobility neurologically possible.	Teach transfer techniques to hemiplegic patient and family. Collaborate with physical therapist to maximize activity.
Altered skin integrity due to impaired mobility, decreased sensory awareness, or decreased sensation	Patient's skin will remain intact.	Inspect pressure points for redness, warmth, tenderness, or edema each time patient is turned. Thoroughly inspect skin every shift. Position and pad joints to prevent pressure ulcers. Formulate regular turning/repositioning schedule and stick to it. Use special mattress or special bed to enhance skin protection. Teach patients in wheelchairs to shift weight q15min. Teach patient and family to inspect pressure areas and skin for beginning signs of breakdown.
Altered self-care ability due to neurologic impairment: paresis, paralysis, decreased LOC, or confusion	Patient will meet self-care needs of hygiene, toileting, feeding, and grooming. Patient will resume self-care at level physiologically and neurologically possible.	Assist with hygiene, toileting, feeding, and grooming as needed. Assist patient to set small, attainable goals for self-care. Explain and demonstrate specific ADL in small, one-task segments. Obtain and demonstrate adaptive devices to assist with ADLs. Offer patience, support, and encouragement for each attempt at self-care. Maintain chart of self-care improvement to track achievement so that patient can see progress.
Altered nutrition due to inability to swallow or danger of aspiration	Patient's nutritional status will remain adequate as evidenced by normal weight and adequate levels of serum protein.	Institute tube feeding as needed. Check tube placement before initiating each feeding; aspirate stomach contents; test acidity if there is doubt about origins of aspirated fluid. Check residual before each intermittent feeding or q4h for continuous feedings; if greater than 150 mL or more than half of previous feeding, replace and delay next feeding for 1-2 hr. Position patient with head of bed up at least 30 degrees when feeding and for 30-60 min after feeding. Monitor for adverse side effects such as diarrhea. Flush tube with 30-60 mL water after each feeding. Instill water between feedings to maintain hydration. Monitor glucose levels after initiation of feedings until blood glucose is stable. Check weight at least twice a week. Monitor intake and output. <i>For patient with dysphagia who can take oral feedings:</i> Serve semisoft foods. Provide six small meals per day; provide nonstressful atmosphere with few distractions for mealtime. Teach to sit upright with head slightly forward and neck flexed; encourage to place food on strongest side of mouth and tongue; encourage to take small bites at a time. Remain with patient to decrease fear of choking; keep suction at hand and turned on during meal. Ensure privacy for meal to decrease embarrassment about drooling, dropping food, or choking. Provide appropriate tube care (see Chapter 28).
Altered elimination/diarrhea/bowel incontinence due to decreased level of consciousness, neurogenic impairment, or side effects of medications	Patient will have normal bowel movements as evidenced by soft, formed stool. Patient will attain bowel continence.	Monitor bowel movements and evaluate regularity based on nutritional intake. Administer stool softeners, rectal suppositories, or enemas as ordered for constipation. Check for and remove fecal impaction if it occurs, guarding against spinal dysreflexia in the paralyzed patient. Institute bowel training program if needed (see p. 495). If diarrhea occurs, determine cause and alleviate if possible. Administer antidiarrheal if ordered. Keep rectal area clean and dry; protect rectal mucosa. Monitor hydration status; evaluate intake and output.
Altered level of consciousness due to neurologic disease or injury	Patient will respond to family interaction as evidenced by movement, hand squeezing, eye opening, or speech. Patient will return to alert state as evidenced by proper orientation to person, time, and place.	Speak of current events or daily happenings while providing care. Encourage family members and friends to speak to patient of day's occurrences or fun times in past. Play music on the radio that is to the patient's taste. Play videotapes on topics of interest to the patient. Turn on the patient's favorite television shows. Ask questions and patiently listen for a response. With a tape recorder, introduce sounds from the patient's home and work environment.
Social isolation due to immobility and intellectual limits imposed by neurologic impairment	Patient will have social interaction with visiting friends.	Encourage friends and family to visit.
	Patient will maintain relationships with family members and loved ones.	Instruct friends and family on how to interact with the patient.
	Patient will make new friends among support group members.	Encourage patient to discuss her feelings regarding social contact. Encourage participation in an appropriate support group. Encourage development of a social network. Encourage participation in church, civic, volunteer, and social groups in community. Provide referrals to community job retraining resources if patient is unable to resume former employment or lifestyle.
Altered family coping due to role changes, uncertainty of the future, and financial constraints	Each family member will demonstrate appropriate coping methods.	Assess strengths of each family member; look for signs of stress.
	Each family member will regain an optimistic outlook.	Provide opportunity for verbalization of fears and concerns and feelings about patient's changed condition.
	Each family member will accept the patient in her changed state.	Refer to social worker and community resources for support services.
	Each family member will use referrals to support groups and community resources.	Arrange for psychological counseling or family therapy as needed. Encourage contact with appropriate support group. Initiate interaction and honest communication between patient and family members when patient and each member is ready. Teach problem-solving methods if coping skills are weak.

ADLs, Activities of daily living; CNS, central nervous system; LOC, level of consciousness; Po₂, partial pressure of oxygen; PRN, as needed; qid, four times a day; ROM, range of motion.

■ Planning

Overall goals for patients with neurologic disorders depend on whether there is a physiologic possibility that full function may be regained. When permanent neurologic deficit occurs, as may occur with some spinal cord injuries, the ultimate goal is for the patient to function at the highest physiologic level. This requires adjusting to limitations imposed by the neurologic deficit so that the patient may live life in a meaningful way. A goal for all patients with neurologic disorders is to prevent injury, whether from complications of immobility, accidents related to lack of sensation, aspiration from difficulty in swallowing, or any of the other problems that the neurologic deficit may cause.

Caring for patients with neurologic deficits can be very time consuming and requires considerable patience and understanding. If the patient has any weakness, paralysis, or decreased sensation in the extremities, or is confused, disoriented, aphasic, or otherwise incapacitated, providing care will take more time than usual. Extended time must be included in the daily work

plan. When a patient is comatose or paralyzed, it is best to team up with another helper to provide care and to turn or reposition the patient. By working together, care is smoother and less taxing.

■ Implementation

Interventions for each problem statement concerning neurologic disorder problems are listed in **Table 21-9**. Patients should be given information about the disorder and taught about diagnostic tests and self-care. Positive coping skills should be reinforced and ongoing support offered. Interventions are discussed in the following sections on common care problems and with the specific neurologic disorders in [Chapters 22, 23, and 24](#).

■ Evaluation

Evaluation of interventions is performed to determine whether goals are being met. Are the interventions chosen helping to meet the specific expected outcomes written? If not, the plan needs to be changed. Progress in the patient experiencing a neurologic deficit is often slow. It may take a considerable time for improvement to be noted. Long-term goals of a realistic nature are appropriate. Keep in mind that certain types of neurologic deficits, such as those caused by spinal cord severance, may not improve.

Common Neurologic Patient Care Problems

Neurologic disorders and illnesses cause many of the same problems. Whether the patient has encephalitis, has a head injury, is recovering from cranial surgery, has suffered a stroke, or has multiple sclerosis or Parkinson disease, she may need nursing intervention in one or more of the following areas.

Ineffective Breathing Pattern

Weakness of the diaphragm or respiratory muscles or interruption of normal brain function may occur with a variety of neurologic disorders. Monitor the adequacy of respiratory effort and promote a patent airway and chest expansion. Elevating the head of the bed 30 degrees allows the diaphragm to drop more easily and promotes chest expansion. This is only done when there is no spinal injury or severe head injury. When consciousness is depressed, the tongue may be flaccid and fall back, blocking the airway. Positioning the patient on the side allows the tongue to fall to the side and opens the airway. Insertion of an oropharyngeal tube or oral airway is helpful.

Assisting the patient with deep breathing and the use of an incentive spirometer can help prevent atelectasis and improve ventilation. Respiratory assessment is performed every shift and includes auscultating the lungs for signs of atelectasis or retained secretions and judging the quality of respiratory effort. If respiratory efforts are considerably impaired, the patient may need intubation and mechanical ventilation. Interventions for patients undergoing mechanical ventilation are presented in [Chapter 14](#).

Impaired Mobility

The nurse, the physical therapist, and the patient work together to help the patient cope with muscle weakness or paralysis. Activities such as proper positioning and range-of-motion (ROM) exercises are started immediately to preserve proper alignment of joints and limbs and prevent contractures and muscle atrophy. Assistive devices, such as splints and slings, may be used. Patients with **hemiplegia** (paralysis and loss of sensation in an extremity) are taught to become aware of arm or leg placement when turning or transferring to a chair to prevent injury to the affected extremity.

For example, a patient with left hemiplegia from a CVA may neglect her paralyzed side. She must therefore be taught to attend to the affected side of her body by scanning it frequently. To prevent discomfort in the shoulder and arm on the affected side and to prevent dislocation of the shoulder, take care not to pull on the affected arm or shoulder during transfers or ambulation. Support the affected arm with pillows or an armrest to keep it from dangling when the patient is seated. Use a sling for comfort and to promote better balance when ambulating and transferring the patient.

Patients with hemiplegia are taught, step-by-step, the safest way to transfer from the bed to a wheelchair and back, and how to use assistance from others. They are also taught how to care for and protect their skin in areas of decreased sensation.

Patients with **hemiparesis** (one-sided weakness) are taught how to strengthen their muscles and use assistive devices, such as walkers, crutches, or canes, to walk. They are taught the best ways to get out of bed and into and out of a chair. Patients with **tetraplegia** (four limbs paralyzed) are helped to learn to cope with this drastic life-changing alteration and how their energies might be directed toward different, but attainable, goals. (An older term for tetraplegia is **quadriplegia**.)

All patients with a recent impairment of mobility need help with the grieving process, support in establishing healthy and effective coping patterns, and assistance with depression.

Attention to pain relief and muscle spasm is necessary for these patients to achieve the highest level of rehabilitation possible. Paralyzed extremities are susceptible to edema; to decrease this problem, extremities should be elevated when the patient is at rest. The patient needs to be turned frequently to prevent complications from pressure and sluggish circulation.

Older adult patients may suffer joint stiffness from arthritis. Assess joints for tenderness and pain before performing ROM, and be gentle and considerate when turning and repositioning them.

Take measures to promote skin integrity. Place the patient on a special bed or protective mattress cover or pad, inspect pressure points frequently, and keep the skin clean and dry. [Chapter 9](#)

discusses the effects of immobility on each body system, along with the nursing activities necessary to prevent disabilities resulting from inactivity. The principles and practices presented in that chapter are relevant to the nursing care of a patient with a neurologic disorder that produces some type of paresis or paralysis and for a patient who is unconscious.

Self-Care Deficit

Neuromuscular impairment may interfere with the patient's ability to perform hygiene activities or other ADLs. She may need assistance with bathing, grooming, oral hygiene, dressing, eating, and toileting. Work with the patient as her condition dictates, assisting with techniques to perform self-care despite disability when possible, offering encouragement, and praising any effort at accomplishing a self-care task.

Inability to carry out the most basic of self-care activities can erode a person's sense of independence and self-esteem. The ability to feed, clothe, and take care of toileting is an important part of independence. Regaining some level of self-care in these areas is of particular concern to the adult who, because of neurologic dysfunction, may have to relearn ways to perform the simplest of daily activities.

If the patient is unconscious, the mouth must be kept clean to avoid infection of the parotid gland. The lips, tongue, and gums are cleansed and lubricated at frequent intervals, because mouth breathing makes them excessively dry. This cleansing may be done by turning the patient to the side, turning on the oral suction device, and—with a toothbrush or a tongue depressor with gauze taped to it—wiping the oral surfaces. A solution of 50% water/50% mouthwash, or water with a small amount of hydrogen peroxide and sodium bicarbonate, may be used to moisten the gauze. Too much hydrogen peroxide will cause excessive foaming. Using an irrigation syringe filled with water in one hand and the oral suction device in the other allows rinsing of the mouth while preventing aspiration of the liquid. It is easiest for two caregivers to work together to rinse and suction the mouth. Each time the mouth is cleansed, the patient should be positioned on the opposite side to ensure thorough cleansing of each side of the mouth. Oral suction should be available and turned on any time mouth care is given to a patient who has a weakened gag reflex, cannot swallow normally, or has weakness of the facial muscles. Studies show that tooth and tongue brushing decreases iatrogenic infection significantly.

When the patient cannot shut her eyes, the nurse or caregiver must provide care to prevent keratitis or corneal ulceration. The eyelids are cleansed with warm sterile water or normal saline every few hours to remove discharge and debris. Artificial tears or a lubricant is instilled as prescribed to prevent dryness. If the corneal reflex is absent, an eye shield or patch is placed over the eye. The eyelid is closed before a patch is applied. The eyes are examined each day for signs of inflammation.

The ability of relatives to learn how to care for the patient, and their willingness to do so, are important parts of assessing and planning for rehabilitation. Goals for rehabilitation must be realistic and mutually agreed on by the patient, her family, and the health care team.

Assistive devices help patients with neurologic deficits to feed and dress themselves. Occupational therapists can help the patient relearn how to perform elementary tasks necessary for daily living. Patients are retaught how to feed themselves; how to get in and out of a bed or a chair; how to select and put on clothes and fasten them; and how to bathe, brush teeth, and comb hair.

Provide assistance when the patient cannot do a task completely, and—most of all—provide encouragement and praise for efforts made. **When pursuing self-help rehabilitation, remember that the patient tires easily; tasks must be spaced apart so that energy is available to achieve them.** Pushing the patient to try another task when she is too tired only sets her up for failure and frustration.

Dysphagia

Every patient who has suffered a neurologic insult (damage) from head injury, stroke, or intracranial surgery should have the swallowing reflex assessed: have the patient try to sip plain water before attempting to eat food. Check periodically that the patient automatically swallows saliva before offering water. Patients who have paresis from a stroke or who suffer from myasthenia gravis or other neurologic disorders often have difficulty swallowing (**dysphagia**). Those patients who have difficulty eating are at risk for nutritional disorders and aspiration

pneumonia. Patients with dysphagia should be sitting upright or in a high Fowler's position to eat. The position should be maintained for at least 30 minutes after a meal (Hughes, 2011). A nonstressful meal environment without distractions is best, because stress makes dysphagia worse.

When the patient cannot swallow without choking or aspirating, tube feeding is necessary. When the patient is receiving nutrients by tube, the caloric intake should be assessed frequently. Tube-fed patients are weighed twice a week and intake and output are recorded and evaluated. Interventions for the patient receiving tube feedings are outlined in [Chapter 28](#).

Incontinence

Many patients with CNS disorders experience temporary or permanent urinary or fecal incontinence. Some patients experience constipation. The patient must be kept clean and dry. A condom catheter for male patients or incontinence briefs or pads are used for urinary incontinence.

Perhaps the first step in planning and implementing either a bladder or a bowel training program is to convince the nursing staff and the patient and her family that something can be done to improve, if not completely relieve, the situation. A negative attitude and lack of persistence can doom a program to failure before it is started. Be content with small successes at first, setting short-term goals that will eventually lead to a satisfactory resolution of the problem.

Bladder Training Program

Bladder training is a program designed to help a patient with some degree of loss of normal bladder function and a resulting disturbance of voiding and bladder control. Loss of control can occur in a variety of neurologic disorders, including stroke, spinal cord injury, and tumors and lesions of the spinal cord.

The purposes of a bladder reconditioning program are to prevent urinary complications such as infection and **calculi** (stones) and to allow the patient freedom from fear of embarrassment and loss of self-esteem. Calculi are less likely to develop when there is a high fluid intake and frequent, complete emptying of the bladder.

Bladder function is assessed to determine the optimal neural and muscular control that can be realistically expected in view of the physiologic cause of loss of control. In developing a bladder reconditioning program, the patient's mental and emotional ability to cooperate and take an active part in carrying out the program is evaluated.

The cause of urinary incontinence must be known, and the specific symptoms manifested by the patient must be clearly defined. Significant data include information about:

- Difficulty in starting to void
- Any methods the patient uses to initiate voiding (e.g., pressure on the bladder)
- Degree of awareness of the need to void
- Ability to empty the bladder completely, and amount of residual urine
- Signs of bladder distention and dribbling or overflow
- Nighttime incontinence
- Stress incontinence
- Usual times for voiding

Spinal cord injuries and lesions produce what is known as a cord bladder or neurogenic bladder. Patients with disorders of this type are not aware of the need to void and must be trained in techniques to initiate voiding and emptying the bladder.

The second step in a bladder training program is to keep an accurate record of actual voiding times for a 2- to 3-day period. Some problems of incontinence can be corrected by a simple scheduling of voiding times. Offering a bedpan or getting the patient up to the bathroom one-half hour before times she is usually incontinent may remedy the problem.

A bladder training program usually begins with a 2-hour schedule for toileting. The patient should attempt to drink 2000 to 3000 mL of fluid between waking up and 6 P.M. Coffee, tea, alcoholic beverages, and soda with caffeine should be avoided after dinner, because they have a diuretic effect. The patient is toileted before retiring for the night. The maintenance of an accurate training record is essential. A trial of 6 weeks is necessary before determining whether the training is successful. Various drugs that affect the voiding process, such as oxybutynin chloride (Ditropan),

flavoxate hydrochloride (Urispas), or solifenacain (VESIcare), may be helpful for certain types of patients. Assess whether the medication is beneficial.

Patients who have nerve damage and paralysis are trained in specific techniques to empty the bladder. The Credé maneuver, in which the open hand is pressed over the bladder area and directed toward the suprapubic area, can facilitate emptying a flaccid bladder. Self-catheterization is taught to patients with paraplegia so that they are not dependent on an indwelling catheter or on other people for their urinary elimination (Sheldon, 2013) (see also [Chapter 34](#)).

Some patients are candidates for the implantation of an artificial sphincter to control bladder release of urine. More and more types of successful devices are developed each year, but these are primarily for patients who have no neurologic control over the bladder.

Every patient undertaking a bladder retraining program needs a great deal of understanding and encouragement and a positive attitude to be successful. Praise for each small achievement should be given. Accidents should be expected and not looked on as "failures." Achieving total continence takes considerable time and effort but is possible for many patients.

Bowel Training Program

Bowel training is used to correct incontinence or prevent constipation and impaction in patients with neurologic disorders or injuries. The bowel training program begins with an assessment of the specific patterns of elimination. It also helps to know the patient's former bowel pattern before illness or injury. Did she regularly rely on the use of enemas or laxatives? Has she been prone to constipation? Next, establish whether the patient is aware of the urge to defecate or has any warning of evacuation.

Bowel training for either constipation or incontinence should incorporate an exercise program that is within the patient's ability, a high-fiber diet, and adequate liquid intake during the day. An accurate recording of bowel movements correlated with times of oral intake over a 2- to 3-day period will help establish the most opportune times to try to stimulate evacuation and thus establish a habit. If incontinence occurs at specific times after eating, toileting 30 minutes sooner and using a rectal suppository or a gloved finger to stimulate the urge to defecate may alter the pattern. Gradually the use of the suppository is discontinued.

For patients who are prone to constipation and incontinence, increasing liquid intake and administering a stool softener can be effective. If this does not work, a planned regimen of suppository or enema use may be necessary to assist with evacuation at a desired time, thus preventing incontinence.

All patients need to be comfortable when attempting to evacuate the bowel. A raised, padded toilet seat, handrails, and perhaps a footstool can provide enough comfort to allow the patient to relax so that evacuation can occur naturally. Privacy is essential. Remember to provide privacy for bedridden patients. Most of all, a positive attitude is needed by staff members. Many times, if the healthcare team and the patient are optimistic and patient, success can be achieved.

Pain

Many patients with neurologic disorders experience pain. The pain often is chronic in nature. Work with the patient to identify the characteristics of the pain, its location and spread, its intensity, and how it is affecting the patient's life. When the patient has suffered a head injury or is experiencing increasing ICP, narcotic analgesics may not be given, because they mask the signs of rising ICP. Other methods of analgesia must be employed.

A trusting relationship between the patient and the nurse is necessary for teaching to be assimilated. Teaching the patient about pain and its relief; the adverse effect of stress, anxiety, and unpleasant stimuli; and the benefits of distraction from the pain become part of the plan. Pain may cause difficulty in sleeping. Pharmacologic agents and alternative methods for pain control are used (see [Chapter 7](#)).

Think Critically

How would you determine whether a patient who has a decreased level of consciousness is experiencing pain?

Depression often occurs with chronic pain and lack of sleep. The combination of an antidepressant and pain medication often is more effective for chronic pain control than either type of drug used alone.

Confusion

Patients with brain tumors, head injuries, and strokes, as well as degenerative diseases, may experience confusion and deficits in memory, intellectual ability, or judgment. Confusion may be acute and short term, or it may be a permanent state. Confusion also may be mild or severe and may be accompanied by anxiety, agitation, and refusal to cooperate. The person is in a state of disorientation, and until the symptoms subside, she cannot behave rationally. She must be supported and protected, or she may injure herself. In states of severe (acute) confusion (**delirium**) the patient may experience hallucinations, delusions, and severe agitation. This is usually an acute, short-term state caused by fever or metabolic imbalance. Patients who experience confusion after a head injury often become combative as their ICP rises. It is not advisable to restrain these patients; be very careful to stay out of range of flailing arms.

Be alert to signs of confusion in any patient with a CNS problem. Subjective and objective assessment data include the following:

- Loss of orientation to person, place, or time
- Inability to cooperate fully with simple tasks and requests, such as eating and bathing
- Inappropriate statements or inappropriate answers to questions
- Restlessness and agitation
- Hostility and anxiety
- Hallucinations or delusions
- Other signs of inability to maintain control over thought processes and behavior

A patient who is confused needs above all else a stable and calm environment. Her thought processes are, in a sense, “fractured” and somewhat beyond her control. Stimuli entering her brain are frightening and threatening to her, and she simply cannot make sense out of most of what is going on around her. A calm, consistent, and orderly approach combined with a set daily routine is most helpful.

Attention to the safety of the patient is a priority. Family members must be taught measures to protect a patient who wanders, is disoriented, or lacks judgment (see [Chapter 47](#)).

Confused patients need a dependable, consistent schedule. If agitation or confusion causes undesirable behavior, the use of distraction can be beneficial. Handing the patient an item, leading her from the area, or decreasing environmental stimuli (turning off the television or radio) can calm the patient.

Patients with memory loss who can still read benefit from written instructions and from a posting of the day's schedule of activities. Measures to protect patients and deal with confusion are presented in [Chapter 47](#).

Aphasia

Aphasia is a defect in the ability to express oneself in speech or writing, or an inability to comprehend spoken or written language. Aphasia is caused by disease or injury of the brain centers controlling language comprehension and expression, located in the Wernicke area of the left cerebral hemisphere.

Aphasia may be **receptive, expressive, or global**. A person with receptive aphasia has difficulty interpreting communications in either spoken or written form. In expressive aphasia, the person has difficulty expressing herself in speech or writing. Global aphasia is when the person has a combination of receptive and expressive aphasia. Aphasias vary in degree and in type of deficit. For example, a person may be able to write a message but not form the words to say it.

A comprehensive assessment of a patient who has aphasia usually is a team effort carried out under the leadership of a specially trained speech therapist. Nurses and others responsible for the care of the aphasic patient can assist by noting specific abilities or inabilities of the patient to communicate with them.

Focused Assessment

Determining Type of Aphasia Problem

Questions to ask when evaluating the type and degree of aphasia a patient is experiencing include:

- Can the patient understand yes/no questions? Are her responses of “yes” and “no” reliable (does that seem to be what she means)?
- Can she point to or look toward objects you have named that are in her line of vision?
- Can she name the objects?
- Is she able to follow simple directions (e.g., “Turn your head.”)?
- Can she repeat simple words? Complex words?
- Can she repeat sentences?
- Can she follow simple written requests?
- Can she write answers to questions?
- Can she write requests?
- Can she read questions or directions?

A patient who suddenly has a problem speaking or understanding words or signs is likely to feel isolated and extremely frustrated unless an effort is made to establish some means of communicating with her as quickly as possible. Once the patient's specific problem is identified, which could be relatively simple or extremely complex, measures are taken to help the patient communicate as fully as her condition will allow.

Goals for the care of aphasic patients are focused on stimulating communication without undue frustration and gradually guiding them to appropriate responses and requests. Reaching these goals may take weeks or months, but there are helpful principles and techniques that can be used by all members of the health team and by family members and friends.

Perhaps the most important rule is to avoid talking to an aphasic person as if she were mentally incompetent. Her inability to communicate does not mean a lack of intelligence. She should be spoken **to**, not spoken **about** as if she cannot hear and understand what others are saying in her presence.

Speak slowly and distinctly in a normal voice as you are facing her. Use body language and sign language to communicate if it seems to help the patient. Your facial expressions, posture, and gestures can often say more than the words you are saying.

Give aphasic patients time to respond to questions. Do not ask more than one question at a time. It takes longer for an aphasic person to process what is being said. If you need to repeat a statement or question, use **exactly** the same words. She may have comprehended only half of the sentence the first time. Only one person should speak at a time. Be certain to establish eye contact with the patient before speaking. Keep the environment orderly, relaxed, and relatively free from distractions that make it difficult to concentrate on communicating.

The speech therapist will plan the patient's speech therapy program and will share with the nurse the details of how best to work with each individual patient. Some general guidelines include:

- Give praise for attempts at communication and for each correctly expressed word or sentence.
- Do not correct the patient's pronunciation, as she is liable to become too frustrated and give up speaking.
- Be very patient.

Problems with aphasia sometimes resolve spontaneously in 3 or 4 months after a CVA. Total speech rehabilitation can take many months and may never reach the pre-aphasia level.

Think Critically

Can you identify three specific techniques you might use to assist a patient with aphasia to communicate her needs?

Among the techniques used to stimulate communication and help the patient deal with her problem of aphasia are self-talk, parallel talk, expansion, and modeling. **Self-talk** helps the aphasic person associate activities with specific words and phrases. The caregiver talks about what he is doing while performing a task (e.g., making the bed). Self-talk is done in the presence of the patient so she can make the connection between what is being said and what she sees being done. **Parallel talk** describes for the patient what she is doing while she is performing some activity. In **expansion**, the person communicating with the patient completes the patient's sentences when she is able to verbalize but cannot yet speak in complete sentences. No new information is added during expansion. In **modeling**, the patient's sentences are completed, and new information is added. New technology is changing our lives daily. Laptops and tablets have programs that can assist aphasic patients through various techniques, such as giving phonemic cues. Often if a patient is just given the first sound of a word she can say the complete word.

It has long been suggested that writing may be the best approach in some cases. New techniques have been developed using text messaging as a lexical writing treatment for individuals with severe aphasia ([Beeson et al, 2013](#)).

All of these techniques are helpful in improving communication. They are forms of therapy, however, and are used only in a planned program that has been designed to meet a patient's individual needs. Whatever techniques are chosen, they should not be used in a condescending manner; an adult patient should always be treated respectfully.

The plan of care for an aphasic patient should not neglect the physical condition of her mouth and tongue. Good oral hygiene is needed to keep the oral mucosa clean and moist and in optimal condition so that it is easier for the patient to form words.

Sexual Dysfunction

Sexual dysfunction from a lesion in neural pathways should be dealt with by allowing expression of the patient's concerns, beliefs, and feelings. Sexual counseling by someone skilled in working with patients with neurologic deficits should be initiated. Alternative techniques for meeting sexual needs must be explored. Many patients can, with teaching, lead a sexually satisfying life.

Psychosocial Concerns

The multiple stresses, alteration in roles, and changes in body image and self-esteem that result from a chronic neurologic disorder can be overwhelming. The patient will need time and assistance in adapting to an altered body image. Be accepting of the patient's expression of anxiety, anger, denial, regression, and depression. Work to support the patient emotionally, attempting to establish realistic hope for quality of life. Exploring the patient's previous methods of coping with adversity, as well as her support systems, talents, and desires, helps to provide clues for how best to help her. Jointly establishing small, accomplishable goals can do much to rebuild self-esteem.

Collaboration with the social worker concerning referral to support groups and interaction with others with similar disabilities who are coping well can prove most beneficial. Contact with community agencies that offer support services and job retraining, if pertinent, is essential. The patient needs a way to be a productive member of society and to contribute to the welfare of her family. The county or state office of vocational rehabilitation may help with funding.

Reentry into the community and a normal social life are other areas for intervention. Often the patient has been out of touch with her normal social circles for many months during the illness and recovery process. Plans should be made before discharge for social contact to be reinstated.

Ineffective Family Coping

A chronic neurologic disorder that disrupts normal function for the patient also disrupts normal roles within the family. Family lifestyle is altered, and changes in roles may lead to family conflict. Family members often feel powerless, ambivalent toward the patient, angry, and guilty for having

angry feelings. Family members need to be included when educating the patient about her disorder, the possibility of remissions and exacerbations, and the self-care measures necessary. Everyone needs time to adjust to the situation. Referrals to counseling and support groups can be very helpful.

Get Ready for the NCLEX® Examination!

Key Points

- When deprived of oxygen, neurons die quickly.
- Many changes occur with aging, and after age 70 years the brain atrophies somewhat.
- Reflexes diminish or are lost as age advances.
- Preventing accidents and head injuries by teaching safety practices reduces the number of neurologic injuries.
- Discouraging recreational drug use helps prevent neurologic damage.
- Teaching patients how to reduce risk factors for stroke can prevent the devastation that a stroke can inflict.
- Nurses routinely perform gross assessment of the cranial nerves, coordination and balance, muscle strength, and reflexes.
- Vital signs, mental function, neuromuscular status, papillary reactions, and level of consciousness are parts of the physical assessment and are always performed as part of the “neuro” check.
- A thorough history is gathered, focusing on areas of neurologic function (see [Focused Assessment](#)).
- Nursing care is individualized, with problem statements/nursing diagnoses, outcome objectives, and interventions chosen to alleviate the various problems (see [Table 21-9](#)).
- Every effort is made to maintain effective breathing for neurologic patients.
- Many neurologic patients experience impaired mobility, and nurses attempt to prevent the associated potential problems.
- Assisting with ADLs when patients have self-care deficits is a major part of nursing care for patients with neurologic disorders.
- Specific techniques are needed for patients with dysphagia to prevent aspiration.
- Many patients with bowel or bladder incontinence can regain continence through bowel and bladder retraining programs.
- Pain control can be a difficult issue, because most pain medications dull the sensorium and will interfere with accurate neurologic assessment and signs of decreasing level of consciousness.
- Many patients with neurologic disorders become confused, and there are special techniques nurses use to assist these patients.
- Learning to work with an aphasic patient is essential to providing care for her.
- When appropriate, neurologic patients should be referred for sexual counseling.
- When a family member has a neurologic deficit, it affects the whole family and can disrupt normal family functioning; families need help to learn to cope.

Review Questions for the NCLEX® Examination

1. The nurse demonstrates understanding of the physiologic changes in the nervous system associated with aging by:

1. providing extra time for the patient to process and answer questions.
2. teaching the patient how to perform activities of daily living.
3. finishing the patient's sentences when she is responding to questions.
4. communicating slowly and loudly with low-pitched tones.

NCLEX Client Need: Health Promotion and Maintenance, the Aging Process

2. A nurse scrapes an object along the sole of a patient's foot and notes that the great toe bends upward and the smaller toes fan outward. The clinical finding is suggestive of:

1. sensory abnormality of the cortex.
2. motor abnormality of the cortex.
3. cerebellar tissue destruction.
4. a normal finding.

NCLEX Client Need: Physiological Integrity, Basic Care

3. A nurse assesses consensual reflex. To do this, he:

1. shines a light in one eye and observes for any change in the other eye's pupil.
2. has the patient look at an object in the distance and then at his fingers 6 inches from the eyes, observing for pupil constriction.
3. has the patient look as far in one direction as possible to determine whether the eyes go back and forth rapidly.
4. holds a tissue to the corner of the eye to see whether the patient blinks.

NCLEX Client Need: Physiological Integrity, Reduction of Risk Potential

4. Which nursing intervention(s) would be appropriate when providing care for a patient with right hemiplegia from a stroke? (*Select all that apply.*)

1. Reminding the patient to pay attention to the left side
2. Protecting the right extremities during transfers
3. Supporting the unaffected arm with pillows
4. Using a sling on the affected arm to promote better balance
5. Initiating ROM exercises

NCLEX Client Need: Physiological Integrity, Safety

5. While reviewing a patient's chart, the nurse notes that the patient has a condition known as *expressive aphasia*. What responses might she expect from the patient upon showing the patient a key and asking, "What is this?"

1. The patient responds, "Argh ooh."
2. The patient looks away and gazes out the window.
3. The patient responds, "It is a key and it is used to eat my food."
4. The patient does not respond.

NCLEX Client Need: Physiological Integrity, Basic Pathophysiology

6. While assisting a patient with feeding, the nurse describes every step in meal preparation in simple language. This is referred to as:

1. parallel talk.
2. self-talk.
3. expansion.
4. modeling.

NCLEX Client Need: Psychosocial Integrity, Therapeutic Environment

7. A nurse is providing discharge instructions to an older adult Iranian man who experienced a stroke. The nurse notices that the patient seems indifferent to teaching. The nurse must consider:

1. talking to the wife or daughter.
2. involving the entire family in the care of the patient.

3. sending the patient to a long-term care facility.
4. stopping and trying again later.

NCLEX Client Need: Psychosocial Integrity, Coping Mechanisms

8. When giving instructions to a patient with some dysphagia, further teaching is needed if the patient states:

1. "I must sit upright when I eat."
2. "I can watch my crime show on TV while I eat."
3. "I should stay upright after eating for at least 30 minutes."
4. "I should be calm and unhurried when eating."

NCLEX Client Need: Physiological Integrity, Safety

9. With an open hand, a nurse presses over the flaccid bladder of a patient. When questioned regarding the nursing action, an appropriate response would be:

1. "The technique increases the muscle tone of the bladder."
2. "The maneuver facilitates removal of urinary sediments."
3. "The technique assists with complete bladder emptying."
4. "The technique reduces the incidence of bladder irritation."

NCLEX Client Need: Physiological Integrity, Basic Care

10. A nurse uses the Glasgow Coma Scale to evaluate the neurologic responses of a patient. The patient opens eyes to pain, makes incomprehensible verbal sounds, and extends extremities with pain. The score would suggest:

1. locked-in syndrome.
2. brain death.
3. coma.
4. lethargy.

NCLEX Client Need: Physiological Integrity, Basic Care

Critical Thinking Questions

Scenario A

Mr. Lawson is to have several diagnostic tests to determine the cause of his neurologic symptoms, which include headache, visual disturbance, muscular weakness, and personality change.

1. How would you explain an electroencephalogram to Mr. Lawson? A computed tomography scan? Magnetic resonance imaging?
2. If you are to assess Mr. Lawson's "neuro signs" and he is using eyedrops for glaucoma that constrict the pupils, how would you evaluate his pupillary responses?

Scenario B

Mr. Horton has experienced a CVA and has incontinence of urine.

1. How would you institute a bladder training program for him?
2. What would you do to protect his skin, and his dignity, during the bladder training?
3. If bladder training cannot be accomplished, what is the best way to handle his urinary elimination?

*Refer to an anatomy and physiology text for a thorough review of the complex nervous system.

CHAPTER 22

Care of Patients With Head and Spinal Cord Injuries

Objectives

Theory

1. Describe the types of injuries that result from head trauma.
2. Compare and contrast the signs and symptoms of subdural hematoma and epidural hematoma.
3. Explain why an epidural hematoma causes an emergency situation.
4. Review the type of procedure performed to relieve a subdural hematoma.
5. Illustrate the pathophysiology of increasing intracranial pressure in a patient who has experienced a severe head injury.
6. Review the reasons why an older adult is more at risk for an intracranial bleed from a head injury.
7. Explain the possible ramifications of spinal cord injury.
8. Plan appropriate nursing interventions necessary to provide comprehensive care for a patient who has suffered a C5 spinal cord injury.
9. Analyze and review the symptoms of low back pain and correlate them with their causes.

Clinical Practice

10. Teach a family member how to properly assess and care for a patient who has suffered a concussion.
11. Perform a neurologic check on a patient who has suffered head trauma.
12. Participate in a collaborative care planning conference for a patient who has sustained a spinal cord injury.
13. Prepare a plan for teaching self-care measures to a patient who suffers from low back pain.

KEY TERMS

- concussion** (kōn-KÜ-shūn, p. 500)
- contralateral** (kōn-trä-LÄT-är- āl, p. 502)
- contusion** (kōn-TÜ-zhūn, p. 501)
- coup-contrecoup injury** (kū kō-trē-kū, p. 501)
- epidural hematoma** (Ě-pě-DÜ-rūl hē-mă -TŌ-mă, p. 501)
- hydrocephalus** (hī-drō-SĚF-ă-lās, p. 509)

subdural hematoma (süb-DÜ-rūl, p. 501)
subluxation (süb-lük-SĀ-shūn, p. 510)

Traumatic Brain (Head) Injuries

Traumatic brain injuries (TBI) are a common cause of injury and death. About 1.7 million people sustain a head and brain injury in the United States each year. Approximately 52,000 die, and 1.2 million are treated for traumatic brain injury and released. Those who survive initial head injury require meticulous observation and care so that damage to the brain cells can be kept at a minimum and death averted. There are about 5.6 million people in the United States who require lifelong help with activities of daily living because of residual disabilities from brain injury (Faul et al, 2010).

Etiology

A blow to the head may cause a laceration of the skin or scalp and fracture of the skull or may only cause a minor contusion. The injury may cause movement of the brain within the skull, tearing blood vessels. Falls are the most common cause of head injury, with motor vehicle accidents being the second leading cause.

Pathophysiology

When a depressed skull fracture occurs, there is bruising, contusion, or laceration of the underlying brain tissue, with the inflammatory changes that occur with any wound. A minor head injury may cause concussion. **Concussion** is the term used to describe a closed head injury in which there is a brief disruption in level of consciousness (LOC), amnesia regarding the occurrence, and headache. A concussion's seriousness is based on the length of time there was loss of consciousness. There can be long-term neurologic deficits from concussion, particularly if an individual suffers repeated concussions from accidents or sports¹.

Skull fractures are described as:

- Linear or depressed
- Simple, comminuted, or compound
- Closed or open

In an **open** injury there is laceration of the scalp and fracture of the skull with damage to brain tissue. A **closed** injury is one in which the scalp and skull remain intact, but the underlying brain tissue is damaged. There may be contused areas or hematoma. In closed injuries a very serious condition known as *increased intracranial pressure* may result.

Older Adult Care Points

The brain atrophies with age and does not take up as much space in the cranial vault. This allows for more movement and more potential for torn vessels and contusions on the brain when an accident occurs that involves a head injury.

In a **contusion**, the brain tissue is bruised, blood from broken vessels accumulates, and edema develops. This could lead to the development of increased intracranial pressure (ICP).

A **coup-contrecoup injury**, or an **acceleration-deceleration injury**, occurs when the head is moving rapidly and hits a stationary object, such as a windshield. The contents within the cranium hit the inside of the skull (coup) and then bounce back and hit the bony area opposite the site of impact, causing a second injury (contrecoup) (Figure 22-1).

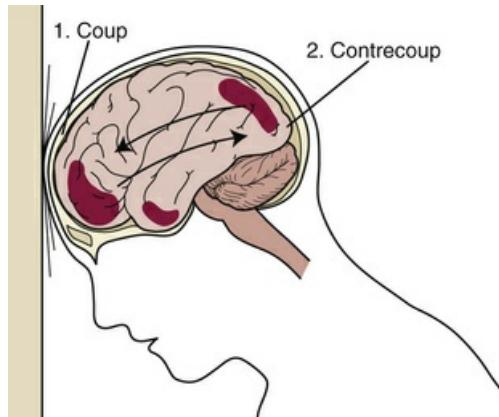

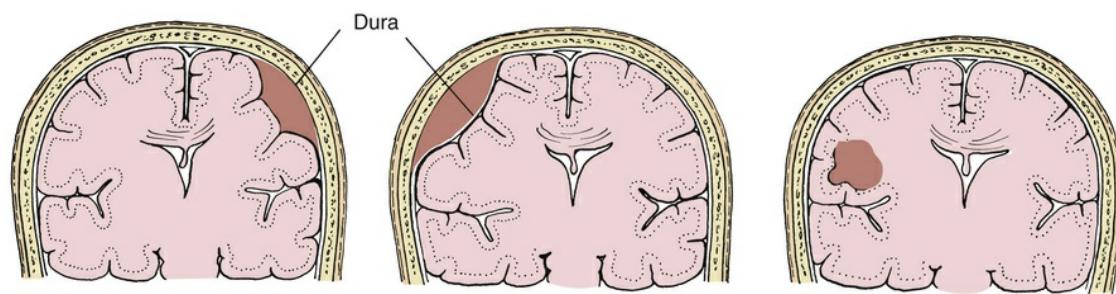

FIGURE 22-1 Coup-contrecoup (acceleration-deceleration) injury.

Subdural hematoma is a common result of head injury. It often happens in older adults as a result of a fall. Anticoagulant therapy puts a patient at greater risk for a subdural hematoma (blood-filled swelling) after even a minor blow to the head. When a blow is delivered to the head, it may rupture the blood vessels that lie between the delicate arachnoid membrane covering the brain and the tough, fibrous dura mater. As the blood leaks under the dura mater (subdural), the hematoma grows in size, pressing against the softer arachnoid and the brain tissue it is covering (Figure 22-2, A).

A Subdural hematoma **B** Epidural hematoma **C** Intracerebral hematoma

FIGURE 22-2 A, Subdural hematoma. As a result of trauma to the head, small ruptured blood vessels leak blood into the space under the dura mater (slower than an epidural bleed). B, Epidural hematoma, the result of a head injury that tears a large meningeal artery, has caused a rapid bleed with a large amount of blood above the dura mater. If not relieved, subdural and epidural hematomas can be fatal. C, Intracerebral hematoma. Small vessels within the brain have torn and bled. (From Black JM, Hawks JH: *Medical-surgical nursing: Clinical management for positive outcomes*, ed. 8, Philadelphia, 2009, Saunders.)

Diffuse axonal injury occurs from a rapid acceleration-deceleration injury in which there is lateral movement. This is often referred to as a *shearing injury* if there is diffuse injury to the white matter of the brain.

Older Adult Care Points

Because the brain of older adults tends to move more in the cranial vault when head trauma occurs, small vessels may be torn, putting these patients more at risk for a slow-developing subdural hematoma. When such an injury occurs, the person should be watched for several months for signs of personality change, decreasing LOC, increased irritability, and other signs of increased ICP.

An **epidural hematoma** occurs more rarely, but when it does, there is rapid leakage of blood from the middle meningeal artery (or, rarely, from some other vessel), which quickly elevates ICP (see Figure 22-2, B). This constitutes a medical emergency. A craniotomy is needed to repair the damaged vessel and relieve the rapidly rising pressure, before death occurs from the increased ICP. An **intracerebral hematoma** may occur within the brain from a blow to the head (see Figure 22-2,

C).

Signs and Symptoms

The severity of brain damage from a head injury is best judged by the symptoms presented by the patient, a neurologic assessment, the history of the type of blow received, and whether and for how long the victim lost consciousness. The outward symptoms of head injury are fairly obvious; these include bruising, swelling, lacerations, and bleeding. There may be a skull fracture with ecchymoses around the eyes (raccoon eyes), or ecchymoses behind the ear (Battle sign) (Figure 22-3). There may be otorrhea (fluid from the ear), rhinorrhea (fluid from the nose), tinnitus (ringing in the ear) or hearing difficulty, facial paralysis, and conjugate deviation of gaze wherein both eyes deviate to one side. Otorrhea and rhinorrhea should be tested to determine whether there is a cerebrospinal fluid (CSF) leak. Testing with a Dextrostix will determine whether glucose is present; the presence of glucose indicates cerebrospinal fluid. A bleeding into the subarachnoid space may be evidenced by **nuchal rigidity** (neck pain with flexion).

FIGURE 22-3 Battle sign. (From Bingham BJB, Hawke M, Kwok P: *Clinical atlas of otolaryngology*. St. Louis, 1992, Mosby.)

Whenever a moderate or severe head injury has occurred, cervical spine injury is assumed, until proven otherwise.

Clinical Cues

If the fluid from the ear or nose is tinged with blood, a Dextrostix will not give accurate results. Collect about a teaspoon of the fluid on a white gauze pad. Within a few minutes blood will move to the center and a yellow ring (halo) will form around it if the fluid is CSF (Figure 22-4).

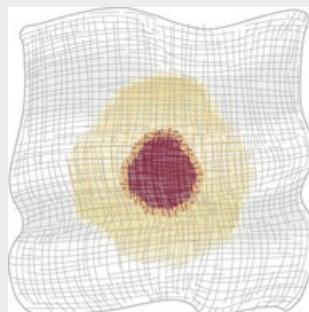

FIGURE 22-4 Assessing for the halo sign on fluid from the nose or ear after a head injury. The blood will draw together in the middle of the gauze pad, leaving a yellow ring (halo) around the blood, indicating the presence of cerebrospinal fluid.

A concussion can cause a brief disruption of the normal LOC, amnesia regarding the event, and headache. A contusion can cause an alteration in LOC and may cause seizures. Box 22-1 shows the downward progression of decreased LOC.

Box 22-1

Decreasing Levels of Consciousness (LOC)

- *Alert:* Responds appropriately to questions and commands with little stimulation. Attends to surroundings.
- *Confused:* Somewhat disoriented to surroundings, time, or people. Judgment may be impaired. Needs to be cued to respond to commands.
- *Lethargic:* Drowsy, but easily aroused; needs gentle touch or verbal stimulation to attend to commands.
- *Obtunded:* More difficult to arouse and responds slowly to stimulation. Needs repeated stimulation to maintain attention and to respond to the environment.
- *Stuporous:* Responds to vigorous stimulation only slightly; may only moan or mutter in response.
- *Comatose:* No observable response to stimulation.

A subdural hematoma² may be acute, subacute, or chronic, building up over time. An acute intracerebral bleed causing hematoma formation is accompanied by unconsciousness, hemiplegia on the **contralateral** (opposite) side, and a dilated pupil on the **ipsilateral** (same) side. However, the symptoms indicating a slow buildup of pressure within the skull are more subtle and less easily detected.

Signs of epidural hematoma may include unconsciousness at the time of the injury, a brief lucid interval followed by decreasing LOC, headache, nausea and vomiting, and dilation of the ipsilateral pupil. The patient is observed for signs of increased ICP, as well as other focal changes (see **Increased Intracranial Pressure** later in this chapter).

Diagnosis

The diagnostic tests and examinations commonly used to determine the extent of head injury include a radiograph of the skull, a computed tomography (CT) scan, magnetic resonance imaging (MRI) with contrast, positron emission tomography, evoked potentials, and electroencephalography (**Figures 22-5** and **22-6**) (see **Table 21-6**).

Think Critically

Why should every patient who has sustained a head injury be monitored closely for 24 to 48 hours?

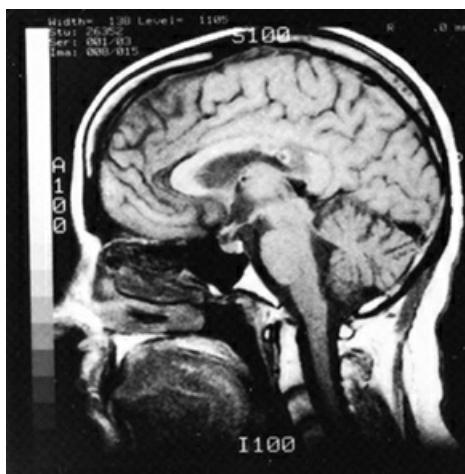

FIGURE 22-5 Magnetic resonance imaging midline sagittal view of the brain. (From Chipp E, Clanin N,

FIGURE 22-6 Electroencephalogram (EEG). (From Fuller G, Manford M: *Neurology*, ed. 3, London, 2011, Churchill Livingstone.)

Treatment

Patients with a head injury usually are initially treated conservatively. If the injury causes an increase in ICP or is a compound fracture of the skull, surgical debridement of the wound and removal of splintered bone from the brain tissues or elevation of the skull fragment is performed. All measures to keep ICP from rising are instituted for serious head injuries.

A patent airway must be secured and the head raised 20 to 30 degrees with the body in correct alignment. Elevation helps reduce ICP. Neurologic signs are monitored closely. An intravenous (IV) line is inserted for access for diuretic drugs, if needed, and for administration of fluid. Intravenous fluids are infused very slowly to prevent fluid overload that would increase the ICP. Diuretics are used to decrease vascular volume and keep ICP as low as possible.

Think Critically

Why would a nurse check for a patent airway before performing a neurologic assessment on a patient with a head injury?

Surgical Intervention

Subdural hematoma is removed surgically either via burr holes or by craniotomy incision. The hematoma is evacuated by suction or surgical instruments. Epidural hematoma necessitates immediate, emergency craniotomy to prevent death from increased ICP. The craniotomy procedure is described in [Chapter 23](#) along with surgeries of the brain.

Preoperative period.

A patient with a hematoma is quickly prepared for surgery. The operative site is shaved after the patient is under anesthesia. For planned surgery, a shampoo may be ordered the evening before surgery. Preoperative preparation is the same as for other surgeries. Any scalp lesions or other unusual conditions that are noted at this time should be reported. Usually the entire head is not shaved, only the operative area, and—if the patient has long hair—any hair that is cut off may be saved to be used as a hairpiece until the patient's hair grows back.

Postoperative period.

During the immediate postoperative period, the patient who underwent a craniotomy is in the intensive care unit for continuous monitoring. Essentially, care will be the same as that for any patient in danger of increasing ICP. Additional postoperative care of a patient who has undergone intracranial surgery includes:

- Positioning the patient according to written orders from the attending surgeon. **Make no exceptions.** Positioning is important to prevent added increases in ICP.
- Keeping the neck in midline and preventing excessive hip flexion to promote venous drainage from the head and keep ICP from rising ([McIlvoy and Meyer, 2012](#)).
- Using nasal suctioning **only** if there is a written order allowing this, because there may be a fracture that allows a pathway to the brain tissue.
- Watching carefully for signs of leakage of CSF from the nose, ear, and operative site, and reporting evidence of leakage immediately. Use aseptic technique in applying dressings to catch the drainage and prevent microorganisms from entering.
- Providing a quiet, nonstimulating environment.
- Administering only those treatments, comfort measures, and medications for which there are specific written orders.
- Reporting promptly any changes in the neurologic status of the patient.

Nursing Management

If it has been determined that there is indeed leakage of spinal fluid through the nose, ear, or an open head wound, special precautions must be taken to prevent infection, and the provider must be notified. These precautions include the following:

- Keep the patient on absolute bed rest with the head of the bed elevated 20 to 30 degrees to promote venous drainage from the head.
- Cover a draining ear with a sterile gauze pad, changing the pad periodically to look for drainage.
- Instruct the patient **not** to blow his nose or pick at it; blowing may increase ICP, and picking may allow entry of microorganisms.
- Do not plug the nose or ear if there is drainage of CSF, because blockage may increase ICP.
- Remind the patient that he is not to change his position **in any way** unless he has been told it is all right to do so, to prevent ICP from rising.

Continued neurologic assessments are an integral part of care. Specific problem statements/nursing diagnoses are listed in [Nursing Care Plan 22-1](#). Specific instruction is required for the observation of a patient treated in an emergency department for head injury and released to go home. The long-term outcome for patients who have suffered a severe head injury is unpredictable. Recovery is a long process, and improvement may occur over many months for some patients. Disabilities may be lifelong.

Patient Teaching

Instructions for Care of a Patient With a Head Injury

Teach the family or significant other to do the following:

- For the first 24 hours, awaken the person every 2 to 3 hours to be certain he can be easily aroused.
- Question the person about where he is, who you are, what happened, and so on, to check orientation.
- Check the pupils to see that they are equal in size and that they will constrict; use a flashlight.
- The patient should avoid strenuous activity for 48 hours.
- Apply an ice bag to areas of swelling for 20 minutes each hour while the patient is awake—continue for 24 hours.

- For 48 hours, watch for and report the following signs:
- Change in level of consciousness (e.g., becoming more groggy, difficult to awaken, confused, restless, agitated)
- Projectile vomiting (vomit travels a distance) without nausea
- Unusual dizziness, sleepiness, loss of balance, or fall
- Change in vision (i.e., seeing double, blurred vision)
- Jerking movements of the eyes
- Increasing headache that is worse when moving
- Any twitching that cannot be controlled (seizures)
- A change in speech or ability to find words or converse
- Behavior that is odd for the individual

Legal and Ethical Considerations

Documenting Patient Teaching

Because there are legal ramifications of inadequate patient and family teaching, document all teaching in the medical record and send home clearly written instructions. It is best to have the patient or family sign a form for the record that indicates that teaching and written instructions have been received.

Think Critically

Why are patients with a head injury positioned with the head of the bed elevated 20 to 30 degrees with the head and neck in proper alignment?

Nursing Care Plan 22-1

Care of a Patient With a Head Injury and Increased Intracranial Pressure

Scenario

Ryan, an 18-year-old boy who suffered a head injury in an automobile accident is groggy, but arousable.

Problem Statement/Nursing Diagnosis

Potential altered cerebral perfusion/*At risk for ineffective cerebral tissue perfusion related to increased ICP from head injury.*

Supporting Assessment Data

Subjective: Hit right side of head on dashboard.

Objective: Nondepressed skull fracture, alteration in LOC, confused as to where he is, what day it is; somewhat combative.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will not display further increase in ICP.	Monitor neurologic status hourly using Glasgow Coma Scale (GCS); notify provider of any pupil changes or signs of increasing ICP, such as widening pulse pressure, change in respiratory pattern, slowing of pulse, increase in temperature, or decrease in LOC.	GCS provides good estimate of neurologic status.	GCS maintaining at 12.
	Monitor for seizure activity; institute seizure precautions. Administer ordered anticonvulsant.	Increased pressure on brain tissue may cause cellular irritability and seizure activity.	No sign of seizure activity. Precautions in place; padded tongue blade at bedside.
	Keep head of bed (HOB) at 30 degrees and body in correct alignment; turn side to side q2h if condition warrants.	Keeping head slightly elevated and in proper alignment helps promote venous drainage from the head.	HOB at 30 degrees; positioned in correct alignment with neck midline. Turned q2h.
	Maintain IV infusion at 50 mL/hr.	Decreasing IV rate helps prevent increased ICP and maintains IV access.	IV infusion at 50 mL/hr; patient without redness or swelling at site.
	Administer diuretic as ordered.	Diuretic decreases vascular volume and intracranial volume, lowering ICP.	Mannitol administered.
	Keep room calm and softly lit; do not disturb more than necessary; talk to patient while giving care; allow rest periods between any invasive procedures; monitor intake and output; reorient patient frequently.	Invasive procedures raise ICP.	Room is tidy and softly lit; care procedures grouped at intervals allowing rest; $I > 400 \text{ mL}$, $O > 375 \text{ mL}$.

Problem Statement/Nursing Diagnosis

Altered self-care ability/*Self-care deficit related to confusion, grogginess, and increased ICP.*

Supporting Assessment Data

Objective: Falls asleep during attempts at bath, etc.; confused about how to use ordinary objects such as toothbrush.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will have adequate assistance with hygiene and dressing.	Provide assistance with all ADLs.	Patient with ICP may require temporary assistance with ADLs	Assisted with morning care.
	Inspect skin when turning; place foam pad on bed.	Pressure-relieving device helps prevent pressure ulcer formation.	No signs of reddened areas on skin. Foam pad on bed.
Patient will resume self-care by discharge.	Encourage self-care as LOC improves.	Resolution of ICP improves ability to perform self-care.	Continue plan. Not ready for self-care yet.

Problem Statement/Nursing Diagnosis

Altered family coping/*Disabled family coping related to patient's decreased LOC and hospitalization.*

Supporting Assessment Data

Subjective: Mother states she is afraid son is going to die.

Objective: Mother keeps trying to rouse the patient when she is in the room.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Mother's anxiety will decrease as she gains information about her son's condition and prognosis.	Explain to family that confusion and grogginess are usual after head injury.	Knowledge decreases fear of the unknown.	Explained patient's condition to family and measures to keep ICP down. Mother seems less anxious. Discussed need for calm and positive talk in room. Continue plan.
	Explain that the danger is if the ICP keeps increasing; tell what measures are being done to minimize increasing ICP; explain all procedures; explain that calm, rest, and positive talk in the room will help.	Knowing the treatment plan decreases anxiety.	
	Call hospital chaplain or own minister if family desires.	Presence of spiritual advisor can decrease anxiety.	
	Keep family informed of changes in patient's condition.	Families need to make informed decisions.	

ADLs, Activities of daily living; I, input; ICP, intracranial pressure; IV, intravenous; LOC, level of consciousness; O, output.

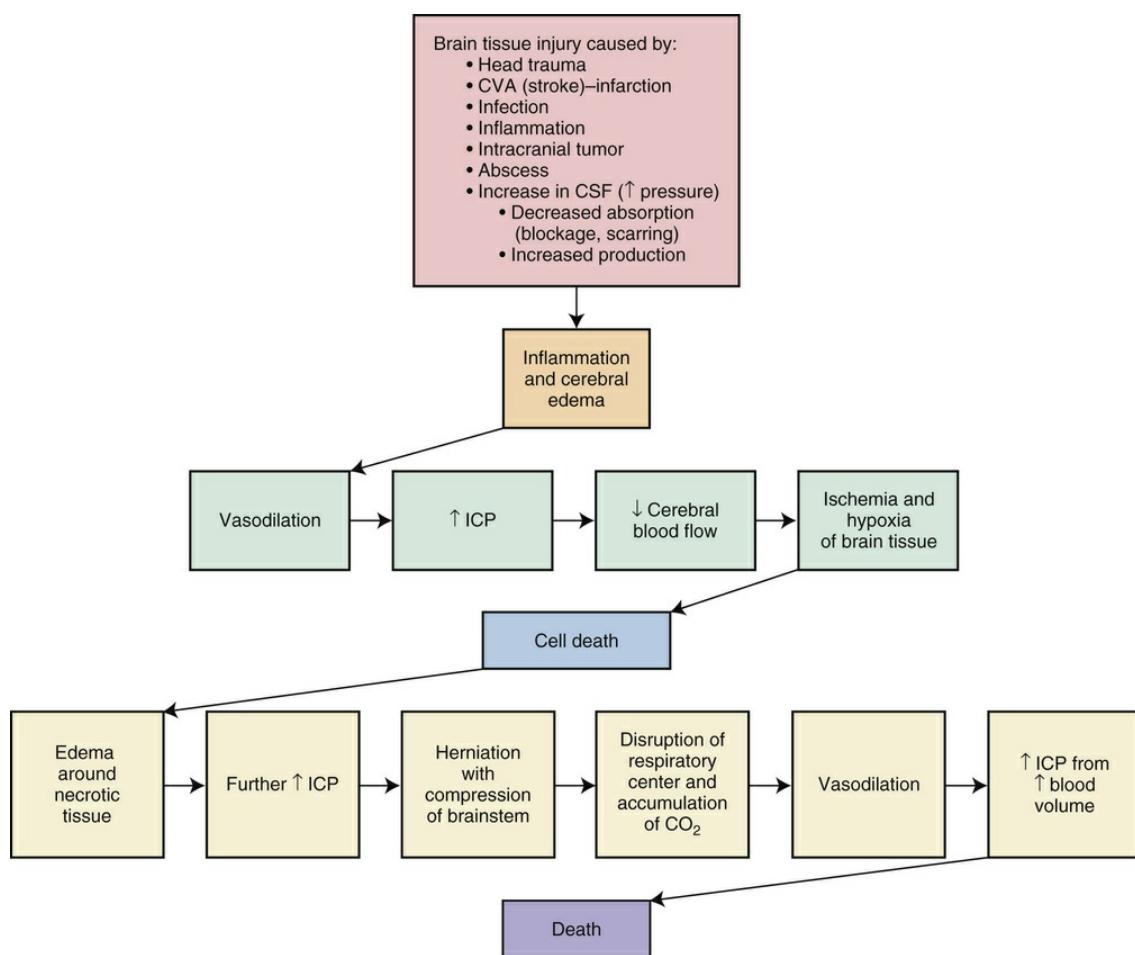

Critical Thinking Questions

- Why would it be contraindicated for this patient to strain to have a bowel movement?
- Why is it important to decrease stimuli and provide a calm, soothing environment for this patient? (Be specific.)

Increased Intracranial Pressure

Etiology and Pathophysiology

Because the skull is a closed bony structure in adults, it is unable to expand. Any lesion or fluid accumulation that begins to take up space within the cranial cavity causes an increase in the pressure within the cavity. Therefore any swelling of the brain tissue from injury or surgery, leakage of blood from ruptured cerebral vessels, excessive production of CSF, or tumors, abscesses, or any other space-occupying lesion within the skull presents an increased ICP risk. Pressure against cerebral veins and arteries interferes with the flow of blood, producing a local ischemia and hypoxia. Pressure against the cells themselves can interfere with their vital functions. If the ICP rises very high and remains high for very long, death can result from inadequate cerebral perfusion or cerebral herniation. Brainstem injuries or pressure on the brainstem from increased ICP cause respiratory depression from pressure on the medulla oblongata—carbon dioxide accumulates, causing vasodilation and further increases in ICP. Normal ICP is 0 to 15 mm Hg. Concept Map 22-1 shows the relationship between the causes and the pathologic occurrences of increased ICP.

Signs, Symptoms, and Diagnosis

When the body can no longer compensate for the increase in volume in the cranial vault, decompensation begins and clinical signs of increasing ICP become apparent. The earliest sign of increasing ICP is lethargy and decreasing consciousness, accompanied by a slowing of speech

and delay in response to verbal cues. **Papilledema** (swelling of the optic disc) viewed with an ophthalmoscope is a classic sign of increased ICP.

When ICP rises, it affects the oxygenated blood perfusion of the brain and tissue hypoxia occurs. Nerve cells are particularly sensitive to hypoxia and cannot be replaced once they have been destroyed. Extended periods of hypoxia cause brain cell death. The body tries to compensate for hypoxia by raising blood pressure, to force more oxygenated blood through the brain tissue. If ICP continues to rise, the brain tissue will herniate through the tentorial notch at the midline of the foramen magnum. This herniation results in pressure on the vital structures of the midbrain, pons, and medulla and causes changes in the vital signs and pupil reactions characteristic of increased ICP.

As brain tissue swells or fluid volume increases in the cranium, damage occurs or pressure is placed on the oculomotor or third cranial nerve. Pupils begin to react slowly; pupil size becomes unequal, progressing to dilation, and then the pupil size becomes fixed as reflexes disappear.

Clinical Cues

Abnormal pupillary responses can reverse to normal if the cause of increased ICP can be resolved in time.

The classic signs of increased ICP, the first three of which are called the *Cushing triad*, are:

- Rising systolic blood pressure
- Widening pulse pressure
- Bradycardia with a full, bounding pulse
- Rapid or irregular respirations (Figure 22-7)

Pattern	Location of Lesion	Description
1. Cheyne-Stokes	Bilateral hemispheric disease or metabolic brain dysfunction	Cycles of hyperventilation and apnea
2. Central neurogenic hyperventilation	Brainstem between lower midbrain and upper pons	Sustained, regular rapid and deep breathing
3. Apneustic breathing	Mid or lower pons	Prolonged inspiratory phase or pauses alternating with expiratory pauses
4. Cluster breathing	Medulla or lower pons	Clusters of breaths follow each other with irregular pauses between
5. Ataxic breathing	Reticular formation of the medulla	Completely irregular with some breaths deep and some shallow. Random, irregular pauses, slow rate

FIGURE 22-7 Common abnormal respiratory patterns associated with coma. (From Lewis SL, Dirksen SR, Heitkemper MM, et al: *Medical-surgical nursing: Assessment and management of clinical problems*, ed. 9, St. Louis, 2014, Mosby.)

These signs tend to be late, as are pupil changes, and signal a severe emergency and the need for immediate action to try to prevent the patient's death.

Think Critically

Why does increasing intracranial edema cause a double threat to the brain?

Treatment

A patient with greatly increased ICP is usually placed in an intensive care unit. Increased ICP is treated with supportive care to keep the pressure from rising further and with interventions to decrease the cranial blood or CSF volume. Osmotic diuretics (mannitol, glycerol, urea) are administered to remove fluid from the body tissues, thereby reducing fluid in the brain. Dosage is determined by body weight, and electrolytes are monitored every 6 hours, because mannitol and diuretic action can cause electrolyte imbalances. Furosemide (Lasix) is sometimes also given. An indwelling urinary catheter is inserted to monitor output. Electrolytes and fluid balance are watched closely.

Dexamethasone (Decadron) may be given to decrease the inflammatory response and cerebral edema if the ICP is caused by a brain tumor or abscess (Porter and Kaplan, 2013). Histamine-2 (H_2)-receptor blockers or proton pump inhibitors are administered to protect the gastric mucosa. With the head of the bed at 20 to 30 degrees, the head and neck must be kept positioned midline so that venous drainage into the body is not restricted. Hip flexion should be less than 90 degrees. Rolled washcloths, towels, or trochanter rolls can be used for positioning.

If ICP is dangerously high as indicated by a Glasgow Coma Scale score of 9 or less and an abnormal CT scan, the surgeon may insert an intraventricular catheter into the lateral ventricle, through which CSF can be drained in small amounts to relieve the pressure. Pressure can be monitored with the catheter or a separate probe positioned in the epidural area. Cerebral perfusion pressure (CPP) must be maintained at 60 to 70 mm Hg to ensure oxygenation of the brain tissue (CPP = mean arterial pressure – intracranial pressure) (Aries et al, 2012). Normal CPP is 70 to 100 mm Hg. A monitoring device connected to the inserted probe may be used to measure cerebral blood flow. Some new devices monitor cerebral oxygenation and blood flow.

If the patient is on a ventilator and is extremely agitated, pancuronium bromide (Pavulon) to paralyze skeletal muscles, in combination with sedation, may be used to prevent further increases in ICP. Because carbon dioxide is a vasodilator and can increase blood volume within the cranial cavity, hyperventilation is sometimes used short term to combat the increased ICP. This is accomplished by increasing the rate of controlled respiration. A CO₂ level between 25 and 30 mm Hg will improve oxygenation to the brain by causing vasoconstriction. Box 22-2 provides general guidelines for the care of patients with increased ICP.

Box 22-2

Guidelines for Patients With Increased Intracranial Pressure (ICP)

Do

- Conduct neurologic checks at least once every hour unless more frequent monitoring is indicated.
- Report changes immediately.
- Maintain a patent airway and adequate ventilation to ensure proper oxygen and carbon dioxide exchange.
- Elevate the head of the bed 20 to 30 degrees to facilitate return of blood from the cerebral veins.
- Use measures to maintain normal body temperature. Elevations of temperature raise blood pressure and cerebral blood flow. Shivering also can increase ICP.

- Monitor intake and output. Restrict or encourage fluids according to provider's order.
- Give passive range-of-motion exercises.
- Space activities apart.

Do Not

- Allow patient to become constipated or perform Valsalva maneuver.
- Hyperextend, flex, or rotate the patient's head.
- Flex the patient's hips (as in female catheterization).
- Place patient in Trendelenburg's position for any reason.
- Allow patient to perform isometric exercises.

Barbiturates are sometimes used along with continuous brain wave monitoring when patients do not respond to the more common therapies for reduction of ICP. Their purpose is to induce heavy sedation and slow metabolism, thereby decreasing ICP. In general, the short-acting barbiturates are used (e.g., pentobarbital [Nembutal] and thiopental [Pentothal]). Phenytoin (Dilantin) may be used to prevent seizures for several months or up to a year after injury.

Temperature control is achieved by placing the patient on a hypothermia blanket for cooling if increased ICP has affected temperature regulation by pressure on the hypothalamus and the patient is feverish. Fever increases cerebral metabolism and cerebral edema.

Warmed blankets and tepid baths can be used to raise the temperature of a hypothermic patient and prevent shivering. Deep vein thrombosis prophylaxis is started early. Intravenous insulin may be titrated if the blood glucose level rises above 110 mg/dL.

Complications

Damage to brain cells from injury and during periods of increased ICP may cause residual scarring and seizures. **Hydrocephalus** (excessive accumulation of CSF) may occur (see [Chapter 23](#)), causing motor deficits, cranial nerve deficits, or decreased cognitive ability. Rehabilitation efforts are focused on eliminating or decreasing deficits and promoting as much cognitive and physical function as possible (see [Chapter 9](#)).

Diabetes insipidus.

Diabetes insipidus may occur from injury or edema of the pituitary gland. Antidiuretic hormone is released in inadequate amounts, resulting in polyuria, and the awake patient may complain of **polydipsia** (excessive thirst). Intravenous vasopressin and fluid replacement are the preferred treatments. Carefully monitor intake and output and electrolyte balance.

Nursing Management

Assessment (Data Collection)

Early recognition of increasing pressure is extremely important. Careful neurologic assessment with monitoring of the patient's LOC, pupillary reactions, level of neuromuscular activity, and vital signs is essential to accurately evaluate the patient's progress. "Neuro checks" are performed every 15 minutes to every 2 hours for acute patients (see [Chapter 21](#)). The following indications that ICP may be rising should be reported immediately:

- Extreme restlessness or excitability after a period of apparent calm
- Deepening stupor and decreasing LOC
- Headache that is unrelenting and increasing in intensity
- Vomiting, especially persistent, projectile vomiting
- Unequal size of pupils and other abnormal pupillary reactions
- Leakage of CSF from the nose or ear

- Changes in the patient's blood pressure, pulse, or respiration; widening pulse pressure; a slow, bounding pulse

Think Critically

Why do you think an older adult is at greater risk when a head injury or other cause of increased ICP occurs?

Nursing Diagnosis, Planning, and Implementation

The appropriate problem statement is Potential for altered cerebral tissue perfusion due to effects of increasing intracranial pressure.

Goals of nursing care are to:

- Maintain cerebral perfusion
- Reduce ICP
- Maintain adequate respiration
- Protect from injury
- Maintain normal body functions
- Prevent complications

The expected outcome would be that the patient will not experience brain damage from increased intracranial pressure.

Maintaining an open airway and adequate respiration may require suctioning and possibly intubation with mechanical ventilation. (If the patient has sustained a head injury, x-rays to rule out a basilar fracture are necessary before suctioning the nonintubated patient to prevent the possibility of the suction catheter entering the cranial vault.) A patient whose consciousness level is decreased and whose gag and swallowing reflexes are impaired is in danger of aspirating blood, vomitus, mucus, and other material into the air passages.

Position the patient on his side and ask him to exhale as you turn him to prevent a Valsalva maneuver, which could raise ICP. Instruct the patient not to grip the side rails or push with his feet or elbows against the mattress during repositioning for the same reason. Plan uninterrupted rest periods between activities that cause an increase in ICP; preferably, plan rest for 1 hour at a time. Provide a soothing environment free of noxious odors and noise. Keep the room temperature adjusted to normalize the patient's temperature and to prevent shivering ([Mcilvoy and Meyer, 2012](#)).

Nutrition supplied early improves outcomes after brain injury and increased ICP, because nutrition promotes healing ([Pillsbury and Oria, 2011](#)). If the patient  is unable to take food orally, supplementation is begun within 3 days after injury. Full nutritional supplementation should be in place by day 7. Nutrition is planned according to determined metabolic needs and the fluid and electrolyte status. Metabolic needs are calculated based on age, weight, and height.

Unless the patient has a tracheostomy or an oral airway in place, he should be positioned on his side—not on his back—because the tongue may occlude the airway, and mucus cannot drain naturally. **An unconscious patient requires care for all basic needs** (see [Table 21-9](#)).

Evaluation

Data are gathered regarding the success of the nursing interventions. If the interventions are not helping the patient meet the expected outcomes, the interventions should be changed.

Injuries of the Spine and Spinal Cord

Etiology

A person may suffer from injury to the spinal cord in a number of ways. Injury in the cervical and lumbar areas is more common because these segments are more mobile. Automobile accidents, gunshot wounds, diving accidents, and other forms of trauma often inflict severe damage to the spinal cord, but tumors, degenerative disease, and infections also can impair the functions of the spinal cord and its branches. Generally speaking, spinal cord injuries are classified according to their anatomic location—that is, cervical, thoracic, lumbar, or sacral (Figure 22-8). There are 12,000 spinal cord injuries per year in the United States (National Spinal Cord Injury Statistical Center, 2012). Whatever the cause of spinal cord injury, motor and sensory losses may occur. The amount of loss of function and sensation depends on the level and extent of injury to the spinal cord.

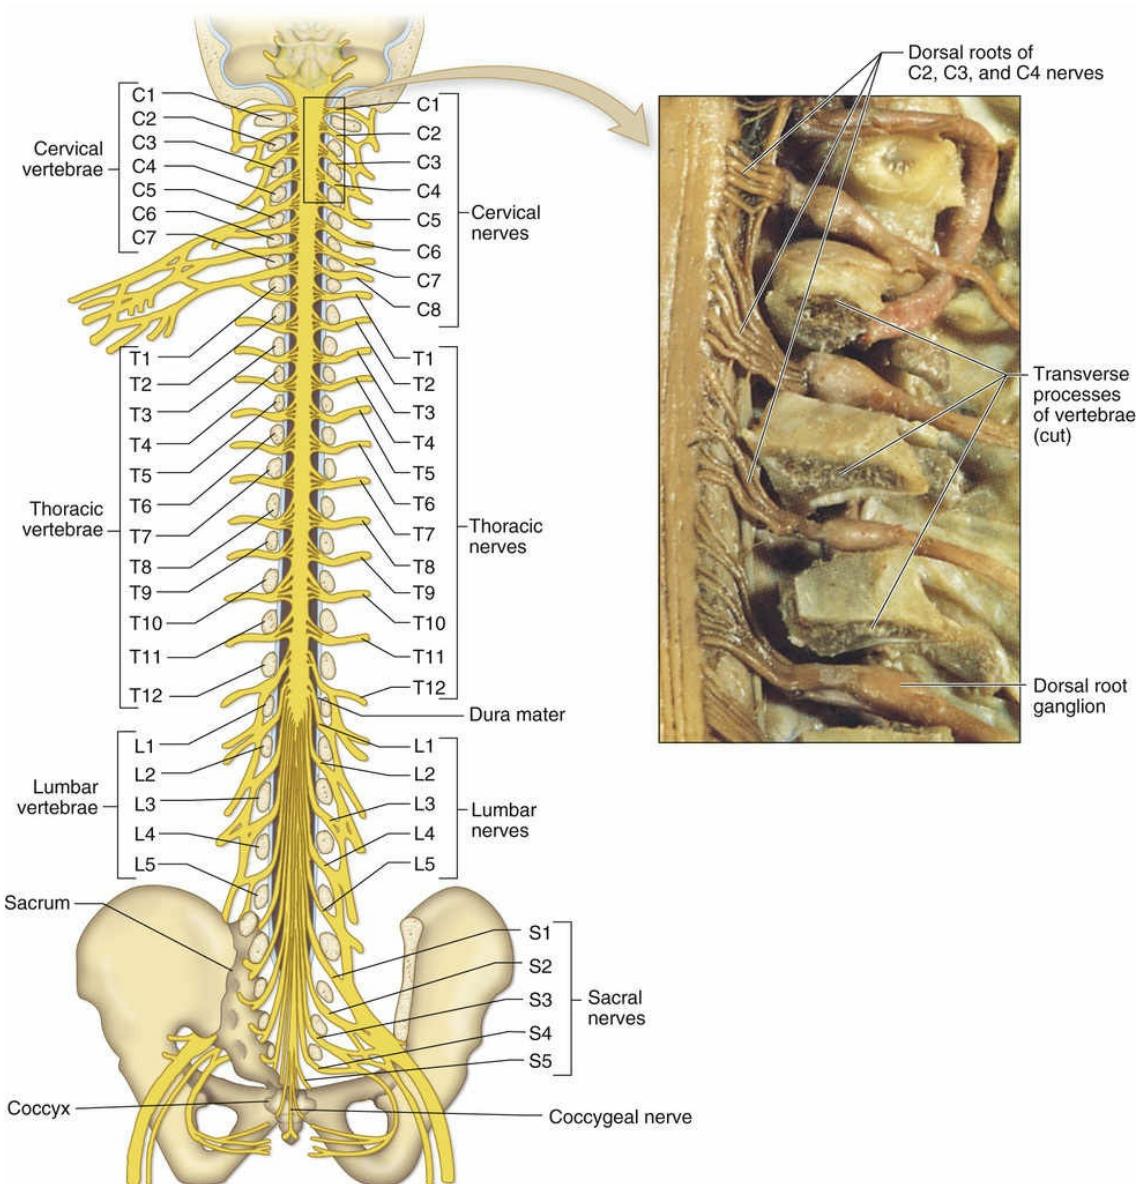

FIGURE 22-8 Divisions of the spinal column and designations of spinal nerves. (From Thibodeau, GA, Patton KT: *Anatomy and physiology*, ed 8, St. Louis, 2013, Mosby. Photo courtesy Vidic B, Suarez RF: *Photographic atlas of the human body*, St Louis, 1984, Mosby.)

Pathophysiology

Fracture, dislocation, or **subluxation** (partial dislocation) of the vertebral column often results in spinal cord damage. Cord injury is caused by compression, pulling and twisting, or tearing of the cord, with two types of injuries occurring: complete and incomplete. Complete injuries result in loss of function below the level of the injury. Incomplete injuries result in various degrees of function and sensation. Penetrating trauma from gunshot or knife wounds or other types of accidents may cause severance, compression, or contusion of the spinal cord. Extreme flexion or hyperextension of the neck, or falling on the buttocks (which causes flexion of the lower thoracic and lumbar spine), all may cause spinal cord damage (Figure 22-9). Tumor growth may compress or destroy spinal cord tissue. Whatever the cause of injury to the spinal cord, nerve transmission to the brain or from the brain may no longer occur below the level of the damage, resulting in various extents of paralysis.

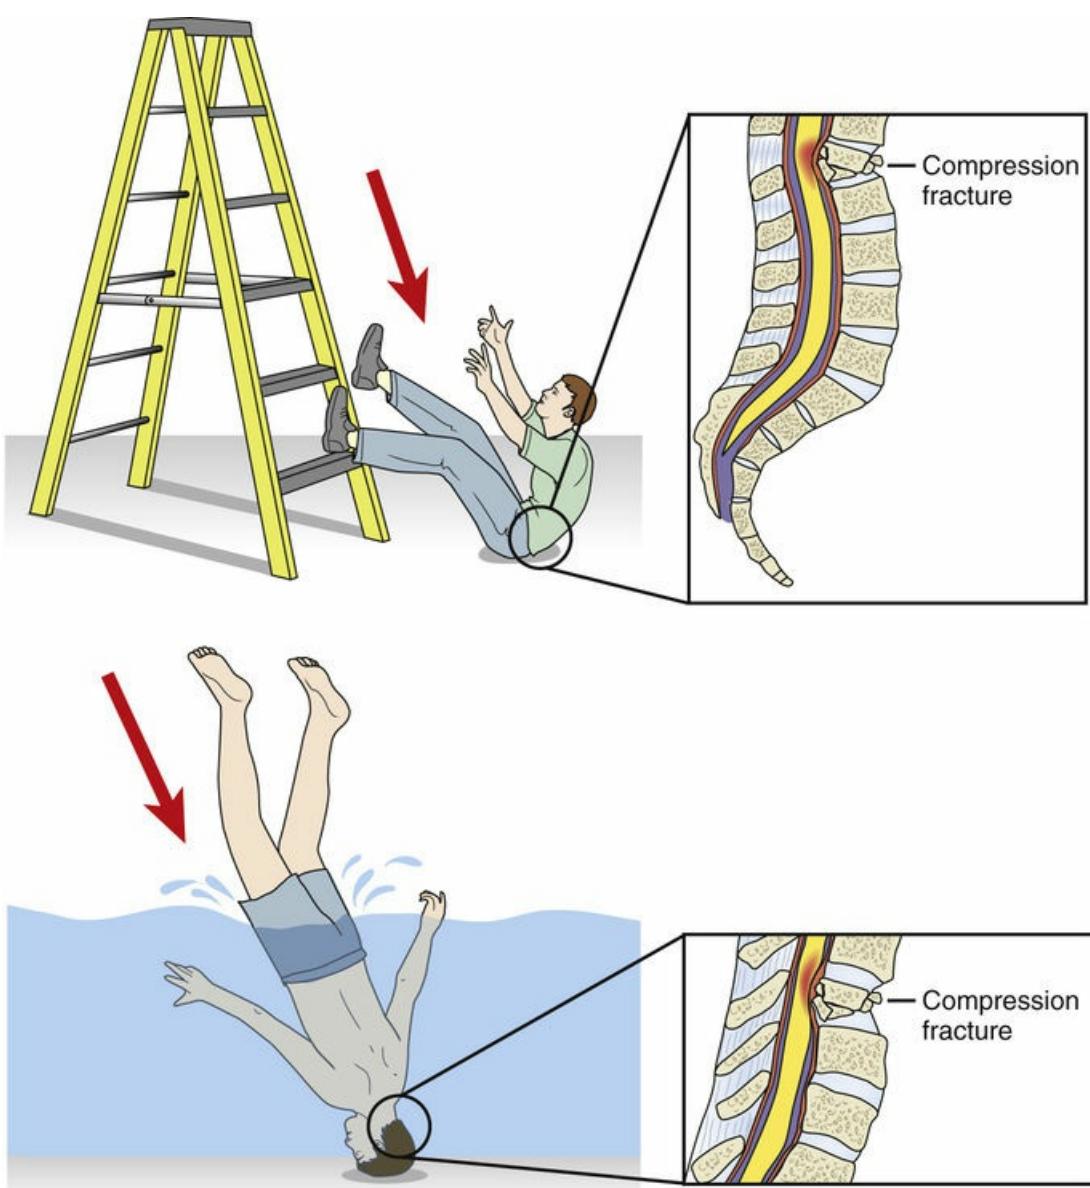

FIGURE 22-9 Accidents can cause vertical compression on the cervical or lumbar spine. (From Ignatavicius DD, Workman ML: *Medical-surgical nursing: Critical thinking for collaborative care*, ed. 7, Philadelphia, 2013, Saunders.)

Microscopic bleeding occurs in the gray matter immediately after spinal cord injury. Irritation of the cells causes edema to develop and spread along the next one or two cord segments. The edema

peaks in 2 to 3 days and subsides in about 7 days after injury. The edema causes temporary loss of function and sensation. Hemodynamic instability with drops in blood pressure may cause decreased blood flow, and hypoxia in the cord increases the initial damage. The inflammatory process may injure the myelin covering the axons, and the chemical and electrolyte changes interrupt nerve impulse transmission.

Signs, Symptoms, and Diagnosis

A complete severance of the spinal cord, or damage to the cord's entire thickness, results in a total loss of sensation and control in the parts of the body below the point of injury. If the cord is damaged in the cervical region, the paralysis and loss of sensory perception may include both arms and both legs (**tetraplegia**), also called **quadriplegia**. Severe injury to the cord above the level of the fifth cervical vertebra often is fatal if emergency care is not immediate, because the phrenic nerves that innervate the diaphragm originate in the third, fourth, and fifth cervical segments. Branches of these nerves play a major role in the control of respiration, and when they are severed, respiration must be maintained by artificial means. If the damage is only partial (incomplete), there will be some losses, but not all motor and sensory innervation is lost².

Interruption of the thoracic spinal cord through L1 and L2 causes **paraplegia** (paralysis of both legs). [Table 22-1](#) presents activities possible with varying levels of cord injury.

Table 22-1
Level of Spinal Cord Damage, Function Present, and Activities Possible

LEVEL OF INJURY	FUNCTION PRESENT/NEUROLOGIC DEFICIT	ACTIVITY POSSIBLE
C1-C3	No respiratory function; usually fatal unless immediate emergency help is available to establish respiration Tetraplegia (quadriplegia)	Respirations stimulated with phrenic pacemaker. Can manipulate electric wheelchair with breath, chin, or voice control.
C4	Loss of diaphragm movement; breathe with assistance Tetraplegia (quadriplegia)	May live if assisted respiration is begun immediately. Can use a mouth stick to turn pages, type, or write.
C5	Partial shoulder movement; partial elbow movement	Can turn head. Able to feed self with special adaptive devices. Able to move wheelchair for short distances and move well with electric wheelchair. Can assist a bit with self-care.
C6	Retains gross motor function of arms; partial shoulder, elbow, and wrist movement possible Tetraplegia (quadriplegia)	Needs adaptive devices; may be able to propel wheelchair. Independent in feeding and with some grooming with adaptive devices. Can roll over in bed. Can drive a car with hand controls. Can assist in transfer. Can self-catheterize the bladder.
C7	Shoulder, elbow, wrist, hand partial movements possible Tetraplegia (quadriplegia)	Manipulates wheelchair with arms; transfers to and from chair; may drive specially fitted car. Excellent bed mobility. Independent in most ADLs.
C8	Normal arm movement; hand weakness Tetraplegia (quadriplegia)	Bed and wheelchair independent. Can perform most ADLs and may achieve vocational and recreational goals. Performs self-catheterization.
T1-T10	Normal arm movement and strength; loss of bowel, bladder, and sexual function	May achieve walking with braces. Able to perform ADLs and achieve vocational and recreational goals.
T11 and below	Loss of bowel, bladder, and sexual function	Wheelchair not essential. Able to perform ADLs, work, and recreational activities.

ADLs, Activities of daily living.

Injury to the spinal cord that does not involve complete severance of the cord may result in a temporary paralysis, which may subside as the spinal cord recovers from the swelling and initial shock of the injury. Initial assessment of the damage is often one or two levels higher than the actual injury because of edema, resulting in decreased function until the edema subsides.

Diagnosis is made by physical examination and testing of reflexes. CT scan or MRI may be performed to determine the extent of the damage and to see whether the cord is completely **transected** (severed). This helps determine whether neurologic deficits are likely to be permanent. A myelogram may be performed when other tests do not reveal sufficient information.

Treatment

There are four main objectives in the treatment and nursing care of a patient with an injury of the spinal cord:

1. To save the victim's life
2. To prevent further injury to the cord by careful handling of the patient
3. To repair as much of the damage to the cord as possible
4. To establish a routine of care that will improve and maintain the patient's state of health and

prevent complications, so that eventual physical, mental, and social rehabilitation is possible

As soon as an injury to the spinal cord occurs, the patient must be handled with extreme care.

Safety Alert

Prevent Further Spinal Injury

Anyone with a head injury is treated as if he has also suffered a spine injury until proven otherwise. The neck must be stabilized to prevent any movement. When no cervical collar is available, use a shirt, towel, coat, or other material rolled and placed around the neck as a collar to keep the neck as straight as possible, preventing it from flexing or hyperextending. If the victim must be moved to safety, he should be rolled like a log, as one straight piece, onto a flat surface, such as a board of plywood or a door removed from its hinges. Roll the patient as one piece onto his side, place the board behind him, and then carefully roll him back onto the board. This is done slowly and carefully to avoid twisting or bending the spinal column. The victim is kept still.

Because a nurse or provider may not be at the scene of the accident to supervise the moving of the victim, laypersons should learn the proper emergency care of such injuries. When an accident victim complains of neck or back pain, or cannot move the legs or has no feeling in them, treat the victim as if he has a spinal cord injury. **To avoid flexion of the neck, no pillow or other kind of support is placed under the head. Do not move the victim unless life-threatening conditions require it.**

Transfer of the patient to the hospital should be done only by trained emergency medical technicians. In the emergency department of the hospital, the patient's condition is stabilized and a thorough examination is conducted to establish the extent of his injuries. Methylprednisolone, a corticosteroid, may be given as soon as the examination and diagnosis of cord injury are made. If given within 8 hours of injury, it is believed to minimize further damage and improve the return of both motor function and sensation (Chin and Kopell, 2014). Use of a corticosteroid is controversial because of recent research about the lack of evidence of benefit versus the many side effects of the drug.

Clinical Cues

Drug metabolism is altered in patients with a spinal cord injury. Drug interactions are more common. Be vigilant in checking for signs and symptoms of drug interactions.

Normal saline is used for fluid replacement, and drugs such as dopamine (Intropin) may be given to sustain a sufficient blood pressure to prevent cord hypoxia. Pulmonary edema and increased ICP if a head injury is present are potential problems, and fluid balance is watched carefully.

Respiratory Management

Intubation and mechanical ventilation are often required to sustain life in patients with an injury at C5 or above. Patients with intact phrenic nerve innervation may receive a phrenic nerve stimulator that assists them to breathe by stimulating action of the diaphragm. Patients who can breathe when they first arrive at the hospital may be intubated, because as cord edema progresses, respiration may become impaired. Mechanical ventilation relieves the muscle work of breathing and conserves the patient's energy during the emergent phase of the injury. An oral airway may be placed if a tracheostomy is unnecessary.

Immobilization and Surgery

Surgery on the spine with removal of bone fragments is performed to relieve pressure, provide stabilization, and prevent further injury. **Cervical spinal cord injury is usually treated with traction to immobilize the affected vertebrae and maintain alignment.** Traction can be accomplished by skeletal traction using Crutchfield or Gardner-Wells tongs with ropes, pulleys, and weights (Figure 22-10) or with a halo ring and fixation pins (Figure 22-11). The halo is often

used for cord injury not requiring surgery and allows for early ambulation.

FIGURE 22-10 Crutchfield tongs for cervical traction. (Courtesy Michael S. Clement, M.D., Mesa, Ariz.)

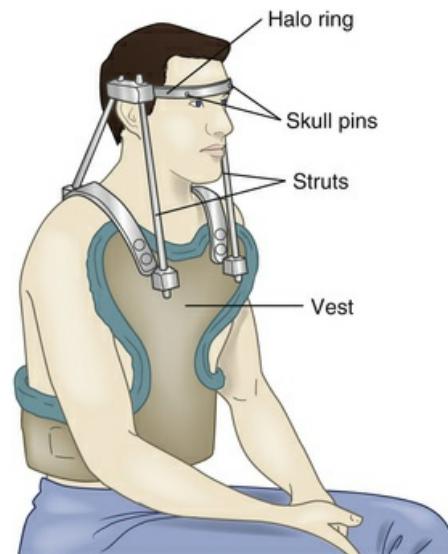

FIGURE 22-11 Halo traction vest for cervical stabilization. Note the rigid shoulder straps and encompassing vest. Various vest sizes are available prefabricated. The halo ring superstructure and the vest are magnetic resonance imaging (MRI) compatible. (Modified from Urden LD, Stacy KM, Lough ME: *Priorities in critical care nursing*, ed. 6, St. Louis, 2012, Mosby. In Lewis SL, Heitkemper MM, Dirksen SR, et al: *Medical-surgical nursing: Assessment and management of clinical problems*, ed. 9, St. Louis, 2013, Mosby.)

Selecting the type of bed to be used for a patient with spinal cord injury depends on many factors. Some providers and nurses prefer placing the patient in a special lateral rotation bed that is designed to prevent the problems of immobility while maintaining traction (Figure 22-12). If halo traction is used and the patient has an incomplete spinal cord injury, a standard orthopedic bed may be used. All measures to prevent the problems of immobility are instituted (see Chapter 9).

FIGURE 22-12 RotoRest Delta Advanced Kinetic Therapy system. (Courtesy ArjoHuntleigh.)

Urinary Management

An indwelling urinary catheter is inserted to prevent bladder distention and protect the skin from reflex bladder emptying. After the first week, a bladder management program will be initiated (see [Chapter 21](#)).

Psychological Care

The short-term and long-term psychological changes brought about by spinal cord injury and paralysis are difficult, if not impossible, to measure. Adjustment to such a drastic change in lifestyle is a continuous process that may well last a lifetime (see [Chapter 9](#)).

Grief and mourning response.

Sustaining a spinal cord injury that causes permanent neurologic deficit brings with it many losses. Most patients experience grief and mourning of the losses experienced and the changes that such losses bring to their roles and lifestyle. [Table 22-2](#) presents a review of the stages of grief and the behaviors that might be seen. In caring for these patients, use active listening, be supportive, and help the patient to focus on positive strengths and the possibilities for the future.

Table 22-2
Stages of Grief and Associated Behaviors

STAGE OF GRIEF OR MOURNING	FREQUENT BEHAVIORS SEEN
Shock and denial	Complete dependence, withdrawal, excessive sleep, struggle for survival, unrealistic expectations.
Anger	Hostility toward caregivers and family, manipulative behavior, abusive language, refusal to discuss paralysis and losses, decreased self-esteem.
Bargaining	Bargaining with a higher power/fate: "If you'll let me walk again, I'll pray every day."
Depression	Sadness, "blue" mood, withdrawal, insomnia, agitation, refusal to participate in education for self-care, suicidal thoughts and comments.
Adjustment	Begins active participation in therapy and education for self-care, planning for future, expresses hope for future functioning, finds meaning in whole experience of injury and therapy, return of usual personality.

Sexual Concerns

One area of concern to the patient and his family members that sometimes receives inadequate

attention is that of sexual function and sexuality after spinal cord injury. Many individuals have difficulty discussing sexual matters. A nurse who wishes to help a patient deal with problems of sexuality must first come to terms with her own feelings and attitudes and clarify her own values. She should not be critical or judgmental in her discussions about the patient's sexuality. The patient and his partner must be encouraged to verbalize concerns and questions and should be given guidance about alternative ways to express sexuality and meet sexual needs.

Complications

Spinal shock and neurogenic shock.

The disruption in the nerve communication pathways between upper motor neurons and lower motor neurons may cause spinal shock. Spinal shock is characterized by flaccid paralysis and loss of reflex activity and of sensation below the level of the injury. Spinal shock occurs immediately after injury and lasts 48 hours to several weeks.

Neurogenic shock may occur within 24 hours and is caused by loss of vasomotor tone caused by the injury; neurogenic shock is characterized by bradycardia, hypotension, venous pooling with decreased cardiac output, and occasionally paralytic ileus. Vital signs become labile. Treatment is aimed at maintaining adequate blood pressure and heart rate. Neurogenic shock may occur with a cervical or high thoracic injury.

Muscle spasms.

Immediately after a spinal cord injury, the patient will usually have a flaccid type of paralysis. Later, as the cord adjusts to the injury, the paralysis will become spastic, and there will be strong, involuntary contractions of the skeletal muscles. These muscle spasms, which may be violent enough to throw the patient from the bed or wheelchair, must be anticipated, and the patient must be secured so that accidents can be prevented. If the upper extremities are involved, he is likely to tip over glasses, water pitchers, or anything within reach of his arms when seized with uncontrollable muscle spasms.

The patient and family may interpret these spasms as a return of voluntary function of the limbs and will have false hopes of complete recovery. The nurse or the provider must explain to them that these spasms are common in patients with spinal cord injuries. To avoid stimulating the muscles when moving the patient and thereby precipitating a spasm of the muscles, avoid grasping the muscle itself. The palms of the hands are used to support the joints above and below the affected muscles. The administration of antispasmodic medications such as baclofen (Lioresal) orally or intrathecally may decrease the severity of the spasms ([Table 22-3](#)).

 **Table 22-3**

Drugs Commonly Used to Treat Head and Spinal Cord Injuries

CLASSIFICATION	ACTION	NURSING IMPLICATIONS	PATIENT TEACHING
Corticosteroid			
Methylprednisolone (Solu-Medrol)	Decreases inflammation by suppression of leukocyte migration to injury site; decreases capillary permeability	Give as IV bolus and as continuous infusion. May cause insomnia, increased susceptibility to infection, and GI distress. May delay wound healing. Monitor electrolyte levels. H ₂ -receptor blocker or proton pump inhibitor often given concurrently to prevent stress ulcer.	Advise to report heartburn or stomach pain.
Skeletal Muscle Relaxant			
Baclofen (Lioresal)	Inhibits synaptic responses in CNS by decreasing GABA, thereby decreasing frequency and severity of muscle spasms	Monitor for seizure activity. Observe for muscle weakness and fatigue. Assess for allergic symptoms: rash, fever, respiratory distress.	Advise not to drink alcohol, because it increases CNS depression. Do not discontinue medication quickly or abruptly.
Adrenergic Action Vasoconstrictor			
Dopamine (Intrropin)	Acts on alpha receptors, causing vasoconstriction in blood vessels, thereby raising blood pressure	Monitor vital signs closely; assess for chest pain. Monitor I&O. Place patient on a cardiac monitor during therapy. May cause nausea, vomiting, or diarrhea. Be certain that IV access is patent, because drug will cause necrosis if extravasation into the tissue occurs.	Explain purpose of drug is to raise blood pressure so that brain has adequate perfusion and oxygen. May cause headache.
Osmotic Diuretic			
Mannitol	Increases osmotic pressure of glomerular filtrate; promotes diuresis	Monitor vital signs closely. Track I&O; assess skin turgor and mucous membranes for signs of dehydration.	Explain that the drug will cause increased urine output and that this is its intended action.

		Monitor electrolytes. Observe for nausea, backache, hives, and chest pain.	
Neuromuscular Blocking (Paralyzing) Agent			
Pancuronium (Pavulon)	Inhibits transmission of nerve impulses, producing skeletal muscle relaxation for surgery, endotracheal intubation, and mechanical ventilation when patient is fighting the ventilator	Be certain that alarms are properly set on the ventilator. Observe patient frequently. Keep Ambu bag at bedside. Monitor electrolytes and I&O. Observe for urinary retention. Observe for allergic reaction: rash, fever, pruritus. Protect the eyes with artificial tears and keep lids closed.	Explain that patient will be paralyzed and unable to move. Assure patient that he will be monitored at all times and that there are backup measures in place in case of power outage when ventilator would not work.

CNS, Central nervous system; GABA, gamma-aminobutyric acid; GI, gastrointestinal; H₂, histamine-2; I&O, intake and output; IV, intravenous.

Autonomic dysreflexia (hyperreflexia).

Autonomic dysreflexia (AD) is an uninhibited and exaggerated reflex response of the autonomic nervous system to some form of stimulation that occurs in 85% of all patients who have spinal cord injury at or above the level of the sixth thoracic vertebra (T6). The AD response is potentially dangerous to the patient, because it can produce vasoconstriction of the arterioles with an immediate elevation of blood pressure. The sudden hypertension can, in turn, cause a seizure, retinal hemorrhage, or stroke. Less serious effects include severe headache, changes in pulse rate, sweating and flushing above the level of the spinal cord lesion, and pallor and “goose bumps” below the level of injury.

AD occurs most often with spinal cord disorders at or above the T6 level. The problem can occur any time after a spinal cord injury; in some cases it has first appeared as late as 6 years after the injury.

Many kinds of stimulation can precipitate AD. Tight clothing around the waist may elicit an AD response. However, most are related to the bladder, bowel, and skin of the patient. For example, catheter changes, a distended bladder, the insertion of rectal suppositories, enemas, and sudden changing of position can provide the stimulation that results in AD (Stephenson, 2015).

Clinical Cues

Careful attention must be paid to keeping the bladder from becoming overdistended. If the patient is on bed rest, check the catheter and drainage tubing for the indwelling catheter every couple of hours. When voiding has not occurred, monitor output and time of voiding for patients who do not have an indwelling catheter, and palpate the bladder for distention every few hours.

When a patient exhibits symptoms of AD, an emergency exists. Efforts should be made to lower blood pressure by placing the patient in a sitting position or elevating his head to a 45-degree angle. If the cause of the stimulation is known—for example, an impacted bowel, overdistended bladder, or pressure against the skin—the stimulus should be removed as gently and quickly as possible. The provider should be notified immediately so that the appropriate medications can be prescribed and administered.

Orthostatic hypotension.

Vasoconstriction is impaired after spinal cord injury, and the lack of muscle function in the legs causes pooling of blood in the lower extremities. Sudden change in position from supine to sitting or sitting to standing may cause dizziness and fainting. Compression stockings, moving slowly, and use of a reclining wheelchair may help prevent this problem.

Deep venous thrombosis.

Decreased blood pressure combined with lack of muscle movement slows venous return to the heart. Thrombosis may occur. Compression stockings, sequential compression devices, and/or heparin injections may be needed to prevent deep venous thrombosis.

Infection.

Impaired respiratory muscles with the resultant decreased cough and shallow respirations predisposes patients with a high spinal cord injury to respiratory infection. Mechanical ventilation with intubation provides an avenue for microorganisms to enter the lungs, so mechanical

ventilation is a risk factor for infection. Urinary catheterization for loss of bladder control is a risk factor for infection as well.

Skin breakdown.

Lack of sensation and inability to move for repositioning places the patient at great risk for skin breakdown and pressure ulcers. Pressure-relieving devices, meticulous skin care with regular inspection, and manual repositioning are essential to prevent this problem.

Renal complications.

Urinary reflux from the bladder to the kidney often results from impaired bladder function. Catheterization and immobility predispose to bladder infection; the infection may travel up the ureters to the kidneys. Permanent kidney damage may eventually occur from such infections.

Think Critically

Can you name three care interventions that might trigger an episode of AD? How could you possibly avoid causing this reaction?

Heterotopic ossification.

Heterotopic ossification may occur with long-term immobility. **Heterotopic ossification** is bony overgrowth that may invade muscle. Assess for swelling, warmth, redness, and decreased range of motion of the extremities to detect ossification.

Nursing Management

There often is a tendency to treat a physically disabled patient as if he were less than a “whole” person with the same desires, hopes, and anxieties that all humans share. You can serve patients by reacting to and interacting with physically disabled patients in an open and honest manner. If unprepared to handle a certain problem, readily admit embarrassment, confusion, or lack of information, and seek assistance from other members of the health care team. Rehabilitation of patients with spinal cord injuries is discussed in detail in [Chapter 9](#).

Assessment (Data Collection)

Continued assessment for signs of decreased oxygenation, blood pressure instability, infection, skin breakdown, gastrointestinal or nutrition problems, and urinary problems is essential. Perform a daily review of systems and collection of data regarding physical status. Assess the tracheostomy tube, traction devices and pins, correct placement and use of sequential compression devices or compression stockings, indwelling catheter, IV cannula, feeding tube, and other equipment each shift.

Nursing Diagnosis

Problem statements/nursing diagnoses appropriate for a patient with a spinal cord injury may include:

- Altered gas exchange due to diaphragm paralysis, diaphragm fatigue, or retained secretions.
- Impaired physical mobility related to vertebral column instability, disruption of the spinal cord, and traction.
- Altered cardiac output due to hypotension and decreased muscle action causing venous pooling.
- Altered nutrition due to increased metabolic demand from healing injuries, slowed gastrointestinal motility, and inability to feed self.
- Constipation due to lack of bowel innervation, decreased fluid intake, and immobility.
- Altered urinary elimination related to decreased innervation of the bladder.
- Pain due to muscle spasms.
- Potential for autonomic dysreflexia due to reflex stimulation of sympathetic nervous system.
- Potential for altered skin integrity due to immobility and loss of sensation.
- Altered coping ability due to loss of control over bodily functions and altered lifestyle secondary

to paralysis.

- Altered body image due to paralysis and loss of control over bodily functions.
- Altered family function due to change in role within the family because of neurologic deficits.
- Grief due to neurologic deficits and to changes in roles and lifestyle. Specific NANDA-I diagnoses can be chosen from the NANDA-I list (see inside back cover).

■ Planning, Implementation, and Evaluation

Specific, individual expected outcomes are written for each problem supported by data gathered. Long-term goals are considered, and planning for rehabilitation begins with hospitalization. The patient will often be transferred to a rehabilitation facility for intensive rehabilitation and retraining for activities of daily living.

Care for a patient with a spinal cord injury can be very complex, depending on the level of the injury. Often a head injury accompanies the trauma to the spinal cord. When a stabilization device is in place on the head, assessment and care of the pin sites are performed every shift initially and then twice a day. Sterile technique is used and is performed according to agency policy. Solutions such as sterile normal saline are used for cleansing, and an antibiotic ointment is applied. Weights used for cervical traction must be kept hanging freely to be effective. Traction pull should never be interrupted. Tongs may stay in place for 4 weeks. If the patient is wearing a halo fixation device, skin care must be given frequently and the skin checked to see that the jacket or cast is not causing pressure ulcers. One finger should be able to slip easily beneath the cast or jacket to be sure it is not too tight. The patient is never moved or turned by holding or pulling on the halo device. **The halo jacket is never unfastened unless the patient is supine, because head movement will immediately occur.** Log rolling must be done with extreme care to avoid twisting the vertebral column and further damaging the spinal cord (Figure 22-13).

■ Assignment Considerations

Inappropriate Delegation

Although many tasks may be delegated to CNAs or UAPs, moving or positioning patients with neurologic injury or surgery should **not** be delegated. If given proper, complete instructions, the CNA or UAP may log roll the patient with the nurse's help and supervision.

FIGURE 22-13 Log-rolling procedure using a lift sheet and three people. (From deWit SC, O'Neill P: *Fundamental concepts and skills for nursing*, ed. 4, St. Louis, 2014, Saunders.)

All the nursing measures designed to prevent the disabilities that may result from immobility, to promote healing, and to prevent complications are used to help the patient achieve the goals of rehabilitation. Bladder and bowel training programs, as well as instruction in moving from bed to chair—and other aspects of self-care—may be necessary. Realistic goals should be set for the patient, and every effort made to achieve them.

Encourage the patient to do whatever he can for himself as soon as is feasible. The overall goal is to promote as much independence as possible. A great deal of encouragement and praise are required. Evaluation is ongoing to determine whether the interventions have been successful in achieving the expected outcomes. If they have not been successful, the plan is rewritten.

Rehabilitation

A full team of professionals will be involved in the care and rehabilitation of patients with a spinal cord injury. The physical therapist, occupational therapist, psychologist, physician, respiratory therapist, pharmacist, and ancillary personnel will collaboratively plan the patient's care. The patient and family are often invited to participate in the planning process.

The use of robotics and computers is providing hope for some patients to walk again ([Rehabilitation Institute of Chicago, 2015](#)). A system called *functional electrical stimulation (FES)* is used to generate neural activity and overcome lost function. The system stimulates muscles to make walking motions. The patient is suspended in a harness to support body weight and is retrained to walk using a treadmill. The antidepressant escitalopram (Lexapro), a selective serotonin reuptake inhibitor (SSRI), has improved results of the therapy for some patients. Research is under way on a neuroprosthetic microchip implant that would help certain patients to walk again. The ReWalk brace support suit that is combined with computerized technology has been approved by the U.S. Food and Drug Administration for use at home and in the community ([ReWalk, 2014](#)). It allows an otherwise healthy paraplegic to walk using Canadian crutches. It runs on a power pack carried on the back. A pacemaker for the bladder is under study for the treatment of urinary incontinence.

Communication between team members is crucial to the success of the individual plan. When the patient is discharged, all plans and specifics required for the patient's care must be shared with home caregivers and home care nurses who will be involved in his care. His primary provider must be fully briefed.

Back Pain and Ruptured Intervertebral Disk (“Slipped Disk”)

Etiology

Back pain occurrence is surpassed only by headaches. Emergency providers treat more than 6 million cases of back pain annually. In people younger than 45 years, back pain is the most common cause of work absence and is the most costly health condition for employers. Carelessness and incorrect methods of lifting contribute to a large percentage of back problems. On-the-job accidents and resultant trauma to the spine is another cause. Obesity and lack of exercise, and poor lifting and moving techniques, contribute to the stress placed on the back muscles and to the occurrence of injury or the severity and duration of pain. Exercise promotes good muscle tone. Other risk factors leading to back pain include lack of exercise (causing poor muscle tone), poor posture, cigarette smoking (which decreases oxygenation to the disks and predisposes to degenerative disease), and stress. Repetitive heavy lifting also may cause back pain. This is often a factor for health care workers. Causes of musculoskeletal back pain include:

- Acute lumbosacral strain
- Instability of lumbosacral spine
- Osteoarthritis of the spine
- Intervertebral disk degeneration and spinal stenosis
- Herniation of the intervertebral disk

Preventing back pain and disorders begins with proper posture and the use of correct lifting techniques. Maintaining one's weight within normal limits also helps decrease back strain. Sufficient physical exercise that maintains the condition of the back muscles and specific exercises to strengthen the abdominal and back muscles can greatly decrease the repeated incidence of injuries that lead to back pain.

Pathophysiology

The bodies of the spinal vertebrae lie flat on one another like a stack of coins. Between the vertebral bodies there is a disk of fibrous cartilage filled with gelatinous substance (in the nucleus) that acts as a cushion to absorb shocks to the spinal column. This gelatinous disk may be ruptured by an injury, such as by the strain caused when lifting a heavy object or by wrenching the spinal column or falling on the back. When the disk ruptures, part of the contents squeezes out from between the vertebrae and disk fragments may lodge in the spinal canal. The disk compression on the adjacent nerve root causes the pain ([Figure 22-14](#)). When protein from the disk content leaks out into the canal, the body perceives it as a foreign substance, causing an inflammatory response, with pain. Thus the person suffers from what is sometimes called a *slipped disk*. Another name for this condition is *herniated nucleus pulposus*.

Older Adult Care Points

Older adults have decreased flexibility of the spine and, as age increases, degeneration of the spine. Many older adults suffer from osteoporosis and osteoarthritis. These factors make older adults more prone to back pain, especially if regular exercise is not performed to maintain flexibility and bone density.

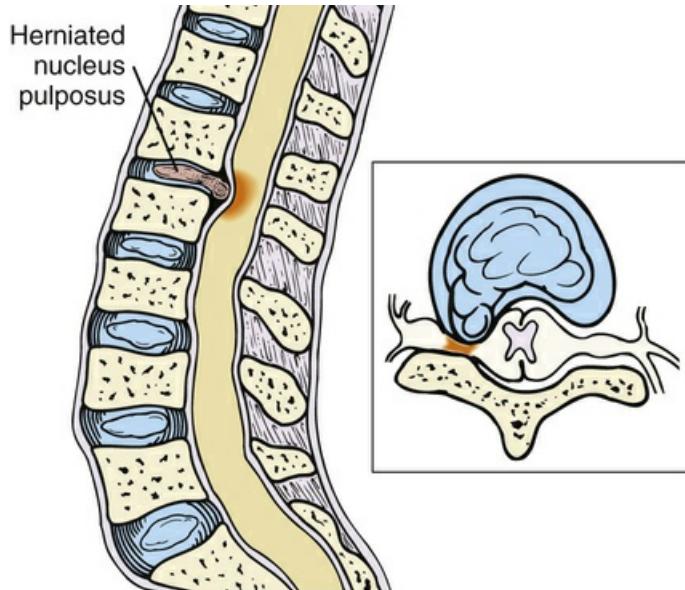

FIGURE 22-14 Herniated disk (nucleus pulposus) with compression of spinal cord. (From Lewis SL, Heitkemper MM, Dirksen SR, et al: *Medical-surgical nursing: Assessment and management of clinical problems*, ed. 7, St. Louis, 2007, Mosby.)

Acute back pain usually occurs from activity that puts stress (hyperflexion) on the tissues of the lower back. Back pain that is a result of muscle spasm is usually self-limiting and often resolves within 4 weeks. Chronic back pain is pain that lasts for more than 3 months or is a repeat episode. Chronic back pain may be caused by degenerative disk disease or osteoarthritis, but lack of exercise, prior injury, and obesity are common factors. The most common sites of disk rupture are L4-L5 and L5-S1. Herniation may also occur at C5-C6 or C6-C7.

Signs, Symptoms, and Diagnosis

Sometimes a lumbar herniated disk causes pain radiating down the sciatic nerve into the buttock and below the knee. Muscle weakness and paresthesias may occur. Cervical herniated disk causes pain in the neck and shoulder, radiating down the arm with numbness and tingling in the hand. Muscle tightening and spasm in the area of injury are common.

Diagnosis requires a history and physical examination. The straight-leg-raising test is often used for low back pain. While the patient is supine, the leg is raised off the bed or examination table with the whole leg straight. If low back pain occurs, the test confirms a disk problem. Reflexes may be decreased or absent. The patient may experience muscle weakness or paresthesias in the legs or feet.

If conservative therapy does not relieve the pain, diagnostic radiographs, MRI, or CT scanning is performed. An electromyogram may be ordered to determine the degree of nerve irritation and to rule out other pathologic conditions.

Treatment

The provider will treat back pain initially with conservative measures in the hope that surgical correction will not be necessary. If there is no sciatic pain, bed rest is not recommended, because research has shown that walking provides a quicker recovery. When sciatic pain is present, bed rest for 2 to 3 days is helpful (Miller, 2015). Ice packs are applied for 5 to 10 minutes at a time each hour for the first 48 hours to reduce muscle spasm in the back. After 48 hours, heat may be more helpful, because heat relaxes strained muscles. Ultrasound treatments are often helpful. Heating pads, hot packs, and hot showers work well to relax the muscles.

Complementary and Alternative Therapies

Help for Pain

Acupuncture, acupressure, and massage therapy have all proven beneficial for back pain. Research from the National Institutes of Health has proven that acupuncture is effective for back pain. For those with chronic back pain, acupuncture is worth trying. Massage and acupressure help relieve muscle spasm, especially when heat is applied to the affected muscles first.

Studies show that wearing a portable heat wrap decreases pain moderately and more than ibuprofen ([Chou and Huffman, 2014](#)). Transcutaneous electrical nerve stimulation may help relieve the patient's pain. Acupuncture has proven useful to help relieve back pain. Back strengthening exercises are prescribed as soon as acute symptoms subside; these exercises are initially supervised by a physical therapist. The exercises are encouraged for a lifetime, because muscles need to be toned to prevent back strain. Specially designed corsets or back braces are sometimes used to maintain proper alignment of the spine when the patient is allowed out of bed. The patient is cautioned not to lift anything heavier than 2 to 5 lb and not to twist when reaching for things. The patient should be up and moving around frequently rather than sitting for long periods. High heels should not be worn.

Swimming or walking for short distances frequently is very beneficial for patients with back pain. Standing for long periods is to be avoided, and when standing the patient should shift weight from one foot to the other frequently. Adjustments and treatments by a chiropractor may also help relieve pain, although chiropractic treatment is not appropriate for all types of back injuries. Chiropractic treatment seems most effective if the pain has been present for less than 16 days. If pain continues beyond 3 to 4 weeks, or if pain is worsening, there is evidence of neurologic deficit, and surgery may be indicated.

For many patients, gentle yoga movements have been more successful than prescribed back exercises for relieving pain. For others, core body stretching and muscle strengthening work well.

Surgical procedures.

For those patients who cannot find relief through conservative measures, surgical removal of the damaged disk may be the only alternative. A discectomy is performed to decompress the nerve root. This is a microsurgical technique that uses a very small incision through which the herniated intervertebral disk material is dissected and extracted. A minimally invasive electrothermoplasty or radiofrequency diskal nucleoplasty may be performed. If the area cannot be handled with microsurgery, an open incision discectomy or laminectomy, which involves removal of the posterior arch of the vertebra along with the disk, is done. A laminectomy may be done in conjunction with spinal fusion.

A percutaneous laser discectomy is an outpatient procedure. A tube is passed through the retroperitoneal soft tissues to the disk's lateral border. Local anesthesia and fluoroscopy are used during the procedure. A laser is used to cut away and destroy the herniated portion of the disk. Small stab wounds are used, there is minimal blood loss, and rehabilitation time is shorter. An artificial Charité disk may be inserted after disk-ectomy when there is degenerative disk disease.

A spinal fusion is necessary in some patients to stabilize the spine. In a spinal fusion, a piece or pieces of bone from the iliac crest or cadaver bone are grafted onto the vertebrae to strengthen them. Fixation with metal rods and screws may be employed to decrease spinal motion and irritability. The Infuse Bone Graft/LT-CAGE device is an alternative option to using bone from the patient for grafting ([Epstein, 2011](#)). Genetically engineered protein contained in the device stimulates new bone growth at the site.

A laminectomy may be performed for conditions other than a ruptured disk—for example, for such degenerative diseases of the spine as Pott disease (tuberculosis of the spine), for fractures of the spine, and for spinal dislocation. Once a laminectomy with a fusion has healed, the fused vertebrae are immobile.

Nursing Management

Preoperatively, a baseline neurologic assessment is performed and documented. Other preoperative care is the same as for other types of general surgery. Postoperatively, the major concern after spinal fusion, laminectomy, or discectomy is to keep the spinal column in alignment so that healing can take place and no further injury occurs to the spinal cord. Pillows are placed under the thighs when the patient is on his back and between the legs when on the side to maintain correct spinal alignment and decrease the pressure to the back. If the surgeon allows the patient to be turned to

the side, log rolling is used to avoid twisting the spine (see [Figure 22-13](#)). Sometimes the surgeon will allow the patient to be positioned only on the back or sometimes the abdomen. Whenever the patient's position is changed, an ample number of people should be available to help move him. Patients who have had cervical spine surgery are placed in a cervical collar and continue to wear a collar for several weeks.

Focused Assessment

Data Collection After Spinal Surgery

Immediately postoperatively, assess every 15 to 30 minutes; after the first 4 hours, assess every 2 to 4 hours postoperatively. Assess the following areas and compare findings with preoperative data:

Sensation

- Check extremities for numbness and tingling.
- Check all anatomic surfaces of forearms and hands, upper and lower legs, and feet.

Movement

- Check for ability to move shoulders, arms, hands, legs, and feet.

Muscle Strength

- Check each extremity for weakness by having the patient push against your hands while you apply downward pressure to the extremity.

Wound

- Assess surgical (and donor) site for drainage, noting amount, color, and characteristics.
- Check carefully for signs of CSF leak at surgical site.
- Determine adequacy of analgesia.

Pain

- Assess for site of pain, characteristics of the pain, and degree of pain on a scale of 1 to 10, with 10 being the worst pain.
- Reevaluate pain after administering analgesia for effectiveness.
- Monitor respirations and vital signs.

Skin Pressure Points

- Check for reddened areas on bony prominences when turning patient.

CSF, Cerebrospinal fluid.

When a patient who has had a laminectomy or spinal fusion is allowed out of bed, a back brace or corset may be prescribed to support the spinal column until complete healing has occurred. For several weeks the patient is not allowed to sit for any length of time. He must walk or lie down. Standing for long periods is discouraged. Patients who have had microdiscectomy are usually up and about the day after surgery. However, weeks to many months of exercises and physical therapy are necessary before recovery is complete.

Clinical Cues

At the time of discharge, the instructions about not sitting or standing for any length of time should be reinforced. Patients tend to overdo sitting or standing when they get home and become very fatigued, have more pain, and become discouraged.

An IV opioid via patient-controlled analgesia pump may be ordered for pain control the first 24 to 48 hours after surgery. Additional boluses for adequate pain control may be needed. Assess frequently for effectiveness of the pain medication. Once fluids are being taken, oral analgesia is started with acetaminophen with codeine, hydrocodone (Vicodin), or oxycodone (Percocet). Muscle relaxants may be given as well.

After spinal surgery a small fracture bedpan is used for toileting if the patient is not to be allowed up. The patient's back must be firmly supported while he is resting on the pan. When the patient is steady enough to be allowed out of bed, a bedside commode (or for the male patient, standing at the bedside) is encouraged to promote complete bladder emptying. Provide privacy for toileting activity. If difficulty with voiding occurs, intermittent catheterization or an indwelling catheter will be required.

Interference with bowel function and paralytic ileus may occur after laminectomy or spinal fusion. Observe for constipation, nausea, abdominal distention, and return of bowel sounds. Stool softeners are used to help prevent constipation. Incontinence or difficulty with bowel evacuation may indicate nerve damage and should be reported to the surgeon.

Permitted activity varies according to the underlying pathology and the patient's progress. Be clear about activity orders, whether a brace or corset is to be worn, and whether it is to be put on while lying down, sitting, or standing.

If a bone graft has been performed, the donor site must be assessed regularly and care provided. Pain is usually greater at the donor site than at the spinal fusion site. If the fibula is the donor site, neurovascular assessments of the limb must be performed on a regular schedule, as edema can occur.

Depending on the type of spinal surgery performed, many weeks to months are needed for complete recovery. The patient must learn to perform activities without twisting the spine.

Patient Teaching

Guidelines for a Patient With Low Back Pain or Spinal Surgery

Do

- Bend knees, with back straight, and crouch to lift an item off the floor.
- Carry items close to the center of your body.
- Perform your back exercises twice a day; periodically review the correct way to do them.
- Maintain appropriate body weight; lose weight if overweight.
- Use a lumbar pillow or roll when sitting and particularly when driving for long distances.
- Stop and walk around at least every 2 hours when on long trips.
- Consider how to safely perform a task before starting to do it.

Do Not

- Lean over without bending the knees.
- Reach to lift items or lift heavy items higher than the elbows.
- Stand or sit for long periods.

- Sleep with legs out straight without pillow cushioning under the thighs or between the legs when on the side.
- Bend from the waist to pick up an item.
- Twist to the side to lift things (e.g., groceries or things in the car or trunk).

Get Ready for the NCLEX® Examination!

Key Points

- Head injuries are open or closed and result in concussion, contusion, acceleration-deceleration injury, skull fracture, or tearing of cranial vessels.
- Subdural or epidural hematoma may result from a head injury; epidural hemorrhage is a life-threatening event.
- A significant head injury causes disruption in normal LOC.
- Drainage from the ear or nose should be evaluated to determine the presence of CSF.
- Any lesion or extra fluid that begins to take up space in the cranial vault causes an increase in ICP.
- The earliest sign of increased ICP is decreasing LOC.
- Treatment of increased ICP includes maintaining a patent airway, administering diuretic agents to decrease edema, monitoring neurologic signs for increased ICP, regulating temperature, maintaining adequate blood pressure, and instituting nursing measures to prevent further increases in ICP (see [Table 21-9](#) and [Nursing Care Plan 22-1](#)).
- Neurologic assessment is performed every 15 minutes to 2 hours for acute patients with injury to or surgery on the brain.
- For maintenance of a patent airway, intubation or a tracheostomy and mechanical ventilation may be necessary.
- Early nutritional support is very important for both head injury and spinal cord injury patients.
- Unconscious patients require care for all basic needs; the eyes must be protected from injury, because the blink reflex may be absent.
- Complications of head injury and increased ICP include hydrocephalus and diabetes insipidus.
- The extent of permanent cord damage often cannot be assessed until many days after injury because of edema and resulting pressure that edema causes on the spinal cord.
- The degree of neurologic impairment and activities that the patient will still be able to perform depend on the level and extent of the injury (see [Table 22-1](#)).
- Autonomic dysreflexia is potentially very dangerous to the patient, because it can severely elevate blood pressure.
- Traction provided by Crutchfield or Gardner-Wells tongs, or a halo ring and fixation pins, immobilizes the spine while healing takes place.
- Back pain can be caused by muscle strain or herniated or ruptured intervertebral disk.
- Back pain should be treated conservatively before surgery is considered.
- Treatment depends on whether or not a disk rupture is present and on the severity of the pain and disability.
- Conservative treatment includes rest, gentle exercise, ice or heat, analgesics, and muscle relaxants. Surgical procedures include minimally invasive procedures, microdiscectomy or laminectomy (with or without fusion), percutaneous laser discectomy, and spinal fusion.
- Postoperative care depends on the type of procedure performed.

Review Questions for the NCLEX® Examination

1. A 75-year-old patient who fell and hit his head a week ago is admitted for apparent personality changes, decreased level of consciousness, and irritability. The provider suspects a possible subdural hematoma. A family member asks about the condition. An accurate explanation would be:

1. "It is the presence of bleeding in the brain parenchyma."
2. "Bleeding occurs between the skull and the dura mater."
3. "It is the collection of blood between the brain and the inner surface of the dura mater."
4. "It is the intermittent blockage of circulation in various areas of the brain."

NCLEX Client Need: Physiological Integrity, Physiological Adaptation

2. A nurse is admitting a patient with a possible skull fracture. Which clinical finding(s) would likely confirm the diagnosis? (*Select all that apply.*)

1. Battle sign
2. Partial blindness
3. Ecchymosis around eyes
4. Rhinorrhea
5. Swallowing difficulty

NCLEX Client Need: Physiological Integrity, Physiological Adaptation

3. Which statement by a high school athlete being discharged after experiencing a concussion indicates a need for more teaching?

1. "I can go to football practice tomorrow."
2. "I need to report a worsening headache to the provider."
3. "I'll have to be awakened every few hours when asleep."
4. "I can expect to be more fatigued for a while."

NCLEX Client Need: Safe and Effective Care Environment

4. A nurse keeps a postcraniotomy patient's neck in midline position and ensures that there is no excessive hip flexion. The rationale for the nurse's action would be that this position:

1. restores neutral position of the joints.
2. prevents a further increase in intracranial pressure.
3. promotes comfort and rest.
4. prevents the formation of blood clots.

NCLEX Client Need: Physiological Integrity, Basic Care

5. A nursing assistant is attending to the needs of a patient with a head injury who is lethargic and has increased ICP. Which action by the nursing assistant indicates a need for further instruction?

1. Stopping the patient from coughing up secretions
2. Monitoring blood pressure every 2 hours
3. Dangling the patient on the side of the bed
4. Reporting blood on the dressing

NCLEX Client Need: Safe and Effective Care Environment

6. The classic signs of increased ICP include which of the following? (*Select all that apply.*)

1. Rising systolic blood pressure
2. Widening pulse pressure
3. Bradycardia
4. Positive Babinski sign

NCLEX Client Need: Physiological Integrity, Basic Pathophysiology

7. The surgeon inserts an intraventricular catheter into the lateral ventricle of a patient with increased ICP. When asked by a relative about the procedure, an accurate response by the nurse would be:

1. "The catheter allows direct visualization of the brain tissue."
2. "The catheter is used to monitor brain waves."

3. "The catheter is used to remove excess fluid inside the brain."
4. "The catheter is used to infuse fluids and medications into the brain."

NCLEX Client Need: Physiological Integrity, Basic Pathophysiology

8. A 30-year-old man is admitted to the emergency department after a motor vehicle accident. After examination, the patient is diagnosed with a T6 spinal cord injury. He has flaccid paralysis, slowed heart rate, low blood pressure, and no bowel sounds. The patient must be developing:

1. autonomic dysreflexia.
2. muscle spasms.
3. spinal shock.
4. diabetes insipidus.

NCLEX Client Need: Physiological Integrity, Basic Pathophysiology

9. A 40-year-old man with a T4 spinal cord injury suddenly complains of severe headache, increased pulse rate, sweating, and flushing above the level of the spinal cord lesion and "goose bumps" below the level of injury. Which immediate nursing action(s) should be included? (*Select all that apply.*)

1. Place flat in bed.
2. Identify the cause of stimulation.
3. Decrease blood pressure.
4. Provide measures to facilitate bowel movement.
5. Clamp indwelling catheter.

NCLEX Client Need: Physiological Integrity, Basic Care

10. Instructions for a patient with a "slipped disk" with acute pain and sciatica should include:

1. using ice packs on the area of back pain for 5 to 10 minutes each hour while awake for the first 48 hours.
2. resting in bed for 2 to 3 days and walking every hour even if walking causes more pain.

3. obtaining a massage each day to loosen the muscle spasms in the back.
4. not lifting anything heavier than 10 lb for several weeks.

NCLEX Client Need: Health Promotion and Maintenance

Critical Thinking Questions

Scenario A

Mary is a 22-year-old college student who received a head injury in an automobile accident. She was healthy before her accident. The emergency medical services team brought her to the emergency department (ED). She is stabilized in the ED, cervical spine injury is ruled out, and she is admitted to the neurologic intensive care unit. She is confused and groggy and has leakage of CSF from one ear and irregular respirations.

1. What assessments would you perform?
2. What specific nursing measures would you include in your care plan concerning the leaking CSF?
3. What measures would you take to provide appropriate respiratory care?

Scenario B

Gus Berrini is a 40-year-old truck driver who received a severe spinal injury when he was shot in the back by a hitchhiker. The bullet severed the spinal cord at the sixth thoracic vertebra.

1. What kinds of activities should Mr. Berrini eventually be able to perform?
2. How would you plan his care during the acute stage of his illness so that efforts at rehabilitation might be successful?
3. What other members of the health care team might participate in his care and rehabilitation?

Scenario C

Henry Jones, a 35-year-old construction worker, comes to the clinic with low back pain. He states that this is not the first time he has had a problem with the back pain. He says that this time it is worse and that he can hardly move. He is unable to work.

1. What tests will the health care provider probably perform or order?
2. What is likely to be recommended in the way of treatment?
3. What should Mr. Jones be taught before he leaves the clinic?

CHAPTER 23

Care of Patients With Brain Disorders

Objectives

Theory

1. Choose the appropriate nursing actions and observations to be carried out for a patient experiencing a seizure.
2. Explain why seizure may be a consequence of a stroke, tumor, or infection in the brain.
3. Compare the subjective and objective findings of thrombotic stroke and intracerebral bleed.
4. Devise a nursing care plan for a patient who has experienced a cerebrovascular accident (CVA, or stroke).
5. Write nursing actions to assist a patient who has developed a complication after a CVA.
6. Summarize subjective and objective findings indicative of a brain tumor.
7. Illustrate the pathophysiology behind the symptoms of a brain tumor.
8. Diagram the mechanism by which infection in the brain may cause increased intracranial pressure (ICP).
9. Recognize the signs of increasing ICP from early to late signs.
10. Compare and contrast symptoms of meningitis and encephalitis.
11. Distinguish the assessment data that differentiate migraine headaches from cluster headaches.
12. Compare the signs, symptoms, and treatment of trigeminal neuralgia and Bell palsy.

Clinical Practice

13. Teach a teenage patient recently diagnosed with epilepsy what she needs to know about her disorder and care.
14. Perform neurologic checks on a patient who is admitted with a suspected CVA.
15. Assist with the care of a patient who has had intracranial surgery.
16. Devise a teaching plan for a patient who has experienced a CVA and has right-sided hemiplegia.

Seizure Disorders and Epilepsy

Etiology

Seizures can be symptomatic of a large number of disorders, including brain injury from a stroke, pressure from a brain tumor, infectious diseases with high fever, end-stage renal disease with uremia, toxicity (such as that occurring in eclampsia during pregnancy or in drug poisoning), epilepsy, and tetanus. **Seizures also can occur any time the brain is deprived of oxygen.**

Seizures may be symptoms of an underlying illness. Metabolic disturbances such as acidosis, electrolyte imbalances, hypoglycemia, hypoxia, and water intoxication may cause seizures. Alcohol or barbiturate withdrawal can cause seizures. In children, a high temperature is a common cause of seizures. There are at least 40 types of seizure disorders linked to genetic defects. Epilepsy is present when correcting a metabolic problem does not stop the seizures. Epilepsy affects 2.3 million adults and 467,711 children in the United States ([CDC, 2014](#)). Incidence increases in those 60 to 80 years of age.

Pathophysiology

Epilepsy is a chronic disturbance of the nervous system characterized by various types of recurrent seizures that are the result of abnormal electrical activity of the brain. Epilepsy is characterized by spontaneous recurring seizures. It is believed that a group of abnormal neurons fire spontaneously. Some unknown stimulus causes the cell membranes to depolarize. The depolarization of the neurons causes abnormal sensory or motor activity and may cause unconsciousness. The neurons involved have a low threshold for excitation. The excitation spreads to surrounding cells, spreading the activity to a small area or throughout the brain. Seizures are classified as **partial** or **generalized**. Each seizure lasts a few seconds or a few minutes. The abnormal electrical activity generated can be captured by an electroencephalogram (EEG).

Signs and Symptoms

Partial Seizures

Partial seizures are further divided into three subgroups: simple partial seizures, in which consciousness is not impaired but there are other motor, sensory, autonomic, or psychological symptoms; complex partial seizures, in which there is some impairment of consciousness with or without **automatisms** (repetitive, automatic actions such as lip smacking); and partial seizures that become generalized as the seizure continues.

Partial seizures also are called *simple* or *focal seizures* and result from an abnormal localized cortical discharge. Partial seizures with complex symptomatology may also be called *temporal lobe seizures*, because they usually originate in the temporal lobe of the brain. Partial seizures can be unilateral, with involvement on only one side of the brain and activity only on one side of the body.

Generalized Seizures

Generalized seizures are bilaterally symmetric (affecting both sides of the body equally) and do not have a local onset; that is, they do not typically begin in one part of the body. Generalized seizures include absence, myoclonic, clonic, tonic, tonic-clonic, and atonic seizures and infantile spasms (usually caused by increased temperature).

Generalized seizures are characterized by bilateral synchronous electrical discharges in the brain. The whole brain is affected and there is no warning or **aura** (preceding sensation). The patient usually quickly loses consciousness lasting for a few seconds up to several minutes.

The manifestations of epilepsy depend on the area of the brain where the abnormal firing occurs. **Absence or petit mal seizures last only a few seconds. The onset is sudden, with no aura or warning and no postictal symptoms.** Seizures of this type tend to affect children between 5 and 12 years of age and disappear during puberty. There usually is a twitching around the eyes and mouth. The person remains standing or sitting and appears to have had no more than a lapse of attention or a moment of absentmindedness.

With tonic convulsions, there is continued contraction of all muscles, and the body becomes rigid.

Grand mal or tonic-clonic seizures usually begin with bilateral jerks of the extremities or focal seizure activity. There is loss of consciousness with both tonic and clonic convulsions. The patient may be incontinent during the attack, and there is danger of biting the tongue. In the **postictal** (after a seizure) phase, the person is confused and drowsy.

Atonic or akinetic seizures are characterized by loss of body muscle tone that results in nodding of the head, weakness of the knees, or total collapse and falling (“drop attacks”). The person usually remains conscious during the attack.

The third major group, unclassified seizures, simply means that not enough data have been obtained to determine which type of seizure the patient is experiencing.

The fourth designation, status epilepticus, indicates prolonged partial or generalized seizure without recovery between attacks. **Status epilepticus** is a grave condition in which there is a rapid, unrelenting series of convulsive seizures without intervening periods of consciousness, and an absence of respiration. **Irreversible brain damage can occur if the seizures are not controlled.**

In classifying epileptic seizures on the basis of origin, seizures are grouped as either idiopathic or symptomatic. Idiopathic epilepsy has no known cause. Symptomatic epilepsy has a known physical cause (e.g., brain tumor, injury to the head at birth, a wound or blow to the head, toxicity, or an endocrine disorder).

Diagnosis

Diagnosis of epilepsy is based on the history and the actual signs and symptoms observed during a seizure. A thorough physical examination and tests for underlying disease are ordered based on the history and physical findings. Confirmation of the diagnosis is by EEG and magnetic resonance imaging (MRI). These tests help locate the site, or **locus**, and possibly the cause of the seizures. Electrolyte levels are determined, because imbalances may predispose to a seizure.

Treatment

When the cause of seizures is known, as in cases of high fever or drug toxicity, medical treatment is aimed at controlling or eliminating whatever is responsible for the seizures. For recurrent seizures, as in epilepsy, the condition usually is managed with anticonvulsant drug therapy. An implanted vagus nerve stimulator is proving helpful for generalized epilepsy for many patients with uncontrolled seizures.

The major antiepileptic drugs are presented in **Box 23-1**. Patient education is extremely important, because the patient will need to report any untoward effects to the provider or nurse clinician so the dosage can be adjusted or the drug changed. All anticonvulsant drugs cause some central nervous system (CNS) depression with grogginess, dizziness, fatigue, and cognitive changes.

Box 23-1

Medications Commonly Used for Seizure Control

Drugs for Generalized Tonic-Clonic and Partial Seizures

- Carbamazepine (Tegretol)
- Diazepam (Valium)
- Felbamate (Felbatol)
- Fosphenytoin (Cerebyx)
- Gabapentin (Neurontin)
- Lacosamide (Vimpat)
- Lamotrigine (Lamictal)
- Levetiracetam (Keppra)

- Oxcarbazepine (Trileptal)
- Phenobarbital (Luminal)
- Phenytoin (Dilantin)
- Pregabalin (Lyrica)
- Primidone (Mysoline)
- Rufinamide (Banzel)
- Tiagabine (Gabitril)
- Topiramate (Topamax)
- Valproic acid (Depakene)
- Vigabatrin (Sabril)
- Zonisamide (Zonegran)

Drugs for Absence, Akinetic, and Myoclonic Seizures

- Clonazepam (Klonopin)
- Divalproex (Depakote)
- Ethosuximide (Zarontin)
- Phenobarbital
- Valproic acid (Depakene)

General Nursing Implications

- Educate the patient about the importance of taking the drug exactly as it is prescribed.
- All these drugs cause some degree of sedation, drowsiness, and lethargy. Warn about driving or operating machinery when these effects are significant. Advise not to drink alcohol or use other central nervous system depressants.
- The patient should not stop taking an anticonvulsant abruptly without consulting the provider.
- Check interactions with other drugs before administering any of these drugs. Interaction with anticoagulants, oral contraceptives, digoxin, aspirin, certain antibiotics, antacids, folic acid, and other drugs are significant. Some anticonvulsant drugs interact with each other (e.g., phenobarbital).
- Periodic blood work, every 1 to 3 months, should be performed when taking an anticonvulsant. It may be used to check therapeutic blood levels or organ dysfunction.
- Dosages of each drug are based on therapeutic blood level of the drug.
- Anticonvulsants have a narrow therapeutic range; toxicity occurs if too much of the drug is taken.
- The patient should be under the close supervision of the health care provider.
- All of the anticonvulsant drugs can produce some unpleasant side effects, such as fever and leukopenia and, in the case of phenytoin, gingival hyperplasia and rash.

- Physical dependence can become a problem for patients taking either phenobarbital or primidone, which is largely converted to phenobarbital in the bloodstream.
- Toxic side effects such as ataxia, drowsiness, nausea, sedation, and dizziness are not uncommon.

A ketogenic diet is beneficial in younger patients with refractory (difficult to control) generalized seizures. A ketogenic diet provides sufficient calories from fats and proteins, but produces a ketotic (acidotic) state that seems to prevent seizure activity.

Biofeedback techniques are geared toward teaching the patient to maintain a certain brain wave frequency that is not susceptible to seizure activity.

Treatment of status epilepticus depends on its cause. Patients who have been diagnosed with epilepsy commonly arrive in the emergency department with status epilepticus because they stopped taking the medication that controls their seizures for some reason. Preferable treatment in these cases involves administering benzodiazepines: intravenous (IV) lorazepam, intramuscular (IM) midazolam, or rectal diazepam. Phenytoin, phenobarbital, valproate sodium, or levetiracetam in a dose sufficiently high to stop the seizures may be used ([Brophy et al, 2012](#)). Care is focused on supporting vital signs and preventing injury. Intubation may be required for respiratory support. If seizures will not stop, an anesthetic agent may be required. Rectal diazepam has been approved by the U.S. Food and Drug Administration (FDA) in a system called *Diastat AcuDial*. It can be used at home by nonprofessional caregivers, and clinical studies have shown that the system resolved seizures in 85% of patients ([Epilepsy Action, 2010](#)).

Surgical Treatment

Surgical procedures involve removing the epileptic focus or preventing the spread of epileptic activity by sectioning the corpus callosum. A temporal lobe resection may eliminate seizures in more than 70% of patients with temporal lobe seizures. For patients with extensive damage in one side of the brain that causes intractable seizures, a hemispherectomy may be performed. These surgeries involve risk and are reserved for those patients whose seizures cannot be managed by medical treatment and in whom the focus of the seizures is accessible.

For intractable partial seizures, a NeuroCybernetic Prosthesis (vagal nerve stimulator) can be implanted in the chest cavity with a wire tunneled to stimulate the vagus nerve. The device acts like a pacemaker and provides a tiny electric jolt every 5 minutes that stimulates the brain to interrupt seizures ([Englot et al, 2011](#)).

Uncontrolled seizures secondary to hypoglycemia (as in improperly controlled diabetes mellitus) can be relieved by IV administration of 50% dextrose. If the unrelenting seizures are caused by chronic alcoholism or withdrawal, treatment consists of IV administration of thiamine.

Clinical Cues

When IV phenytoin is ordered, mix it in 0.9% saline solution and flush the line before and after administration if a glucose IV solution is running. The patient should have cardiac monitoring while given the first or loading doses (usually 10 to 20 mg/kg divided into three doses; maximum dose 1200 mg total for adults). Glucose is incompatible with phenytoin. **Never administer IV phenytoin faster than 50 mg/min because of the risk of cardiac dysrhythmia, hypotension, or bradycardia.** For patients with a history of heart problems, administer the solution no faster than 25 mg/min.

❖Nursing Management

■ Assessment (Data Collection)

Patients with a known seizure problem usually are treated on an outpatient basis but may be encountered in a hospital or long-term care facility. Assess these patients carefully to provide optimal safety and care. Significant history information includes the kind of seizures they experience, whether they have any sensation just before the appearance of clinically observable signs, what medications they are taking, and what measures are known to be helpful either to prevent a seizure or to assist during a seizure and afterward. Assessment should include any factors that could have triggered the seizure (e.g., hyperventilation, bright lights [photosensitivity], alcohol

and other drugs, fluid and electrolyte imbalances, lack of sleep, and emotional stress).

Focused Assessment

Observations to Make During a Seizure

Observe as much of the following as possible and document your findings.

- Time the seizure began and the time it ended
- What the patient was doing just before the seizure (was the patient picking at clothing?)
- Where in the body the seizure began; what parts of the body are involved
- Which way the eyes are moving; whether they constrict or dilate, deviate to the right or the left, or roll upward
- Which side the head turns toward
- Whether the patient cries out or screams as the seizure begins
- Whether there is evidence of repetitive movements: lip smacking, chewing, grimacing, tapping, or “pill rolling”
- Whether movements are bilateral and symmetric
- Incontinence of urine or stool, vomiting, frothing at the mouth, or bleeding
- Whether the patient becomes apneic or cyanotic
- Changes in skin color or profuse perspiration

Postictal assessment, after a patent airway is ensured, includes determining:

- Length of time before regaining awareness
- Presence of lethargy or confusion
- Presence of headache
- Presence of speech impairment
- Presence of muscle soreness
- Whether there was an aura before the seizure began
- Effects of the seizure on the patient's vital signs

When caring for a patient who is likely to experience a seizure during an acute illness, periodically observe the patient for tremors, unexplained sensory or motor changes, mental changes that indicate confusion or disorientation, and restless or agitated behavior. In many cases, a change in the neurologic status of a patient can signal the possibility that a seizure might occur.

Nursing Diagnosis, Planning, and Implementation

The main problem statement for a patient who experiences seizures is Potential for injury due to seizure activity. Specific NANDA-I diagnoses can be chosen from the NANDA-I list (see inside back cover). Expected outcomes are written for the individual patient and the type of seizure disorder, possible triggers, and manifestations.

Nursing care of patients with epileptic seizures is concerned with immediate care during and after a seizure and long-term management and control of seizures and their psychosocial

implications. Witnessing a seizure for the first time can be a frightening experience. Your first responsibility is to stay calm, remain with the patient, and call for assistance.

The environment of a patient at risk for seizure should be made as safe as possible. If the patient is very likely to have seizures, the side rails and headboard of the bed are padded. **Never try to pry open the patient's mouth or insert something into it once the jaw is clamping down, because teeth may be broken and the airway may become obstructed.**

If a seizure comes on without warning and the patient drops to the ground, leave her wherever she is lying. If she is on a hard surface, her head should be protected from injury by placing a rolled blanket or coat under it. The head should be turned to the side, if possible, to prevent aspiration of secretions. Do not attempt to restrain the patient's movements or to move her to a bed or chair during the seizure. If supplemental oxygen is near, it should be administered, if possible. Call for help and provide privacy, if possible. When the seizure is over, turn the patient to the side, and suction the airway if needed. Check oxygen saturation with a pulse oximeter. Check the glucose level, if possible, and assess for injuries. Stay with the patient until she is completely conscious. When consciousness is regained, reorient and reassure her. The patient should be allowed to rest or sleep after the seizure. Thoroughly document the event in the medical record with time, duration of the seizure, and observations of the seizure activity and any aura that occurred before its start.

Safety Alert

If a patient who is receiving phenytoin is receiving tube feedings, stop the tube feeding for 2 hours before and 2 hours after administering phenytoin to ensure proper drug concentration and absorption.

The long-term management of epileptic seizures is primarily focused on providing the patient with the information and support she needs to care for herself and to avoid recurring and debilitating seizures. Psychosocial support is necessary to encourage the patient to talk about her fears and concerns. Lifestyle changes will have to be made if she is not permitted to drive. Most states allow resumption of driving when a patient has been seizure free for 1 year. A referral to the local epilepsy society for connection with a support group can be very helpful for both the patient and her family.

Most individuals who have epileptic seizures have normal mental function between seizures; they are not otherwise mentally handicapped and are quite capable of being contributing members of society if only they are provided resources and support to manage effectively.

Patient Teaching

Patients With Epilepsy

Cover these points in the teaching plan:

- Treatment and side effects of anticonvulsant therapy
- Triggers for seizures and how to avoid them (lack of sleep, alcohol and recreational drugs, stress, photosensitivity)
- Necessity of taking medication daily and as close to the same time each day as possible
- The greatest trigger for a seizure is not taking the medication
- Handling a missed dose or inability to retain medication
- Not using over-the-counter or prescription medications without consulting the provider who prescribed the anticonvulsants
- Schedule for laboratory work to determine drug therapeutic levels
- Need for medical alert bracelet, necklace, and wallet card listing provider's phone number and

drugs being taken

- Resources for assistance available in the community
- Need for proper nutrition; dangers of erratic meals
- Avoiding alcohol and excessive fatigue
- Relaxation therapy for stress reduction
- Danger of swimming alone
- Refraining from driving or operating dangerous machinery until seizures are well controlled
- Keeping follow-up appointments with the provider

For Women

- Risk of seizure during menstruation
- Necessity of consulting the provider before becoming pregnant, because some anticonvulsant drugs may cause congenital abnormalities

For the Family

- What to do in the event of a seizure
- How to protect the patient during a seizure:
- For tonic-clonic generalized seizure: assisting to the floor, protecting the head, loosening clothing, turning to the side
- When medical assistance is necessary

Patient Education

Self-care for an epileptic patient requires that she understand the nature of her disorder, the purpose of her prescribed medications, their side effects, and the signs of toxicity that should be reported to the provider. The patient must understand the necessity for compliance with the prescribed regimen to prevent recurrent seizures. She will need assistance in developing coping mechanisms to deal with the psychosocial impact of having epilepsy.

Evaluation

Evaluation is based on whether the expected outcomes are being achieved. This includes whether the patient is seizure free or whether the number of seizures has decreased. Patient compliance with the medication regimen and avoidance of triggers for seizure activity are evaluated as well. Patient teaching may need to be reinforced. If progress toward the achievement of outcomes is not occurring, the plan must be revised.

Think Critically

What safety measures would you teach a 22-year-old man who has just been diagnosed with grand mal seizures?

Transient Ischemic Attack

Between 200,000 and 500,000 Americans experience **transient ischemic attacks (TIAs)** each year. TIAs are caused by a brief interruption in blood flow. Narrowed arteries and vascular occlusion, perhaps by small emboli or vasospasm, cause the interruption. Recreational drugs that constrict vessels are another cause of TIAs. TIAs are warnings that a more serious neurologic event may occur; 11% of patients who experience a TIA have a stroke within 90 days. During the TIA, the person may feel a sudden weakness or numbness on one side of the body, slurring of speech or inability to talk, visual disturbances such as blindness or double vision, confusion, diminished coordination or ability to balance, and a headache. Symptoms are similar to those of a stroke. These symptoms generally last no more than an hour and completely resolve without residual deficits ([Nanda and Singh, 2014](#)). It is very important that the person be evaluated by medical personnel, because the same symptoms may indicate a stroke that will not resolve without treatment.

A thorough history of the event is essential: how it began, the symptoms experienced, and how long it lasted. If carotid obstruction is suspected, carotid duplex ultrasound studies are done to determine whether obstruction in the carotid arteries is preventing normal blood flow from reaching the brain. Multiple tests may be performed if carotid occlusion is ruled out, including blood tests, MRI, and EEG. If there is near-total occlusion of the carotid artery, either an angioplasty procedure with stent implantation or a carotid endarterectomy is considered. If occlusion from plaque obstruction is less than 60%, medical treatment with diet and lifestyle modification and medication to prevent platelet aggregation (i.e., aspirin, clopidogrel [Plavix], dipyridamole [Persantine]) is prescribed.

Cerebrovascular Accident (Stroke, Brain Attack)

Etiology

More than 795,000 first and repeat strokes occur in the United States each year. Stroke is the leading cause of disability and the fourth leading cause of death ([CDC, 2014b](#)). The incidence is about 19% higher in males than in females. About 34% of cases occur in people younger than age 65 years ([CDC, 2014b](#)). An increase in public education about the risk factors for and signs of stroke could result in decreased disability and death from stroke.

Health Promotion

Risk Factors for Stroke

Educate all patients about the risk factors for stroke and encourage measures to alter those factors that can be changed.

Modifiable Risk Factors

- Cigarette smoking
- Using cocaine or other recreational drugs
- Drinking more than two alcoholic drinks (male) or one alcoholic drink (female) per day
- Heart disease (especially atrial fibrillation)
- Diabetes
- High blood pressure
- High cholesterol
- Sedentary lifestyle
- High red blood cell count (polycythemia)
- TIAs
- Use of oral contraceptives or hormone replacement therapy

Nonmodifiable Risk Factors

- Age older than 65 years
- Asymptomatic carotid bruit (indicates atherosclerosis, which increases stroke risk; a bruit is a swishing sound in an artery)
- Heredity (family history of stroke increases individual risk)
- Prior stroke
- Race (African Americans have a 60% higher risk rate)
- Gender (incidence is 30% higher in men)

Cultural Considerations

Greater Incidence of Stroke in African Americans and Hispanic Americans

African Americans have about a 50% greater incidence of stroke than whites and are more likely to die of a stroke. A study at the University of Michigan found that Hispanic Americans have a far greater chance of having a stroke than non-Hispanic whites. Untreated hypertension may be the risk factor involved ([CDC, 2014b](#)).

Control of high blood pressure, quitting cigarette smoking, decreasing intake of cholesterol and controlling blood lipids, maintaining a normal blood sugar level, avoiding excessive alcohol intake, getting sufficient exercise, preventing obesity, and living a lifestyle that helps prevent heart disease can help reduce the risk of stroke. Atherosclerosis is a major cause of stroke, because it can predispose to thrombus formation in the brain vessels or plaque in other arteries that can break off and become emboli.

Pathophysiology

A cerebrovascular accident (CVA) is the result of an interruption of blood flow to a specific area of the brain (i.e., **cerebral ischemia**). Ischemia of cells directly causes cellular **necrosis** (death) and **infarct** (area of tissue that has become necrotic from lack of blood supply) ([Figure 23-1](#)). Ischemia can be caused by:

- Cerebral thrombosis (formation of a blood clot in a cerebral artery)
- An **embolus** (a traveling clot, fat, bacteria, or tissue debris that lodges in a vessel, occluding it)
- Intracerebral hemorrhage (the blood vessel ruptures and leaks blood into brain tissue, or an aneurysm or arteriovenous malformation in the brain leaks or ruptures)
- Pressure on a blood vessel (tumor)

Health Promotion

Dangers of Cocaine or Methamphetamine Use

Caution people about the dangers of using cocaine or methamphetamine. Both of these drugs can cause vasoconstriction and brain ischemia. Cocaine may also cause hemorrhage. Using these drugs causes a fivefold increase in the incidence of stroke. The incidence of this type of stroke has greatly increased in young adults ([Agarwal, 2013](#)).

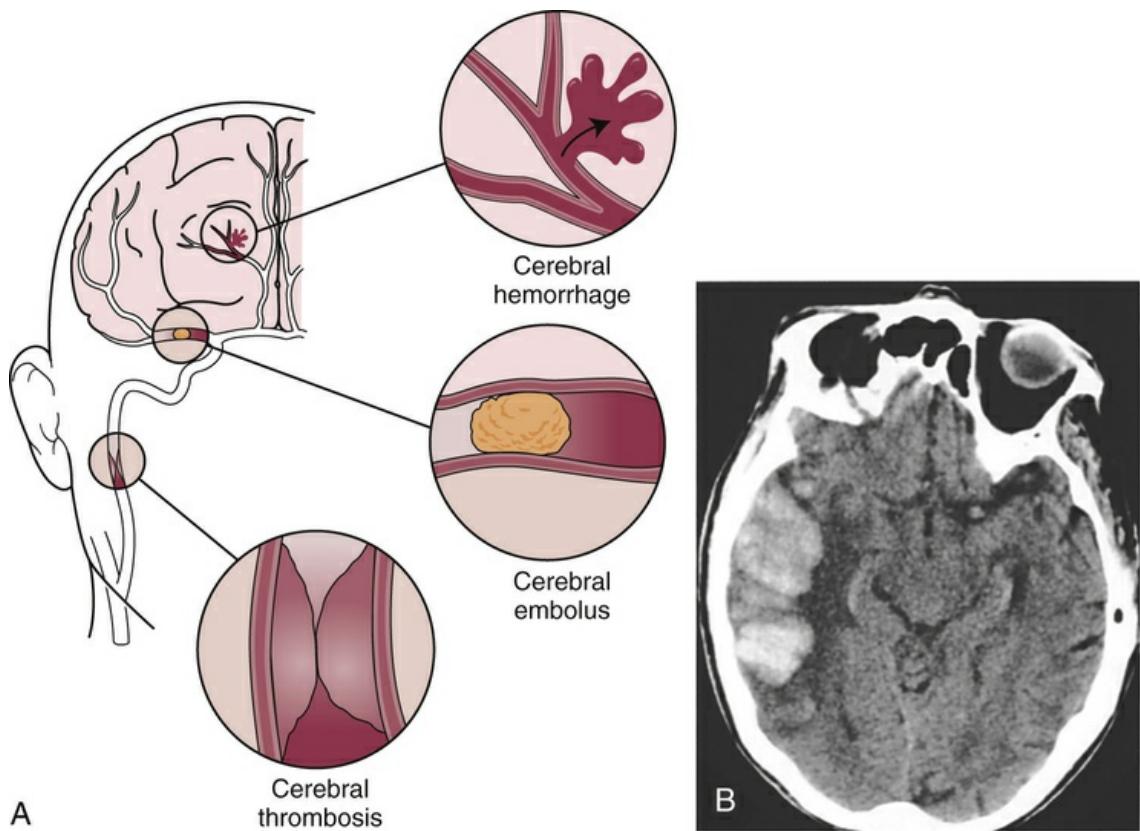

FIGURE 23-1 **A**, Events that cause stroke. **B**, Magnetic resonance imaging showing hemorrhagic stroke in the left cerebrum.

The carotid arteries supply a major portion of the blood that goes to the brain (Figure 23-2). If plaque forms in these arteries as a result of atherosclerosis, the person is at risk for a stroke as blood supply to the brain is diminished or stopped. Less common causes of stroke are arterial spasms, compression of cerebral vessels by a tumor, local edema, rupture of a cerebral aneurysm, or another disorder.

Think Critically

How many risk factors for stroke are present for each member of your family?

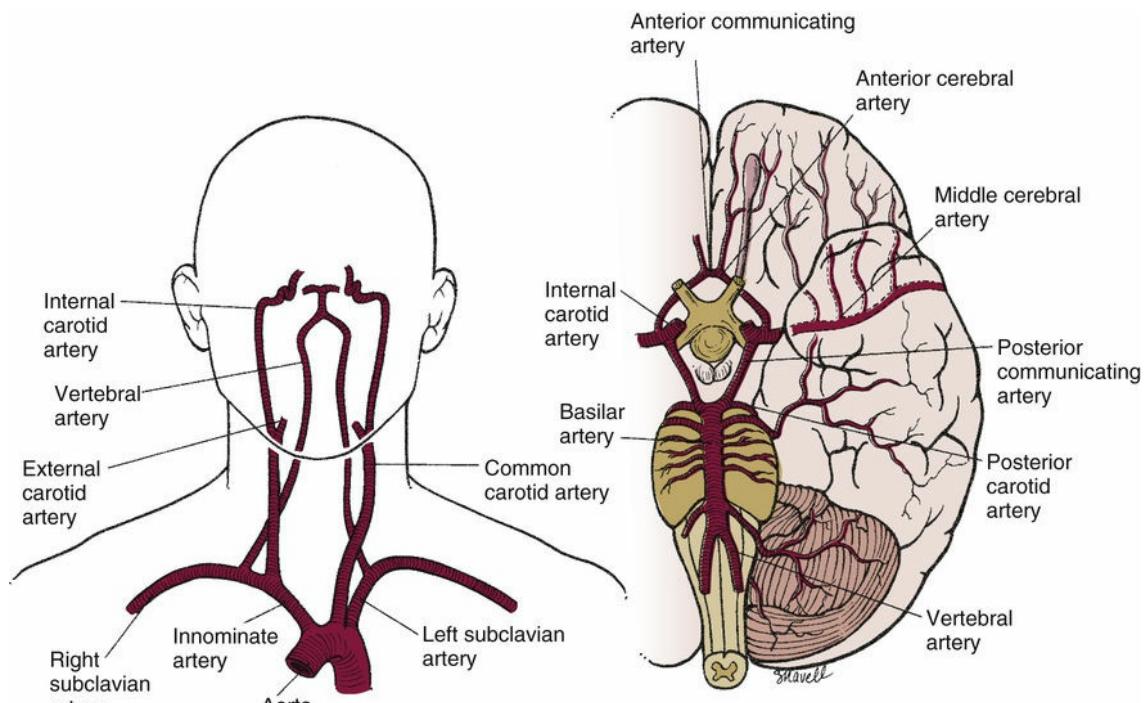

FIGURE 23-2 Major arteries supplying blood to the brain. Blockage of any major artery precipitates a cerebrovascular accident (CVA).

Cerebral Aneurysm and Arteriovenous Malformation

Structures that can cause an intracerebral hemorrhage are an aneurysm and an arteriovenous malformation. An **aneurysm** is an abnormal ballooning of an artery wall (Figure 23-3). It may be congenital or caused by a weakening of the artery wall from chronic hypertension. Rupture of a brain aneurysm causes bleeding into the subarachnoid space or into the ventricles. An **arteriovenous malformation (AVM)** is a congenital abnormality and is a tangled mass of malformed, thin-walled, dilated vessels that form an abnormal communication between the arterial and venous systems. An AVM can leak, causing an intracerebral hemorrhage. Vasospasm often occurs after intracerebral bleeding, leading to further ischemia of the brain tissue and more neurologic impairment. Resultant deficits are the same as for other kinds of strokes.

FIGURE 23-3 Dissected circle of Willis showing a large cerebral aneurysm. (From Cotran RS, Kumar V, Collins T: *Robbins pathologic basis for disease*, ed. 6, Philadelphia, 1999, Saunders.)

Subarachnoid hemorrhage, which refers to bleeding in the brain below the arachnoid, often causes rapid onset of neurologic deficit and loss of consciousness. A leaking cerebral aneurysm may cause a severe headache. However, sometimes bleeding is slower, producing a more gradual progression of headache, neck stiffness, and other neurologic signs, such as blurred vision.

Stroke Prevention

Many strokes can be prevented either by surgical procedures or by medical management of diseases that predispose a person to a CVA. An angioplasty with stent placement is an option for opening occluded carotid arteries. Care for patients undergoing vascular surgery is presented in [Chapter 20](#).

Aneurysms and AVMs can sometimes be surgically corrected, if found before rupture. Medical preventive measures are aimed at eliminating or managing some of the conditions that predispose a person to stroke. Control of hypertension and the effective treatment of inflammatory heart disease, congenital heart defects, cardiac dysrhythmias, and atherosclerosis have significantly reduced the incidence of stroke. Teaching people to seek assistance immediately when signs of stroke occur may allow medical intervention that will decrease permanent neurologic deficit.

Patient Teaching

Warning Signs of Stroke

Teach people to seek immediate medical attention in an emergency department if any of the following warning signs of stroke appears:

- Sudden weakness, numbness, tingling, or loss of feeling in the face, arm, or leg
- Sudden trouble seeing in one or both eyes; double vision
- Sudden confusion, slurred speech, trouble talking, or difficulty understanding what others are saying
- A sudden, severe headache for no known reason
- Sudden trouble walking, dizziness, or a feeling of spinning around
- Loss of balance or coordination
- Blackouts

Should any of these signs occur, ask the person to:

- Smile
- Shrug the shoulders
- Repeat a sentence or repeat what you say
- Tell you who she is and where she is

Clinical Cues

Valve disorders and arrhythmias such as atrial fibrillation predispose to stroke from emboli. Emboli form in the chambers of the heart when blood flow is abnormal, and these emboli can be ejected into the cerebral circulation.

Aspirin or another drug to reduce platelet aggregation and decrease the chance of thrombosis often is prescribed to prevent the recurrence of stroke from thrombosis ([Table 23-1](#)). A combination of results from two inflammatory marker blood tests is showing promise in predicting which

middle-aged people (age 45 to 64 years) are at risk for a stroke. Researchers reported that C-reactive protein and lipoprotein-associated phospholipase A₂ (LP PLA₂) were higher in those who later had an ischemic stroke than in those who did not have a stroke (Feng et al, 2014).

 **Table 23-1**

Drugs Commonly Used for Patients After a Cerebrovascular Accident

DRUG	ACTION	NURSING IMPLICATIONS	PATIENT TEACHING
t-PA (alteplase; tissue plasminogen activator)	Converts fibrin to plasminogen, causing lysis of thrombus or embolus of CVA	Frequent VS; monitor for dysrhythmias; frequent neurologic checks; assess for bleeding until 24 hr after infusion. Monitor for hypersensitivity; monitor clotting/bleeding studies. Do not give concurrently with anticoagulants, antiplatelet aggregation drugs, or NSAIDs.	Explain that the intermittent IV infusion is for the purpose of breaking up the clot stopping blood flow to part of the brain.
Aspirin (Ecotrin)	Decreases platelet aggregation	Administer with food; observe for signs of intestinal bleeding, tinnitus. Monitor blood count and liver enzymes.	Instruct to take with a full glass of water and when in an upright position. Ask to report any blood in stool, bleeding gums, nose bleeds, or excessive bruising. Report ringing in the ears or skin rash. Caution not to crush the pill. Warn not to take OTC products containing aspirin or salicylic acid.
Phenytoin (Dilantin)	Alters ion transport, inhibiting spread of seizure activity to motor cortex	Assess for skin rash; monitor drug levels, CBC; observe for respiratory depression. Shake suspension well; dilute before giving via feeding tube. Flush IV line with NS before and after administering slowly by IV piggyback. May cause Stevens-Johnson syndrome.	Teach that PO doses should be taken with meals; urine may turn pink; not to stop taking drug abruptly; to take as directed; to brush teeth and floss thoroughly and regularly and visit dentist q3-6mo; to not use alcohol. Instruct to not use antacids within 2 hr of the drug. Caution to adjust to drug before operating machinery or performing hazardous activities.
Nimodipine (Nimotop)	Inhibits calcium ion flux across cellular membrane; decreases or prevents cerebral vasospasm	Frequent neurologic assessment and VS; monitor liver enzymes; assess BP and apical pulse immediately before administration. Hold if systolic BP is <90 mm Hg Monitor for hypotension. Should be held for heart rate <60 beats per minute.	Advise that the drug may cause hypotension and dizziness with movement.

BP, Blood pressure; *CBC*, complete blood count; *CVA*, cerebrovascular accident; *IV*, intravenous; *NS*, normal saline; *NSAIDs*, nonsteroidal anti-inflammatory drugs; *OTC*, over the counter; *PO*, oral; *t-PA*, tissue plasminogen activator; *VS*, vital signs. See Chapter 20 for information on warfarin (Coumadin).

Cerebral ischemia caused by thrombosis causes signs that progress slowly. Thrombosis develops in an area of the vessel where there is atherosclerotic plaque. Lodging of an embolus in a major cerebral vessel causes sudden neurologic deficit. Emboli most often are the result of heart disease and resultant atrial fibrillation, a cardiac dysrhythmia.

Signs and Symptoms

The neurologic effects of stroke can range from mild motor disturbances to profound coma. Figure 23-4 shows selected control zones of the brain and motor and sensory functions likely to be affected by a stroke. Signs and symptoms will depend on the type of event that has caused the stroke and the location of the clot or bleed. There may be weakness (**hemiparesis**) or paralysis (**hemiplegia**), difficulty or inability to speak or understand (**dysarthria** or **aphasia**), difficulty with vision, loss of balance or poor coordination (**ataxia**), decreased level of consciousness, and confusion. Incontinence may occur. Bleeding into the brain or edema around necrotic tissue causes intracranial pressure (ICP) to increase (see Chapter 22 regarding increasing ICP).

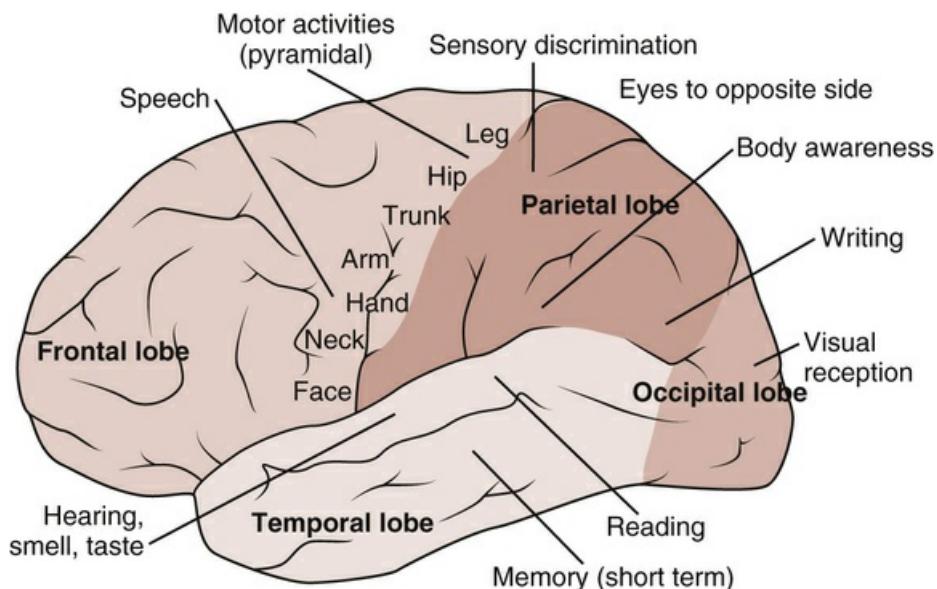

FIGURE 23-4 Each area of the brain controls a particular activity.

Motor function deficits affect mobility, respiratory function, swallowing, speech, gag reflex, and self-care abilities. Because the pyramidal pathways cross at the level of the medulla, injury to brain cells in the right hemisphere affects the left side of the body and damage to cells in the left hemisphere affects the right side of the body. There may be hemiplegia or hemiparesis. Muscle tone is usually flaccid at first, and then there may be spasticity and hyperreflexia. Keeping the body in good alignment to prevent contractures is very important.

Language disorders involve expression and comprehension of both written and spoken words. Aphasia or **dysphasia** (minimal speech activity) or a mixed type of aphasia may occur (see Chapter 21). Many stroke patients experience **dysarthria** (difficulty in speaking) because of lack of muscular control of the tongue. A speech therapist works with the patient to improve speech capability. There are computer software programs for rehabilitation of patients with aphasia that have been beneficial to many.

The frustration of trying to perform a function that has always been easy before the stroke may cause the patient to cry. Alternatively, the patient may display an angry emotional outburst, and sometimes foul language.

Clinical Cues

Because of the damage to the nervous tissue, fatigue is another problem for stroke patients. When working with a patient to relearn walking, dressing, or other activities, keep the session short and allow for adequate rest periods between activities.

Memory and judgment may be affected by the stroke. The ability to learn may be affected, which makes relearning activities to promote independence a slow process. A great deal of patience and encouragement is needed from the staff working with the patient.

Spatial-perceptual deficits may cause the patient to totally neglect input from the affected side of the body (**unilateral neglect**). She must be taught to attend to the body parts on that side of the body to protect them from injury. **Homonymous hemianopsia** (blindness in part of the visual field of both eyes) adds to the spatial-perceptual problems by making it difficult to judge distances (Figure 23-5). The patient is taught ways to deal with the problems of the particular type of visual defect developed. **Agnosia** (inability to recognize an object by sight, touch, or hearing) makes it difficult to do ordinary tasks. **Apraxia** (the inability to carry out learned sequential movements on command) adds to the difficulty in regaining independence.

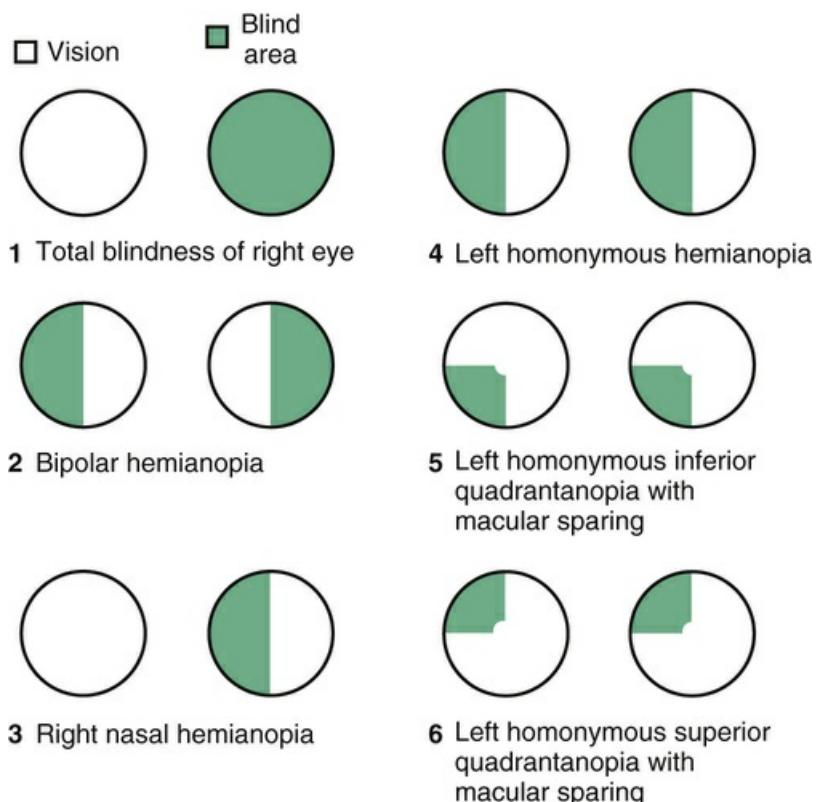

FIGURE 23-5 Homonymous hemianopsia: visual field defects that can occur after a stroke. (Adapted from Black JM, Hawks JH: *Medical-surgical nursing: Clinical management for positive outcomes*, ed. 8, Philadelphia, 2009, Saunders.)

Bladder and bowel incontinence are often temporary after a stroke. Constipation does occur because of immobility, weakened abdominal muscles, dehydration, and diminished response to the defecation reflex. The patient's inability to express needs and her difficulty in managing clothing contribute to bladder and bowel incontinence and constipation. With time, these problems can be overcome.

Diagnosis

In addition to a complete physical and neurologic examination, the provider may order an MRI scan, computed tomography (CT) scan, or cerebral angiogram to determine the specific cause of the stroke and whether there is bleeding in the brain. An EEG is performed; brain scans or transcranial Doppler flow studies and carotid artery Doppler studies may also be ordered. Testing for blood levels of glutamate, which increases during a progressive ischemic stroke and damages brain tissue, may alert providers to patients whose condition is likely to rapidly deteriorate. If a hemorrhagic stroke is suspected, a lumbar puncture will be performed to determine the presence of blood in the cerebrospinal fluid.

Treatment

When a stroke is suspected, the first priority is to maintain an open airway. All constricting clothing around the patient's neck should be removed, and the patient should be turned to one side to prevent aspiration of saliva and obstruction of the air passages. When outside of the hospital, no attempt should be made to move the person until an ambulance has arrived. Reassure the patient, regardless of whether or not she is able to respond. Elevate the head slightly to reduce ICP.

Once under medical care, supplemental oxygen is started. If breathing is impaired or the patient is comatose, an artificial airway is inserted to maintain a patent airway, and the patient may be mechanically ventilated. Hypovolemia is treated with fluids, and hypertension of greater than 220/130 mm Hg is treated. Vital signs may be unstable. Two IV lines for drug and fluid access are inserted, and normal saline is administered. Electrolytes are assessed frequently to prevent imbalances. If the temperature is elevated and rising, a hypothermia blanket may be used to keep

the temperature down ([Samaniego, 2013](#)). Measures to prevent deep vein thrombosis are instituted.

Clinical Cues

There is a fine line between keeping blood pressure high enough to perfuse the brain when an obstruction is present and keeping blood pressure low enough to prevent vessel rupture or increased bleeding from a rupture that has occurred.

Once the specific cause of the stroke has been determined, the provider is able to plan a more effective regimen of care. Activase (alteplase) or systemic tissue plasminogen activator (t-PA) is used to dissolve clots and emboli in ischemic stroke. It must be administered within 3 to 6 hours of the onset of symptoms and clot location ([Jauch et al, 2013](#)). It has been estimated that this window could be met 28.6% of the time if patients arrived soon after onset. The drugs are effective in about one of eight patients treated. Sometimes the fibrinolytic drug is directed to the clot via a catheter positioned during angiography. Another drug, caffeinol, improves the outcome in ischemic stroke when administered IV. It is a combination of caffeine and ethanol. Platelet inhibitors and anticoagulants may be given to prevent further clot formation. If t-PA has been given, no anticoagulants or antiplatelet aggregation drugs are given for 24 hours. **The drug is not administered to anyone with a known risk of bleeding or who has had an intracerebral bleed.** Antihypertensive drugs are prescribed as appropriate. The patient may be started on oral warfarin (Coumadin) after the acute stage of a thrombotic stroke.

Safety Alert

Cranberry Juice Interaction

The consumption of cranberry juice while taking warfarin can produce an interaction that increases the serum level of the drug, extending clotting time. Patients who drink cranberry juice should consult their providers. Off-and-on intake of cranberry juice will affect the prothrombin time and international normalized ratio (INR).

A recombinant human interleukin-1 receptor antagonist has been shown to be effective in patients with acute stroke symptoms in reducing the amount of injury and residual deficits; research is continuing. Use of a natural growth factor, neuregulin-1, which protects brain cells from the damage caused by stroke, is also under study. The biggest benefit of neuregulin-1 is that its therapeutic window is much longer than t-PA, and it can be administered up to 13 hours after the onset of the stroke. This drug has shown no adverse side effects to date. Desmoteplase is a genetically engineered version of a protein in vampire bat saliva that prevents clotting. The drug can break down a clot without affecting the coagulation system, thereby decreasing the risk of intracerebral bleeding. It works when given within 9 hours of a stroke and is in phase III clinical trials.

Nimodipine or nifedipine may be given to decrease arterial spasm if the stroke is from subarachnoid hemorrhage. Testing of new drugs continues in an effort to find a way to decrease the resultant damage from a stroke. Statins are being studied for their neuroprotective effect ([Jauch et al, 2013](#)). Hypertonic saline infusion is being studied as a treatment for hemorrhagic stroke to improve oxygenation of the brain and to decrease ICP. The patient is given sedation and analgesia for the headache and neck pain. Blood glucose levels are monitored and controlled.

Surgical Procedures

About one third of all strokes can be traced to obstruction of any one of the four arteries in the neck that supply blood to the brain. These arteries are generally accessible, so the surgeon can open the artery and remove the obstruction, which is usually from plaque buildup. The vessel wall is then sutured or a Dacron patch is sewn at the incision, leaving the vessel larger than before.

The Mechanical Embolus Removal in Cerebral Ischemia (MERCI) Retriever can be used up to 8 hours after the onset of an ischemic stroke to remove a thrombus. A catheter is threaded up through the femoral artery to the brain, and a wire device is guided through the catheter to the brain. The

end of the wire resembles a corkscrew and ensnares the clot, which is pulled out through the catheter (Jauch et al, 2013). The interventional radiologist performs this procedure during angiography. If successful, blood flow can be restored to the brain within 20 minutes. Several mechanical methods for clot dissolution or retrieval are undergoing trials. Clot aspiration is another retrieval method. Several methods of mechanical removal of a clot are undergoing trials. There are risks of bleeding with these procedures that must be considered.

A cerebral aneurysm may be repaired during a craniotomy by placing a clip around the stalk of the aneurysm. The aneurysm may be wrapped with a material that prevents the wall from rupturing if it cannot be clipped or resected. A radiologic procedure in which a small platinum wire is guided carefully into the aneurysm is another option. Coils of wire are curled into the aneurysm sac, filling it (Figure 23-6). Electricity is sent down the wire to break the wire off and leave the coils in the aneurysm. Thrombosis completes the solidification of the aneurysm, effectively eliminating it. AVMs are treated in much the same way, but may be eliminated using radiosurgery. More than one type of intervention may be used.

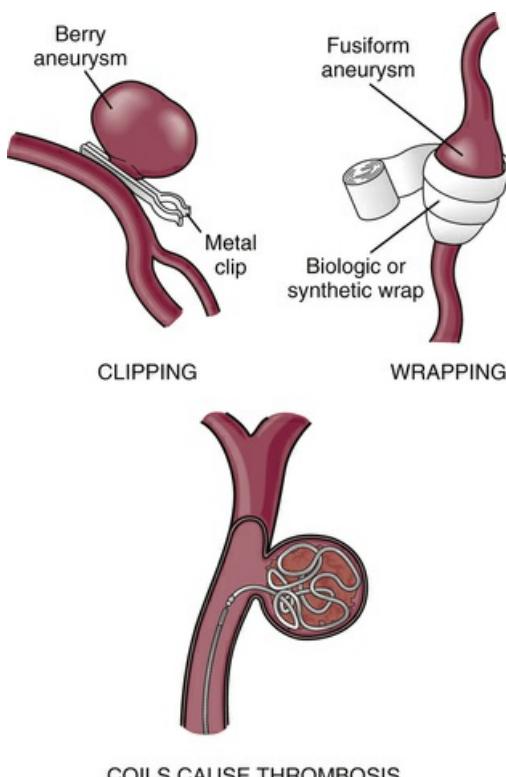

FIGURE 23-6 Techniques used for aneurysm repair.

Neurologic assessments are performed often to monitor closely for signs of increasing ICP (see Chapter 22). Measures are instituted to prevent or alleviate a rise in ICP. Increased ICP occurs most commonly with subarachnoid hemorrhage.

Complications

Extension of Hemorrhage or Rebleed

If initial symptoms were caused by a leaking cerebral aneurysm, rupture is a danger until the aneurysm is repaired. Neurologic signs and level of consciousness are watched closely to detect deterioration of the patient's condition because of further bleeding and a rise in ICP. The patient is kept as quiet as possible, with outside stimuli kept to a minimum. An aneurysm that is repaired by wrapping or embolization has a greater chance of bleeding again than one that is repaired with a clip.

Seizures

Seizures are a common complication of a stroke, because neural pathways are interrupted when blood flow is blocked or there is irritation of the cerebral cortex from an intracerebral bleed. The type of seizure depends on the area of the brain involved and the extent of the intracerebral bleed or blockage of blood flow. Generalized seizures may occur. The patient may be started on an anticonvulsant to prevent seizure occurrence. The tensing of muscles during a generalized seizure increases ICP. Anticonvulsant therapy may be continued for many months to 2 years after the last seizure occurs.

Hydrocephalus

If blood has leaked into the ventricular system, it interferes with the resorption of cerebrospinal fluid (CSF), causing hydrocephalus. This is more common when a subarachnoid hemorrhage has occurred. It may be necessary to prevent increased ICP by shunting the fluid out of the brain; a catheter is placed into the lateral ventricle and then tunneled down to the right atrium or the peritoneal cavity to drain the excess fluid.

❖Nursing Management

When a patient is first admitted to the hospital after a stroke, the general state of health is assessed as well as effects of the stroke. The American Heart Association Council on Stroke and Cardiovascular Nursing has issued clinical practice guidelines for poststroke rehabilitation. The guidelines cover care for inpatient and outpatient settings, for chronic care, and for end of life. It is based on the World Health Organization's framework for an interdisciplinary approach to rehabilitation ([Miller et al, 2010](#)).

Care of patients after a stroke can be divided into three phases: **phase 1**, or initial care; **phase 2**, which is concerned with rehabilitation efforts; and **phase 3**, during which plans are made for continuity of care once the patient returns home. These are not phases in the sense that one begins only after another is finished. There is overlapping of activities in each phase. Because approximately 80% of all stroke patients survive the first or initial phase of their illness, rehabilitation and plans for self-care are of the utmost importance. The Joint Commission's Core Measures require that the patient receive venous thromboembolism prophylaxis, be discharged on antithrombotic therapy and statin medication, receive thrombolytic therapy if appropriate that is discontinued by day 2, receive stroke education, and be assessed for rehabilitation. [Chapter 9](#) discusses concepts of rehabilitation.

Assess stroke patients for risk of falls and institute appropriate interventions to prevent falls. Assess pain regularly using an appropriate validated pain scale. A nutritional and dysphagia screening should be completed within 24 hours of the patient being awake and alert (Edmiston et al, 2010).

■ Assessment (Data Collection): Phase 1

Immediate assessment of breathing and respiratory rate is essential. Level of consciousness (LOC) is assessed next. Initial care of stroke patients includes careful assessment to determine the extent to which neurologic functions have been affected. Complete hemiplegia is a common effect of stroke. Aphasia often indicates ischemia of the brain cells on the left side of the brain and is usually accompanied by right-sided hemiplegia. [Figure 23-7](#) illustrates deficits often experienced by damage to the left or right side of the brain.

☒ Clinical Cues

If any change in the patient's thought processes or LOC occurs, or the patient becomes more restless, notify the provider immediately, because it may be an early sign of increasing ICP. Treatment to decrease ICP may prevent disability and may prevent death from herniation of the brain.

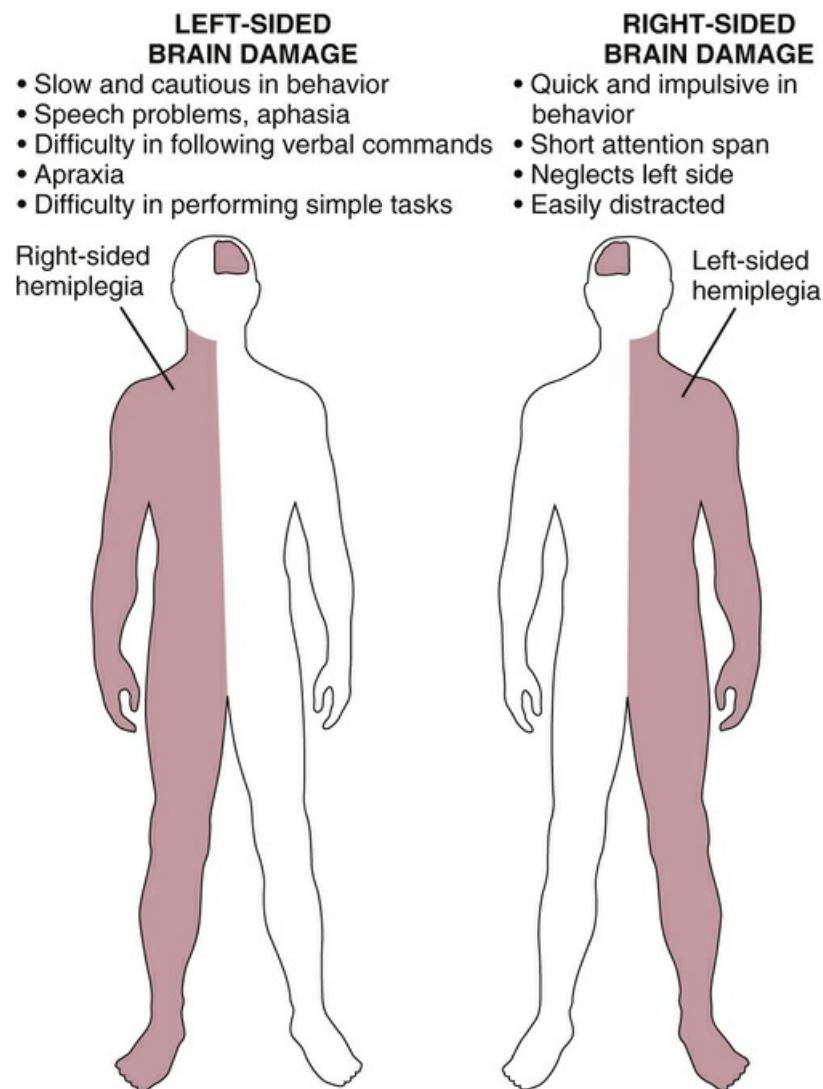

FIGURE 23-7 Comparison of deficits and behavior related to damage to the left and right sides of the brain.

After the acute stage of the stroke has passed and the patient is physiologically stable, an assessment of functional abilities is performed so that rehabilitation goals and plans can be devised. Assessment of and nursing intervention for patients with problems of immobility, incontinence of urine and feces, aphasia, delirium or confusion, and altered LOC are discussed in [Chapter 21](#). Because a patient who has had a stroke is at risk for a second occurrence, assessment for new signs of neurologic impairment is ongoing.

Nursing Diagnosis and Planning

Problem statements for a patient who has experienced a CVA commonly include:

- Potential for injury due to weakness, paralysis, confusion, decreased consciousness, or unilateral neglect.
- Altered physical mobility due to weakness or paralysis.
- Altered nutrition due to impaired swallowing and hemiparesis or hemiplegia.
- Altered self-care ability due to inability to perform activities of daily living (ADLs; feeding, bathing, grooming) without assistance.
- Altered urinary function due to neurologic deficits.
- Altered bowel function due to impaired mobility and neurologic impairment.
- Potential for altered skin integrity due to decreased mobility, paresis, or paralysis.
- Altered communication ability due to inability to clearly verbalize or inability to comprehend

communication.

- Altered body image due to neurologic damage and hemiplegia.
- Altered sensory perception: visual—due to loss of vision in parts of visual field; kinesthetic—related to decreased sense of touch on one side of the body.
- Decreased self-esteem due to alteration in body image and to dependence on others.
- Altered coping ability due to loss of usual lifestyle, neurologic deficits, and dependence on others.
- Potential for injury due to lack of sensation in extremity.

Specific NANDA-I diagnoses can be chosen from the NANDA-I list (see inside back cover).

Planning for specific goals must take into account the individual patient's previous lifestyle, age, general health or illness status, and specific problems of care. An 80-year-old retired person will not have the same goals for rehabilitation and recovery as a 47-year-old mother of three who had been working full time as a schoolteacher before her attack.

Major nursing goals during the first phase are to:

- Maintain an adequate airway
- Establish baseline data regarding vital signs, LOC, neuromuscular function, and neurologic status
- Preserve joint and muscle function
- Prevent complications that may interfere with rehabilitation

Specific individual expected outcomes are written for each identified problem or nursing diagnosis ([Nursing Care Plan 23-1](#)).

Nursing Care Plan 23-1

Care of a Patient Who Has Experienced a Stroke

Scenario

Mr. Lewis, age 68 years, had an ischemic stroke, or cerebrovascular accident (CVA), 4 days ago. He is experiencing left-sided paresis, decreased alertness, and difficulty swallowing.

Problem Statement/Nursing Diagnosis

Altered cerebral tissue perfusion/*Risk for ineffective cerebral tissue perfusion related to obstruction from a thrombus.*

Supporting Assessment Data

Subjective: "What day did you say it was?"

Objective: Requires shaking his shoulder and calling his name to arouse him. Thrombotic ischemic CVA.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will show no further decrease in LOC.	Monitor neurologic status q2h. Notify provider of decreasing LOC, pupil changes, change in respiratory pattern, widening pulse pressure, slowing of pulse, or increase in temperature.	Changes in neurologic signs may indicate rising intracranial pressure.	No changes in neurologic signs. Difficult to arouse, but orients quickly.
	Monitor for seizure activity.	Seizure activity is common after a brain injury or CVA.	No signs of seizure activity.
	Administer medications to prevent clot formation as ordered.	Aspirin is effective to help prevent clot formation.	Managed to swallow the enteric-coated aspirin tablet.
	Monitor for bleeding gums, blood in urine or stool.	Anticoagulants may cause bleeding.	No signs of blood in urine or stool; gums not bleeding.

Problem Statement/Nursing Diagnosis

Altered swallowing ability/*Impaired swallowing related to weakness of swallowing muscles.*

Supporting Assessment Data

Subjective: "I almost choked on that capsule."

Objective: Coughing when trying to swallow capsule.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will not aspirate food or pills.	Place in high Fowler's position for meals, snacks, and oral medication administration.	Gravity will assist swallowing in this position.	Raised to high Fowler's for oral intake.
	Instruct to tilt head and neck forward when attempting to swallow.	Facilitates elevation of the larynx and posterior movement of the tongue, allowing food to go into esophagus rather than trachea.	Is tilting head and neck forward when swallowing.
	Have swallow a sip of water before eating or taking an oral medication.	Ensure that patient can swallow.	Swallows sip of water without much difficulty now.
	Assist to choose foods for meals that are easily swallowed.	Custard, eggs, canned fruit, mashed potatoes, and other soft foods are more easily swallowed.	Choosing soft foods for tomorrow's meals.
	Encourage to take small bites of food.	Small amounts are more easily swallowed than large amounts.	Is taking small bites of food.
	Use a thickening agent in liquids if they are particularly hard to swallow.	Thickening makes liquids easier to swallow without aspirating.	Thickening agent not needed.
	Avoid putting foods of different texture in the mouth at the same time.	More than one food texture creates higher risk of aspiration.	Is eating one type of food at a time.
	Reinforce swallowing techniques/exercises recommended by speech therapist.	Muscle strengthening exercises may improve swallowing if done regularly.	Is practicing techniques suggested by speech therapist to improve swallowing.

Problem Statement/Nursing Diagnosis

Potential for injury/*Risk for injury related to muscle weakness in left extremities.*

Supporting Assessment Data

Subjective: "I can't put full weight on my left leg."

Objective: Left leg unable to push much against resistance; when trying to stand, left leg will not support full weight.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will not fall or sustain injury before or after discharge.	Assist to stand and walk to the bathroom.	Assistance prevents falling.	Using gait belt and cane to walk to bathroom.
	Instructed not to get up without assistance.	Assistance prevents falling.	Asking for assistance to go to the bathroom.
	Place call bell within reach each time he is repositioned.	Allows patient to call for help when wishing to arise.	
	Encourage ROM exercises and strengthening exercises taught by physical therapist.	Working the muscles may improve muscle tone.	Performing ROM and strengthening exercises three times per day.

Problem Statement/Nursing Diagnosis

Altered self-care ability/*Self-care deficit related to weakness and post-stroke fatigue.*

Supporting Assessment Data

Subjective: "I'm too weak to hold the razor properly to shave."

Objective: Hand shakes when trying to grip razor and shave.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will resume some self-grooming by discharge.	Assist with bathing, dressing, and grooming.	Assistance prevents undue fatigue. Assistance helps accomplish daily hygiene activities.	Assistance with bathing, dressing, and grooming provided.
	Encourage patient to attempt to comb hair and brush teeth.	Small accomplishments provide hope of independence.	Attempted to comb hair with right hand; praise given.
	Praise for every successful attempt at self-care.	Praise reinforces desired behavior.	Patient attempted self-grooming activity.
	Help to practice shaving with electric razor using right hand.	New skills improve with practice.	Wife will bring in an electric razor for him tomorrow. Continue plan.

Problem Statement/Nursing Diagnosis

Limited coping ability/*Ineffective coping related to memory impairment, difficulty swallowing, and paresis of left extremities.*

Supporting Assessment Data

Subjective: "I don't want to be a burden to my wife."

Objective: Tends to forget what wife or nurses have told him; eyes fill with tears at times.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will express hope of full recovery before discharge.	Assure that it is too early to tell whether there will be any permanent disability from the stroke.	Validates that the future is not known at this time.	Assurance given during bathing discussion.
	Help patient explore his fears and anxieties about his condition and his future.	Expressing fears decreases anxiety.	Spoke about fear of being dependent on wife for daily care.
	Actively listen with patience when patient shares his thoughts.	Actively listening establishes trust and provides emotional support.	Sat with patient, established eye contact, and listened to his concerns.
	Do not express negative thoughts or opinions about his condition or progress in his or his wife's presence.	Negative thoughts can destroy hope.	No negative comments made.
	Point out each small bit of progress in self-care, eating, and mobility.	Acknowledging progress toward recovery helps dispel fear of permanent dependence.	Acknowledged improvement in swallowing at noon meal. Continue plan.

Critical Thinking Questions

1. How would you incorporate Mrs. Lewis into the care of her husband?
2. What might be accomplished with an occupational therapy consultation for this patient?
3. How could a social services consult be helpful for this patient and his wife?

CVA, cerebrovascular accident; LOC, level of consciousness; ROM, range of motion.

■ Implementation

The amount of activity permitted a stroke patient during the initial acute stage of her illness depends on the cause of the stroke. If there is danger of continued hemorrhage from a ruptured artery and resultant increase in ICP, physical activity will necessarily be limited. When there is no danger of further damage to the brain, the patient usually is encouraged to become active as soon as her condition has stabilized.

■ Think Critically

What interventions would you use to help a patient with unilateral neglect?

Many patients have **dysphagia** (difficulty swallowing) after a stroke. A speech therapist should be called to do a swallowing study and to devise a plan to improve swallowing. Be certain the patient has had the evaluation to ensure intact swallowing before feeding orally. When the patient has dysphagia, aspiration when eating is a real danger.

Measures to prevent complications, such as subcutaneous low-molecular-weight heparin injections and elastic stockings to prevent deep venous thrombosis, skin care to minimize the risk of skin breakdown, physical therapy and splinting to prevent contractures and spasticity, and measures to prevent falls, are included in the complete plan of care. To reduce the possibility of recurrence of a stroke, risk factors are identified and teaching is begun to modify them.

Listening to music after a stroke seems to improve recovery, according to studies done in Finland ([Särkamo and Soto, 2012](#)).

■ Evaluation

Evaluation is based on whether the interventions are effective in achieving the expected outcomes. Assess whether the overall goals have been met. If the outcomes are not being met, the care plan must be revised.

■ Rehabilitation: Phase 2

Plans for rehabilitation should begin the moment the patient is admitted.  This means maintenance of an adequate airway and aeration of the lungs, proper positioning, range-of-motion exercises for affected limbs, adequate nutrition and fluid intake and output, prevention of pressure ulcers, use of devices to keep extremities in anatomic position, and all other nursing measures directed toward maintaining normal body functions until the patient is able to maintain them on her own.

If the patient has homonymous hemianopsia, she has a visual defect affecting the same half of the visual field in each eye. She will not be able to see past the midline toward the side opposite the lesion and must turn her head to scan that side (see [Figure 23-5](#)). The problem may cause accidents when ambulating. The patient must be taught ways to deal with this visual problem. Teach patients with unilateral neglect to bathe both sides of the body. Demonstrate how to dress the affected side first. The weakened arm and/or leg must be positioned in correct alignment when the patient moves. A sling may be used to prevent shoulder subluxation of the affected upper extremity.

If disabilities from inactivity are prevented, rehabilitation has a much better chance of success. During phase 2, various members of the health care team collaborate with the patient and her family to help resolve both psychosocial and physical problems. The team members may include a physical therapist, speech pathologist, social worker, psychologist, and occupational therapist. The patient usually is transferred from the hospital to a rehabilitation facility. The patient is encouraged with physical therapy to strengthen her muscles as well as her resolve to help herself. She will need

to exercise her muscles actively and retrain them.

■ Nutrition Considerations

Patients With Dysphagia

To help prevent aspiration, tell the patient:

- Sit up straight to eat, and tilt your head slightly forward.
- Place only one teaspoon of food in your mouth at a time.
- If you have paresis from a stroke, the food should be placed on the unaffected side of your mouth.
- Place your chin on your chest and swallow; wait a few seconds and swallow again.
- Refrain from taking liquids and solids at the same time.
- Sip from the cup or glass rather than use a straw.
- Remain in an upright position for 45 to 60 minutes after a meal.

Interventions to assist the patient to eat without aspirating include:

- Plan a 30-minute rest and relaxation period before each meal.
- Allow plenty of time for a relaxed meal.
- Serve food cold or well warmed; lukewarm foods are more difficult to swallow.
- Serve foods in the consistency ordered; some patients find semisolid food easier to swallow.
- Avoid serving peanut butter, syrup, and bananas, because they are sticky and difficult to swallow.
- Avoid serving dry foods such as rice, popcorn, toast, or crackers, because they tend to be more difficult to swallow and can stick in the throat.
- Keep the container for liquids more than two-thirds full so that the patient does not have to tilt the head back too far to drink. Tilting the head back tends to cause fluid to go into the trachea.

There are many ways to encourage the patient. Instead of feeding her every item on her tray, let her hold bread and other "finger foods," suggesting that she feed herself these things. Chewing may be slow at first; the patient should not be hurried, nor should she be allowed to chew to the point of exhaustion. Eating often is difficult and messy, and privacy must be provided. If hemiplegia is causing the patient to "pocket" food in the folds of the mouth, the mouth should be checked after meals.

Combing and brushing the hair is good exercise for the arm and shoulder, as are brushing the teeth and washing the face and hands. The patient may not be able to carry all these procedures through to completion at first, but with occupational therapy and encouragement she can gradually improve until she is able to perform much of her own personal care. **The patient who has sustained a brain injury becomes fatigued very quickly, and this must be kept in mind when performing self-care activities.** Encouragement and praise for the smallest accomplishment can help the patient's tattered self-esteem.

Stroke patients can be prone to rapid mood swings and spontaneous weeping. All health care workers must be patient and accepting, and an explanation to the patient and family that this is common after a stroke can ease the patient's embarrassment.

Various rehabilitation techniques are undergoing trials to determine whether more function can be regained in the extremities. Further information on rehabilitation programs is provided in

Chapter 9.

■ Continuum of Care: Phase 3

In phase 3, plans are made for discharge and referral to individuals and agencies outside the hospital that will help the patient and her family adjust to her new way of life. A visiting nurse often is assigned for a period of time to coordinate rehabilitation efforts, assist with teaching, and assess the patient's status. The patient continues rehabilitation as an outpatient under the provider's supervision. In some rural areas, TeleHealth services using the Internet and telephone are available to provide continued speech therapy.

Brain Tumor

Etiology and Pathophysiology

About 200,000 new brain tumors are discovered each year in the United States. About 69,000 of those are primary tumors, and the rest are metastatic tumors from a different site of origin (Table 23-2). It is not known how brain tumors begin, and there are more than 120 different types. Low-grade astrocytomas are more common in young people than in older adults (American Brain Tumor Association, 2015). High-grade gliomas are more prevalent in older adults. Cerebellar tumors are more common in children.

Table 23-2
Different Types of Brain Tumors*

TUMOR	BURDEN†	TYPE OF TISSUE
Gliomas (malignant)	30	Gluey or supportive tissue of the brain
Glioblastoma multiforme	17 (54% of all gliomas)	Primitive stem cells (glioblasts)
Astrocytoma	7 (22% of all gliomas)	Astrocytes and glial cells
Medulloblastoma	1	Primitive neuroectodermal cells
Oligodendroglioma	2	Oligodendrocytes
Pituitary adenoma (usually benign)	13	Pituitary gland cells
Acoustic neuroma (usually benign)	9	Myelin sheath cells of cranial nerve VIII
Meningioma (most often benign)	34	Cells of the meninges
Hemangioblastoma (benign)	1	Cells from blood vessels in the brain
Lymphoma	2	White blood cells
Metastatic tumors (malignant)	2	Mostly from lung, breast, kidney, thyroid, and prostate carcinomas

*Primary brain tumors are classified by the type of tissue from which they derive.

†Refers to portion of total primary brain tumors by type; prevalence.

Neoplasms within the confines of the skull are space-occupying lesions and thus create problems of increasing ICP by compressing adjacent tissues. If the tumor arises from brain cells, the cranial nerves, or the pituitary gland, the neoplastic cells can infiltrate and destroy these structures; other types of tumor can destroy tissue through pressure. Many brain tumors are benign, such as meningiomas and acoustic neuromas. However, because of the increased ICP that tumors cause and the way they can invade brain tissue, a benign tumor also presents a serious condition.

Intracranial tumors may begin in the brain itself, or they may begin in the meninges, cranial nerves, or pituitary gland. Primary malignant brain tumors rarely metastasize outside the brain. Tumors in the cerebral hemispheres are termed *supratentorial*, and those located beneath the tentorium (fold of dura mater) are termed *infratentorial*. This area of the cerebral hemisphere contains the structures of the brainstem and the cerebellum.

Signs, Symptoms, and Diagnosis

There can be as many symptoms of intracranial tumors as there are functions of the structures within the skull. The symptoms depend on location and may appear gradually, or—if the tumor is a highly malignant, fast-growing type—they may appear suddenly. In a slow-growing type of tumor, the patient may first show personality changes, disturbances in judgment and memory, loss of muscular strength and coordination, or difficulty in speaking clearly. Headache awakening the patient is a key sign. Vomiting, visual problems, and other signs of increased ICP also may occur. Approximately 20% to 50% of adults with brain tumors develop seizure activity. Diagnostic procedures to identify the site and extent of intracranial tumors include skull x-rays, MRI and CT scans, and arteriography.

Treatment

The three modes of therapy for intracranial tumors are the same as those for neoplastic diseases elsewhere in the body: surgery, radiation therapy, and chemotherapy. Radiation is usually given 5 days a week for 6 weeks. With brachytherapy, tiny radioactive particles are inserted into the tumor tissue via an implanted catheter. This treatment extends over approximately 5 days. Radiation precautions are needed during this period. If the tumor is found while it is still very small, a stereotactic Cyberknife or gamma knife procedure may destroy it. Gamma knife procedures use a

steel frame attached to the head with ports through which radiation is directed from several angles. Cyberknife procedures use a molded head mask or body mask to keep the patient from moving during treatment. Measurements are calculated by a computer to precisely locate the tumor, and the radiation is delivered only to the tumor, which spares surrounding tissue. These procedures also can be used for small recurrent tumor growth (see [Figure 8-4](#)).

Most chemotherapy drugs cannot cross the blood-brain barrier. To get the drugs into the brain circulation, an Ommaya reservoir may be implanted between the scalp and the skull. An Ommaya reservoir consists of a port attached to a catheter that is placed in the lateral ventricle of the brain ([Figure 23-8](#)). Chemotherapy drugs can be injected into the port and instilled into the CSF in the ventricle. In this way the chemotherapy drug is carried to the tumor cells in greater quantity than can be achieved by infusion of the drugs into the bloodstream. The FDA has approved a wearable device that blasts glioblastoma brain tumors via an electrical field (Printz, 2015).

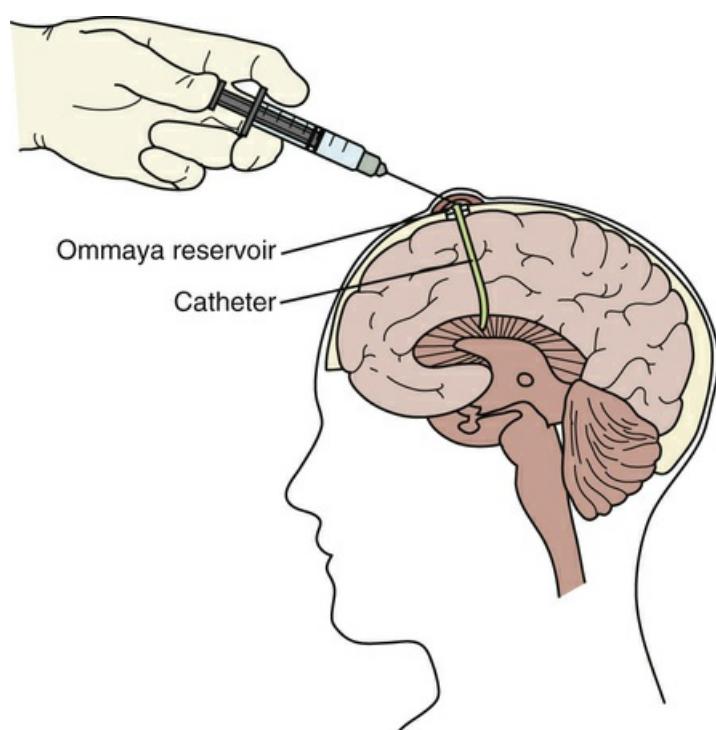

FIGURE 23-8 Implantation of an Ommaya reservoir for chemotherapy of a brain tumor.

In patients for whom chemotherapy and radiation have previously failed, implantation of carmustine (BiCNU; Gliadel) wafers into a glial cell tumor slows growth. The drug is inserted into brain tissue after removal of the glioma, to fight the malignancy and slow or prevent regrowth. Temozolomide (Temodar) is an oral chemotherapeutic drug that crosses the blood-brain barrier. Trials with local hyperthermia, biologic therapy, electrochemotherapy, and immunotherapy are under way. Molecularly targeted drugs include erlotinib (Tarceva), gefitinib (Iressa), and bevacizumab (Avastin). Treatments are discussed more thoroughly in [Chapter 8](#). If there are signs of increased ICP, measures are instituted to try to lower the ICP and to provide supportive care (see [Chapter 22](#)).

Surgery

Surgery is used to remove intracranial tumors, then other modes of treatment are used to destroy remaining cells. Sometimes, however, the tumor has infiltrated vital parts of the brain that must not be traumatized by surgical procedures. If the tumor is located in the cerebrum, a **craniotomy** is performed. A “window flap” of scalp and bone is cut and pulled down, the dura is opened, and the tumor is removed. Tumors in or near the **cerebellum** are removed through an incision under the occipital bone. If all of the tumor cannot be removed, a portion of the tumor may be removed to relieve compression of the brain against the skull. This procedure is only a temporary measure to

relieve the patient's symptoms. Care of patients after brain surgery is presented in [Chapter 22](#).

Think Critically

How should a patient who has had a craniotomy for a supratentorial tumor be positioned?

Nursing Management

Routine neurologic assessments are performed, and the patient's ability to perform ADLs is evaluated. Pain assessment and control are important. Helping the patient and family to communicate fears and cope with the situation should be part of the care plan. Problem statements commonly used for a patient with a brain tumor are:

- Potential for decreased tissue perfusion due to tumor pressure and cerebral edema.
- Pain due to cerebral edema and increased ICP.
- Altered self-care ability due to altered neuromuscular function, sensory deficits, or decreased LOC.
- Anxiety or fear due to diagnosis and prognosis.
- Potential for injury due to seizure activity caused by the tumor.
- Potential for injury due to increasing ICP from tumor growth.
- Altered memory due to damaged cells from pressure.
- Altered home maintenance ability due to physical impairments.
- Decreased self-esteem due to inability to work.

Specific NANDA-I diagnoses can be chosen from the NANDA-I list (see inside back cover).

Specific outcomes appropriate for the individual are written and interventions are planned to help the patient meet the outcomes. Evaluation is based on data that indicate the outcomes are being met. (See [Chapter 21](#) for care for common problems and interventions for various problem statements related to neurologic problems; see [Nursing Care Plan 23-1](#) and pp. 537-539 for further interventions.)

Complications

- *Hydrocephalus.* Obstruction of CSF flow may require placing a shunt to reduce CSF pressure and prevent increased ICP. A shunt is a tube placed in a ventricle and attached to a small manual pump that moves excess CSF fluid from the ventricles to the peritoneal cavity or into the atrium of the heart, from where it is absorbed ([Figure 23-9](#)).

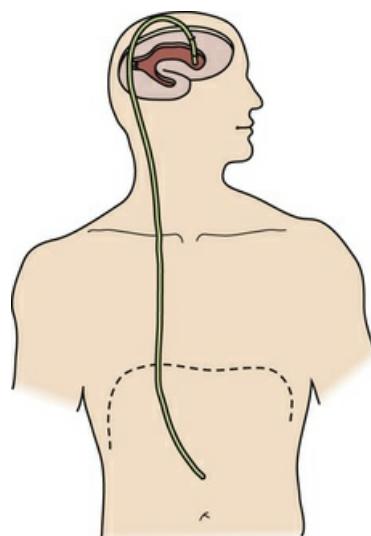

FIGURE 23-9 Ventriculoperitoneal shunt to drain excess cerebrospinal fluid into the peritoneal cavity, where it is absorbed through the mucosa.

- *Intracerebral hemorrhage.* Bleeding in the brain may occur as the tumor erodes blood vessels. Depending on the condition of the patient, the size of the tumor, and prognosis, various measures to stop the bleeding and reduce ICP will be used.

Infectious and Inflammatory Disorders of the Nervous System

Bacterial Meningitis

Etiology and Pathophysiology

Meningitis is an inflammation of the membranes covering the brain and spinal cord and is caused by an infectious agent. Viruses, bacteria, and fungi can cause meningitis. Fungal meningitis occurs mostly in patients with AIDS. The membranes can become infected in a number of ways, because infectious agents can be carried through the bloodstream to the membranes, or brain tissue can become affected as an infection in a particular area of the brain spreads. Infection can spread from the spinal cord or sinuses to the brain. Two examples of how infectious organisms may enter the cranial vault other than via the bloodstream are (1) through an opening in the skull in a head injury or from surgery or (2) by accidental introduction of infectious agents into the spinal canal during spinal puncture.

Many different strains of bacteria can cause meningitis, but the causative organisms are usually *Streptococcus pneumoniae* or *Neisseria meningitidis*. In children the causative organism may be *Haemophilus influenzae* type B. Bacterial meningitis commonly follows an upper respiratory infection. Immunization of all young adults against bacterial meningitis is recommended.

Health Promotion

Meningitis Immunization

Meningitis vaccine is available and is required for all students entering college. It is recommended for all adolescents and for others at increased risk for meningitis. It should be encouraged for adults living in a communal situation. Meningitis can spread quickly when people are in proximity, such as in classrooms or dormitory rooms.

A consequence of bacterial meningitis can be an increase in circulating CSF because of obstruction of the normal mechanisms of CSF absorption. Bacteria, white blood cells, and debris block the arachnoid villi, resulting in an obstructive **hydrocephalus** (increased CSF in the ventricles of the brain) that increases ICP. Meningitis can cause permanent neurologic damage and may cause severe vasoconstriction that requires amputation of part of a limb.

Signs and Symptoms

The most obvious symptoms of meningitis are the **sudden onset of fever and a severe and persistent headache that is greatly aggravated by moving the head**. Other signs of meningeal irritation include pain and stiffness of the neck when flexing the neck (**nuchal rigidity**), exaggerated deep tendon reflexes, irritability, photophobia, and hypersensitivity of the skin. A positive Brudzinski sign can be elicited by placing a hand behind the patient's head and, with the other hand on the chest, gently flexing the patient's neck forward by moving her chin toward her chest. If there is flexion of the knees and hips when you try to flex the neck, the Brudzinski sign is positive and indicates meningeal irritation. To elicit a Kernig sign, have the patient supine and, with the hip and knee flexed at 90-degree angles, slowly extend the knee (Figure 23-10). If there is pain, not just discomfort, behind the knee, the Kernig sign is positive, indicating meningeal irritation. Meningococcal meningitis commonly is accompanied by a petechial rash covering the chest and extremities. Seizures are also typical, as are nausea and vomiting. Quick medical attention is needed to prevent death.

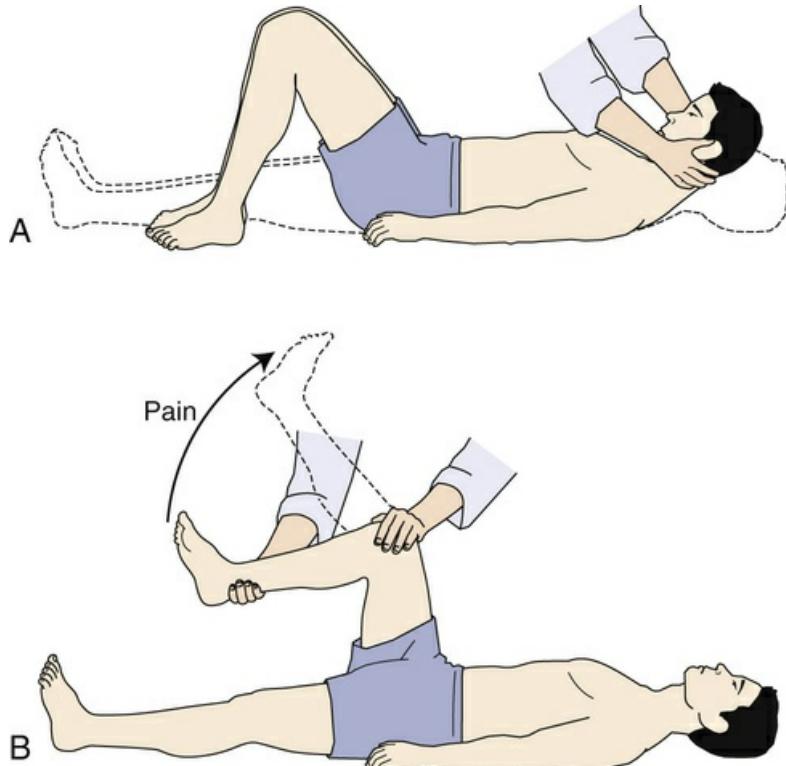

FIGURE 23-10 **A**, A positive Brudzinski sign: Passive flexion of the head and neck causes flexion of the thighs and legs. **B**, A positive Kernig sign: Inability to extend the leg from a position of 90-degree flexion at the hip because of pain and spasms in the hamstring muscle.

Diagnosis

When meningitis is suspected, a spinal tap is performed, and the CSF is examined for the number and type of organisms present. The organisms that cause meningitis produce bacterial toxins that damage the blood-brain barrier, increasing vascular permeability and causing cerebral edema. Thus, the CSF will be elevated (see [Chapter 21](#)). A Gram stain identifies the causative organism. Blood tests may be performed to rule out other disorders that can mimic meningitis.

Clinical Cues

When meningitis is present, the spinal fluid may appear milky as a result of the increased number of white cells suspended in the fluid. Other abnormal findings in the CSF include the presence of protein and decreased amounts of glucose.

Treatment

Successful treatment of meningitis and prevention of permanent disability depend on early recognition and prompt treatment. Antibiotics are started immediately for bacterial meningitis, and when the causative organism has been identified, specific antibiotics to which the organism is sensitive are administered. A combination of two antibiotics is common. The disease usually responds well to IV antibiotic therapy followed by oral doses given for a total of 10 days. Dexamethasone along with the antibiotics has proven beneficial to decrease inflammation for many patients ([Hasbun, 2014](#)). Anticonvulsive drugs are administered to control seizures, and ibuprofen, aspirin, or acetaminophen is given for headache.

Clinical Cues

Narcotics are rarely used for pain control in patients with increased ICP, because they cause sedation and prevent accurate neurologic assessment.

Prophylactic antibiotics are usually given to those in close contact with the patient to prevent the spread of the disease. Death occurs in about 25% of cases.

Viral Meningitis

Several viruses can cause meningitis; the most common are enteroviruses, arboviruses, HIV, and herpes simplex virus. Viral meningitis tends to be milder than bacterial meningitis. The initial signs and symptoms include a headache, fever, photophobia, and stiff neck. Brain involvement symptoms are not common.

The CSF is examined to confirm the diagnosis. A complete blood count will show increased lymphocytes (**lymphocytosis**). A polymerase chain reaction (PCR) test to detect virus-specific deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) can diagnose CNS viral infection.

The disease is self-limiting and is managed symptomatically. Full recovery typically occurs within 7 to 10 days. Sometimes residual effects such as persistent headaches, mild mental impairment, and lack of coordination occur.

❖Nursing Management

■ Assessment (Data Collection) and Nursing Diagnosis

In addition to noting the specific signs and symptoms of meningitis, assess the patient for subjective and objective data relevant to each of the patient care problems that might accompany the disease. Examples include convulsive seizures, elevated body temperature, nausea and vomiting, delirium, pain, increased ICP, and fluid and electrolyte imbalances. Ongoing, vigilant neurologic assessment is a high priority in monitoring for signs of increasing ICP, changes in condition, and response to treatment. An ongoing assessment should be performed each shift.

▣ Focused Assessment

Assessment of a Patient With Brain Infection

An assessment (data collection) should be performed each shift for the following areas:

- Neurologic check for increasing intracranial pressure
- Stiff neck or paralysis
- Temperature and monitoring of temperature trend
- Assessment for electrolyte and fluid imbalance; skin turgor, mucous membranes, condition of lips; intake and output
- Gastrointestinal assessment: bowel sounds, distention, constipation, diarrhea, nausea, vomiting
- Intravenous access site
- Skin condition
- Psychosocial concerns

Problem statements are written for the specific problems identified during the data collection (see [Table 21-9](#) and [Nursing Care Plan 23-1](#)).

■ Planning, Implementation, and Evaluation

Expected outcomes are written for the problem statements chosen. Specific nursing interventions in the care of patients with meningitis are primarily concerned with measures to:

- Conserve the patient's strength
- Prevent seizures

- Promote healing

Preventing the spread of infection includes use of Standard Precautions and droplet precautions.

The patient's room should be quiet and dimly lit. Sudden noises or bright flashes of light can cause a seizure, because the sensory input activates nerve impulses. Care and treatments are coordinated to allow as much rest as possible. Meningitis often produces mental confusion and delirium, as well as the possibility of seizures. *Herpes simplex* (fever blister) commonly accompanies meningitis.

Clinical Cues

The presence of herpes lesions, in addition to drying of the lips and mouth from fever and dehydration, requires special mouth care. Using Standard Precautions (see Appendix B), the lips and mouth should be cleansed and lubricated at least every 2 hours during the acute stage of the disease.

Fluid volume deficit is a common problem. Monitor the patient's intake and output and prevent dehydration. Report excessive vomiting or outward signs of early dehydration promptly so that IV fluids may be given to correct fluid volume deficits. Administration of corticosteroids, mineralocorticoids, estrogens, and progestin can increase ICP, because they cause fluid retention.

Irritation of the neural centers in the brain may cause a decrease in the peristaltic action of the intestines in a patient with meningitis and can lead to an accumulation of flatus and fecal material with severe abdominal distention. Check the patient's abdomen for distention, and note bowel sounds and record them in the medical record. Rectal suppositories, simethicone, or small-volume enemas (less than 150 mL) may be prescribed for relief.

The patient will need support and reassurance because the severity of this illness is frightening. If confusion occurs, frequent orientation is necessary. The family needs information and reassurance as well.

Once the acute stage of the disease is over, the patient is allowed to gradually resume her former activities. Side effects of the disease, such as paralysis, deafness, and visual defects, sometimes occur, but these **sequelae** (results) of meningitis do not usually occur if the disease is diagnosed and treated in the early stages. Gather evaluation data regarding the effect of the interventions performed. Determine whether the expected outcomes are being met. If outcomes are not being met, the plan must be revised.

Encephalitis

Etiology and Pathophysiology

Encephalitis is less common than meningitis. It is an acute inflammation of the brain that is serious and sometimes fatal. Some of the viruses responsible for encephalitis are associated with particular seasons of the year or with geographic locations. Ticks and mosquitoes are the vectors that transmit the disease. Examples of viruses in the United States that cause encephalitis are eastern equine encephalomyelitis, western equine encephalomyelitis, La Crosse encephalitis, St. Louis encephalitis, and West Nile viruses. Encephalitis may occur as a complication of the viral diseases chickenpox, measles, and mumps. Postviral encephalitis is an immune-mediated disorder and follows the end of the viral infection by 2 to 12 days. Herpes simplex virus 1 (human herpesvirus 1) is commonly the cause of non-vector-transmitted encephalitis. Cytomegalovirus encephalitis is a complication in patients with AIDS.

Health Promotion

Protect Against Mosquitoes and Ticks

During mosquito season, wear insect repellent and protective clothing. Prevent water from standing in containers around the home and property to discourage the breeding of mosquitoes. Avoid being out of doors for recreational purposes at dusk and at night, when mosquitoes are more likely to be out. Use insect repellent and protective clothing when out in wooded areas. Skin

should be inspected for ticks after the outing.

Clinical Cues

Whenever a patient is admitted with symptoms of a brain infection, check the skin thoroughly and question the patient about a recent history of herpes lesions. If you find any herpes lesions or are told that they were present within the past several days, notify the provider immediately. Herpes encephalitis can be fatal if not treated early.

Once the virus crosses the blood-brain barrier and enters neural cells, disrupting normal neural function, hemorrhage and an inflammatory response occur in the gray matter.

The severity of the illness may be mild or fatal. The most common type of viral encephalitis in the United States is that caused by herpes simplex virus 1. West Nile virus has emerged as a cause of encephalitis since 1999.

Neurologic impairment is caused by direct infection of neural cells. Western equine encephalitis is usually seen in June and July. Herpes simplex encephalitis spreads from neural tissue to the CNS. It can be a primary or secondary infection and can occur from reactivation of latent virus. **If treatment for the herpes simplex is not started before coma occurs, death is almost certain.**

Signs, Symptoms, and Diagnosis

The onset of encephalitis may be either sudden or insidious. There may be behavioral and personality changes and a decreased LOC. **Stiff neck, photophobia, and lethargy are classic symptoms of encephalitis. Seizures, acute confusion, and flaccid paralysis may occur.** CNS signs usually appear 1 to 4 hours after the onset of other symptoms. Lethargy may progress to coma. A patient with herpes simplex encephalitis may exhibit fululike symptoms that rapidly progress.

Encephalitis symptoms differ from those of meningitis in that with encephalitis there is altered mental status, motor or sensory deficits, and speech or movement disorders.

Diagnosis is confirmed by the presence of the virus in the CSF or bloodstream. The CSF in herpes simplex encephalitis will show a slightly elevated white blood cell count, a small increase in protein, and normal glucose levels. PCR tests for herpes simplex virus DNA and RNA levels in CSF allow for early diagnosis. MRI, positron emission tomography scanning, and an EEG may be performed to demonstrate inflammation and the disruption of normal neural impulses. A brain biopsy may be required to verify the responsible organism so proper treatment can begin.

Treatment and Nursing Management

The treatment of encephalitis is primarily symptomatic, with general supportive measures to maintain cardiac and respiratory function, maintain the patient's strength, promote healing, and prevent complications. Herpes simplex type 1 encephalitis is treated with antiviral IV acyclovir. There is no specific drug treatment for other types of encephalitis.

Specific nursing measures are essentially the same as for any patient who is subject to seizures, high fever, delirium, or altered LOC (see [Table 21-9](#)). The nursing care plan must be individualized to the patient's needs.

Complications

Permanent neurologic disabilities may occur, such as problems with walking, paralysis, cognition, memory, and self-care. About 65% of encephalitis survivors have long-term problems.

Brain Abscess

A brain abscess is a collection of purulent material in a cavity within the brain. A bacterial infection that has traveled from the gums or teeth, sinus, ear, or mastoid region to the brain usually is the cause. An abscess can form from bacteria introduced at the time of any type of head injury or cranial surgery. **Signs and symptoms are headache, fever, and progression to lethargy and confusion.** If the abscess is not treated, ICP will rise as the size of the abscess increases. Teach patients who experience sinus infections with purulent drainage to seek treatment if symptoms last for more than a few days. A combination of antibiotics is used to eradicate the abscess. Surgery may be required to drain the abscess or relieve ICP.

Headaches

Headaches are the most common cause of complaints of pain. Headaches are commonly caused by allergy and related sinus problems or by tension, or are vascular in origin. Arthritis, cervical spondylitis, and temporomandibular joint syndrome may also cause headaches. The pain of a headache may be minor or severe. Persistent headache requires testing to rule out organic problems such as anemia, brain tumor, or cerebral aneurysm.

Treatment for severe, recurrent headaches begins with determining the cause, if possible, and identifying factors that seem to precipitate the headache. Mild headaches usually are relieved by rest and a mild analgesic.

Migraine Headaches

Approximately 23 million Americans have at least one migraine headache a year. Women experience them more than men. It is believed that constriction and subsequent dilation of cerebral arteries cause migraine headaches. Attacks usually occur irregularly and may begin with an aura such as visual disturbances or “spots before the eyes” (**scotoma**). Many patients with migraine do not have an aura preceding the attack. Pain usually begins on one side of the head and is described as throbbing in character. A migraine headache is often accompanied by nausea and vomiting. Symptoms may last for 4 to 72 hours. Light or sound cause irritation and sensitivity, and for some patients with migraine, certain types of light set off the headache. Frequent migraine headaches are very debilitating.

Safety Alert

Triptans and Antidepressant Use

Patients who are taking triptans as migraine medication should not also take antidepressant or mood disorder medications that are selective serotonin reuptake inhibitors (SSRIs) or selective serotonin-norepinephrine reuptake inhibitors (SNRIs). There is a greater risk of increased serotonin levels occurring if triptans are combined with SSRIs or SNRIs, and the resulting serotonin syndrome can be life threatening. Signs and symptoms of serotonin syndrome include restlessness, hallucinations, loss of coordination, tachycardia, rapid changes in blood pressure, hyperthermia, overactive reflexes, nausea, vomiting, and diarrhea. Consult with the provider rather than abruptly stopping the SSRI or SNRI medication.

Lying in a darkened, quiet, odor-free room with eyes closed decreases the symptoms. Sometimes doing this at the very beginning of symptoms can prevent a full-blown migraine headache. Metoclopramide (Reglan), droperidol (Inapsine), or chlorpromazine (Thorazine) is often prescribed for the nausea that accompanies a migraine. Various behavioral treatments such as biofeedback, acupuncture, and relaxation therapy, combined with lifestyle adjustments and medication, seem to offer the best result (NINDS, 2014).

Clinical Cue

Patients should be told that long-term use of metoclopramide may cause tardive dyskinesia (a neurologic disorder) (FDA, 2009).

Treatment consists of using one or more of the agents listed in Box 23-2 (Gilmore and Michael, 2010; Silberstein et al, 2012). A cold compress to the temple, eye, and occiput areas is helpful. Identifying food or other substances that seem to trigger an attack is very important.

Box 23-2

Medications Used for Migraine Headache Treatment

Drugs That Abort Migraine Symptoms

- Acetaminophen-isometheptene-dichloralphenazone (Midrin)
- Almotriptan (Axert)
- Dihydroergotamine (D.H.E. 45 injections, Migranal nasal spray)
- Eletriptan (Relpax)
- Ergotamine tartrate (Cafergot)
- Frovatriptan (Frova)
- Methysergide (Sansert)
- Naratriptan (Amerge, Naramig)
- Rizatriptan (Maxalt, Maxalt MLT)
- Sumatriptan (Imitrex, Imitran)
- Zolmitriptan (Zomig, Zomig ZMT)

Preventive Drugs (Taken Daily)

- Level A: Established efficacy
 - Divalproex sodium (Depakote)
 - Frovatriptan
 - Metoprolol (Toprol)
 - Propranolol (Inderal)
 - Timolol (Blocadren)
 - Topiramate (Topamax)
- Level B: Probably effective
 - Amitriptyline (Elavil)
 - Atenolol (Tenormin)
 - Nadolol (Corgard)
 - Naratriptan (Amerge)
 - Venlafaxine (Effexor)

- Zolmitriptan (Zomig)

If migraine headache tends to occur around the time of menses, taking a prescribed diuretic for 3 to 5 days before onset of menstruation may be effective in preventing the headache.

■ Nutrition Considerations

Finding Foods That Trigger a Migraine Headache

Ask patients who have migraine headaches to keep a food diary to determine whether any of the following foods or additives are triggering the attacks:

- Alcohol
- Caffeine
- Chocolate
- Artificial sweeteners (aspartame, sucralose, saccharin)
- Monosodium glutamate (MSG)
- Citrus fruits
- Meats with nitrites (bacon, salami, etc.)
- Salt
- Foods containing tyramines: peanuts, raisins, vinegars, soy sauce, aged cheese, yogurt, sour cream, chicken livers, sausages, bananas, avocados, pickled herring, freshly baked breads, pork, beans

Various neurostimulator devices are under investigation. Deep brain stimulation has resulted in side effects, but several trials with minimally invasive stimulation are currently under way ([Hoffmann and Suprsonsinchai, 2013](#)). Botox received FDA approval for the treatment of chronic migraine in October 2010. Botox blocks nerve impulses carrying pain messages to the brain. It has not been shown to be effective with any other type of headache ([The Migraine Trust, 2015](#)).

■ Complementary and Alternative Therapies

Vitamin B₆, Herbs, and Vitamin B₂

If taking a diuretic drug is contraindicated, taking time-release vitamin B₆ tablets for 3 to 5 days before the start of menses will often cause enough diuresis to be helpful. Vitamin B₆ should not be taken continuously, because toxic levels can occur that cause neuropathy. All herbs should be approved by the health care provider, because they may interfere with other medications the patient is taking. Herbs that have been found to help prevent or alleviate migraine headache are:

- Bay
- Feverfew
- Ginger
- Lemon balm
- Purslane

- Red pepper
- Willow

A supplement of 400 mg/day of vitamin B₂ is sometimes helpful in preventing migraine headaches.

Cluster Headaches

Cluster headaches have a higher incidence in men and are not as common as migraine headaches. A cluster headache causes the most severe headache pain. The pain is abrupt in onset and usually lasts 30 to 90 minutes. It may start during sleep. The headache may recur several times a day, and the clusters usually last 2 to 3 months. The cause and pathophysiology are not clearly known, but the trigeminal nerve is implicated. Vasodilation occurs, causing the headache. It is believed that the disorder may be caused by dysfunction of the biologic clock mechanisms of the hypothalamus. Alcohol can trigger this type of headache.

Signs and symptoms include severe unilateral orbital, supraorbital, or temporal pain along with one of the following: redness of the conjunctiva of the eye, tearing, nasal congestion, dripping nose, facial swelling, pupil constriction, or **ptosis** (drooping) of the eyelid. The person becomes restless and often paces the floor and is sensitive to touch.

History usually is sufficient to diagnose a cluster headache, but CT, MRI, or magnetic resonance angiography may be performed to rule out tumor, aneurysm, or infection. Treatment for cluster headache includes a combination of analgesic and 100% oxygen by face mask, sumatriptan succinate (Imitrex) and other triptans, internasal lidocaine 4% aqueous solution, or intranasal capsaicin. Opiates should not be used because they can cause rebound headache.

Safety Alert

Caution When Taking Analgesics

Fiorinal should not be used long term, because it contains a barbiturate and is habit forming. Drugs containing acetaminophen should be used within the dosage guidelines and not used daily; acetaminophen can cause liver failure and impaired renal function. The guidelines are to refrain from taking more than 4 g of acetaminophen per 24 hours. Remind patients who take acetaminophen not to combine it with alcohol because doing so can cause liver damage in some people. Those taking aspirin, ibuprofen, or a drug containing either should monitor themselves for peptic ulcer and gastric bleeding. Signs and symptoms to report are epigastric pain, dyspepsia, black stool, or vomiting of blood. Fatigue, headache, and dizziness may indicate anemia from a slow gastric bleed.

Tension Headaches

Tension headaches are quite common but are not as severe as migraine or cluster headaches. This type of headache usually also involves neck stiffness and limitation of range of motion of the neck. Analgesic medication, muscle relaxants, tension-reducing medication or relaxation techniques, massage, yoga, and biofeedback are often helpful. Biofeedback can be very effective in preventing or averting headaches for many people.

Cranial Nerve Disorders

Trigeminal Neuralgia (Tic Douloureux)

Etiology and Pathophysiology

Trigeminal neuralgia is a relatively rare facial pain syndrome. The cause of trigeminal neuralgia is not known, although it can be related to pressure on the nerve root by a tumor or to a lesion of the blood vessels. Multiple sclerosis can be a factor. In many cases, no cause can be found and the disorder is considered idiopathic. This disorder most commonly affects people older than 60 years.

Trigeminal neuralgia involves one or more branches of the fifth cranial (trigeminal) nerve. The three branches of this nerve are the ophthalmic, the mandibular, and the maxillary (Figure 23-11). In most cases of trigeminal neuralgia, the ophthalmic nerve is not involved. The mechanism of pain production is controversial. It may be a result of increased afferent firing in the nerve or failure of inhibitory mechanisms.

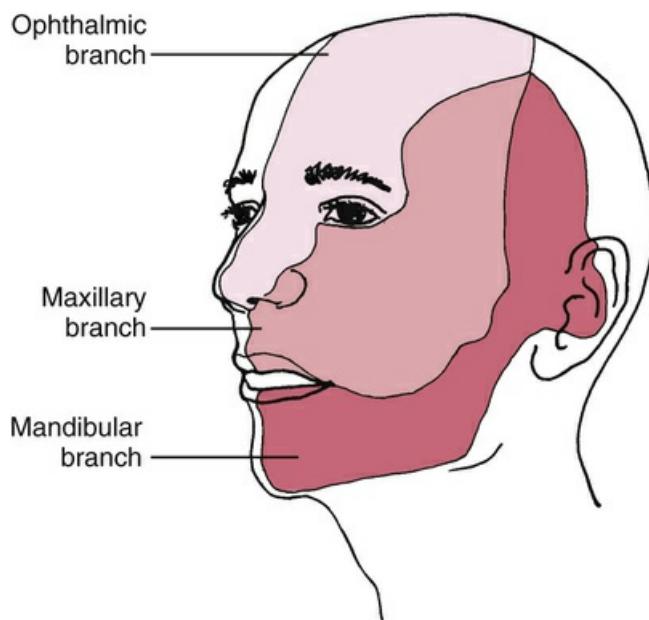

FIGURE 23-11 Areas of innervation by each of the three branches of the trigeminal nerve.

Signs, Symptoms, and Diagnosis

The most notable symptom of trigeminal neuralgia is severe facial pain, which is described as sharp and intense, lasting for 1 to 2 minutes, and located along the pathway of one of the branches of the trigeminal nerve. The pain is localized on one side of the face, rarely affecting both sides. It can extend from the midline of the face across the cheek and jaw to the ear.

Attacks are usually triggered by exposure to drafts, light touch or vibration, drinking cold or very hot liquids, chewing, brushing the hair, shaving, or washing the face. The pain causes a brief muscle spasm of the facial muscles—the tic. Between acute flare-ups the patient may experience no pain or may report a dull ache. The pain during the acute phase is so severe that many patients live in constant fear they will do something to provoke an attack.

Diagnosis is based on the patient's history and chief complaint and tests to rule out a cerebellopontine angle tumor that is affecting the nerve. There is no test to confirm the diagnosis, and there are no observable pathologic changes.

Treatment

Medical management usually is preferred to surgical intervention, because the latter involves dissection (damage) of nerve rootlets with resultant loss of motor and sensory function. Should

dissection be necessary, the patient should be instructed to chew on the side opposite the dissection to prevent injury. The drugs typically prescribed to prevent or relieve spastic pain are the anticonvulsants carbamazepine (Tegretol) and phenytoin (Dilantin) and the muscle relaxant baclofen (Lioresal). Other anticonvulsants are effective in some patients. Intranasal spray of lidocaine or calcitonin may be effective for temporary relief. Relief of severe pain usually can be obtained by injecting glycerol into the terminal branch of the trigeminal nerve (glycerol rhizotomy). Percutaneous stereotactic rhizotomy or microvascular decompression are neurosurgical choices.

❖Nursing Management

■ Assessment (Data Collection) and Nursing Diagnosis

Observing the patient between acute attacks can help identify clues to confirm the presence of trigeminal neuralgia. The patient may not want to wash her face (male patients may not want to shave), and the patient will guard her face or hold it immobile to avoid an attack. The patient is very sensitive to any contact with her face and will indicate the area of pain by pointing to but never touching it.

The problem for patients with trigeminal neuralgia is, of course, Pain. Because chewing can provoke an attack of pain, the patient may be susceptible to nutritional deficit. Small, frequent feedings consisting of food that is moderately warm can help provide adequate nutrition while avoiding precipitating an acute attack.

■ Planning, Implementation, and Evaluation

Specific expected outcomes are written for the patient regarding the control of pain and its triggers. Nursing interventions for a patient who is being treated medically include instruction about the expected actions and adverse side effects of the drug she is taking. Phenytoin can produce **ataxia**, skin eruptions, overgrowth of the gums, nystagmus, and Stevens-Johnson syndrome (a serious immune reaction). Carbamazepine can damage the bone marrow and produce such hematologic reactions as leukopenia, aplastic anemia, and decreased platelet count. Skin eruptions also can occur as a reaction to carbamazepine or baclofen. The patient's blood count and liver function must be closely monitored to detect early signs of drug toxicity. Baclofen may cause transient drowsiness, nausea, weakness, or fatigue.

Surgical treatment of trigeminal neuralgia results in a potential for damage to the cornea when the ophthalmic branch is dissected. The patient must be taught to avoid rubbing her eyes or exposing them to foreign objects, because the normal protective corneal reflex is no longer functional. She should get into the habit of wearing protective goggles when there is the possibility of getting dust and debris in her eyes and should try to blink her eyes often to cleanse their surfaces.

Dissection of the second or third branches of the trigeminal nerve creates a risk of potential damage to the oral mucosa and teeth. The patient cannot feel hot liquids and foods and could be burned, could bite the inside of the mouth without realizing it, or may have dental caries that will not cause pain. Good oral hygiene and periodic dental examinations are particularly important when the body's natural warning system is not operative. Immediately postoperatively, an ice pack is applied to the cheek for 3 to 4 hours to prevent swelling.

Evaluation data are gathered to determine whether the specific expected outcomes are being met.

Bell Palsy

Bell palsy is weakness or paralysis of the muscles supplied by the facial nerve. It usually affects only one side of the face and usually occurs in people older than 30 years. The disorder affects about 23 per 100,000 people and typically affects the right side of the face. The etiology of Bell palsy is controversial. It is believed to be caused by edema and ischemia that compresses the facial nerve. The herpes simplex type 1 and herpes zoster viruses are believed to be a cause ([Taylor and Zachariah, 2013](#)). Stress can be a factor also. Exposure to cold is a risk factor. Sometimes the disorder occurs during pregnancy, most often in the third trimester. **Signs and symptoms are numbness and partial or total paralysis of the facial muscles suddenly or over a few days.** There may be taste disturbances. The eyelid on the affected side loses its blink reflex and the mouth droops, causing problems with drooling.

Diagnosis is by history and exclusion of other neurologic or muscular disorders and Lyme disease. If the patient is asked to raise the eyebrows, the eyebrow on the affected side will not move.

When asked to smile, the face becomes distorted, because the affected side of the mouth and face will not move normally.

Treatment consists of closing and patching the eye if it loses the blink reflex. Artificial tear eyedrops also are used to prevent dryness of the cornea. Corticosteroids are given if they can be started right after the beginning of symptoms. They are ineffective if delayed more than 7 days. Acyclovir may be prescribed as well, because herpes virus may be a causative organism ([Taylor and Zachariah, 2013](#)). Recovery is individual; some patients with total paralysis may not achieve full recovery but will improve as inflammation declines. Between 80% and 90% of patients recover completely within 6 weeks to 3 months. Bell palsy recurs in 10% to 15% of patients.

Get Ready for the NCLEX® Examination!

Key Points

- Many conditions can cause a seizure. Epilepsy is a chronic condition in which abnormal electrical activity is triggered in the brain without an underlying metabolic cause.
- Seizures are classified as generalized or partial.
- Irreversible brain damage can occur if seizures are unrelenting and uncontrolled.
- Treatment of epilepsy is by drugs and/or surgery (see [Box 23-1](#)).
- Close observation of a seizure with documentation by is very helpful (see [Focused Assessment p. 527](#)).
- Patient education is extremely important for safety and for the prevention of recurrent seizures.
- A cerebrovascular accident is caused by a thrombus, embolus, or an intracranial hemorrhage that interrupts circulation to an area of the brain.
- Risk factors for stroke are high blood pressure, atherosclerosis, cigarette smoking, excessive alcohol intake, insufficient exercise, high cholesterol, obesity, and diabetes.
- t-PA is best given within 3 to 6 hours of the onset of symptoms to be effective for thrombotic stroke.
- Cerebral aneurysms and arteriovenous malformations may leak or burst and cause a stroke.
- Subarachnoid hemorrhage is a medical emergency.
- A thrombosis causes cerebral ischemia that progresses slowly; an embolus causes sudden neurologic deficits.
- Homonymous hemianopsia, hemiplegia or hemiparesis, agnosia, apraxia, aphasia, and dysphagia are some of the problems caused by a CVA.
- Fatigue and emotional lability with crying or outburst may be common after a stroke or other injury to the brain, depending on the area of the brain involved.
- Hydrocephalus may be a complication of several disorders of the brain; a shunt can be placed to divert the excess CSF to the peritoneal cavity (see [Figure 23-9](#)).
- Rehabilitation is extremely important for stroke patients and takes extensive work.
- Brain tumors may be benign or malignant; many are metastatic from a different malignant site (see [Table 23-2](#)).
- Brain tumors compress adjacent tissue, causing problems and increased ICP.
- Some common signs of brain tumors are personality change, disturbance in judgment and memory, loss of muscular strength and coordination, and difficulty speaking clearly. Headache, projectile vomiting, visual problems, and signs of increased ICP may be present.
- Depending on the site and type of brain tumor, treatment is by surgery, radiation, and/or chemotherapy. Viral and bacterial infections cause the inflammation of the membranes covering the brain and spinal cord in meningitis.
- Severe and persistent headache with nuchal rigidity are classic signs of meningitis, but a spinal tap is needed for diagnosis.
- Meningitis causes an increase in ICP.
- West Nile virus is a cause of encephalitis and is spread by mosquitoes.
- Encephalitis is most commonly the result of a viral infection or the toxins produced by viral organisms such as measles, chickenpox, and mumps.
- Stiff neck, photophobia, and lethargy are classic symptoms of encephalitis.
- Nursing care for encephalitis is geared toward the problems of seizures, high fever, and delirium resulting from altered LOC (see [Table 21-9](#)).
- A brain abscess can develop from a severe sinus, ear, tooth, or gum infection.
- Headaches are common, and approximately 23 million Americans get migraine headaches.
- Tracking triggers for migraine, avoiding them, and taking medication help prevent migraine attacks (see [Nutrition Considerations on p. 547](#)).

- Migraine may be preceded by an aura and most often causes pain on one side of the head.
- Cluster headaches cause severe pain and tend to be periodic in nature.
- Trigeminal neuralgia is a painful disorder affecting the fifth cranial nerve and the muscles of the face. Only one side of the face is usually affected.
- Bell palsy is believed to be caused by edema and ischemia that compress the facial nerve. It causes weakness or paralysis of the muscles supplied by the nerve.
- Numbness and partial or total paralysis of the facial muscles, usually on one side, occur with Bell palsy.
- Corticosteroids and acyclovir are the drugs used to treat Bell palsy.

Review Questions for the NCLEX® Examination

1. A nurse determines that the appropriate problem statement for a patient with status epilepticus would be Potential for injury due to seizure activity. An appropriate expected outcome would be:

1. everyone will stay calm during the episodes.
2. the caregiver will stay with the patient during the episodes.
3. the patient will be free from any injuries associated with the seizures.
4. standing orders will be obtained to medicate acute seizure episodes.

NCLEX Client Need: Safe and Effective Care Environment, Safety and Infection Control

2. Nursing care of a patient who **just** had a seizure includes which nursing intervention(s)? (*Select all that apply.*)

1. Assess for injuries.
2. Check the glucose level.

3. Reassure and reorient the patient.
4. Provide uninterrupted periods of sleep and rest.
5. Provide a 24-hour sitter.

NCLEX Client Need: Physiological Integrity, Basic Care

3. Which patient statement indicates a need for further teaching regarding the prevention of seizures?

1. "I need to avoid situations that could potentially trigger a seizure."
2. "Alcohol can lower the seizure threshold."
3. "I must avoid becoming overly fatigued and should pace activities."
4. "I am less likely to have seizures during menstruation."

NCLEX Client Need: Health Promotion and Maintenance

4. A man and his wife are sitting in their pajamas in the living room when the man cries out. He attempts to rise from his chair, but he falls when he discovers the left side of his body has become paralyzed. The left side of his mouth and his left eye are drooping. What should his wife do?

1. Help him stand and walk to the car. She can drive him to the hospital, because it is only 3 miles away. He will receive care more immediately than if the wife calls an ambulance.
2. Sit with him for an hour to see if his condition resolves. If it worsens, she should transport him to the hospital.
3. Call 911 immediately. The emergency team will be able to assess him, give supportive care, and transport.
4. Assess the man's pulse and breathing. If he is in no immediate cardiac distress the wife can help the husband change into street clothes before driving him to the hospital.

NCLEX Client Need: Safe and Effective Care Environment

5. Which are **true** regarding an ischemic stroke? (*Select all that apply.*)

1. The onset may evolve over a period of hours.
2. A fibrinolytic drug may be given.
3. Aspirin therapy may be started within 48 hours, but no earlier than 24 hours after receiving t-PA.
4. Increased intracranial pressure occurs immediately.
5. It may occur as a complication of atrial fibrillation.

NCLEX Client Need: Physiological Integrity, Basic Pathophysiology

6. A patient has had a cerebrovascular accident. The nurse assesses the patient's readiness for transfer to another level of care. The patient continues to have agnosia and apraxia. These clinical findings indicate that the patient would:

1. require assistance with undertaking activities of daily living.
2. demonstrate independence in performing ordinary tasks.
3. prompt self to complete sequential tasks.
4. not understand verbal communication.

NCLEX Client Need: Physiological Integrity, Physiological Adaptation

7. Intracranial tumors may be treated by several modes of therapy. What types of therapy are you likely to see? (*Select all that apply.*)

1. Insertion of tiny radioactive particles into the tumor through an implanted catheter
2. High oral doses of iron for 5 days, followed by a selenium infusion
3. Brain surgery where most or all of the tumor is removed
4. Chemotherapy through a reservoir that is placed between the scalp and the skull to get past the blood-brain barrier

NCLEX Client Need: Physiological Integrity, Physiological Adaptation

8. A 21-year-old man complains of a sudden onset of fever, severe headache, and stiffness of the neck. The nurse notes a petechial rash over the chest and extremities. Which nursing action(s)

would be appropriate? (*Select all that apply.*)

1. Institute Standard Precautions and droplet precautions.
2. Administer antibiotics as prescribed.
3. Maintain a quiet and dimly lit patient room.
4. Encourage active range-of-motion exercises.
5. Administer narcotic analgesics for headache and neck pain.

NCLEX Client Need: Physiological Integrity, Basic Care

9. A patient is admitted to the urgent care center for complaints of an abrupt onset of severe headache. Clinical history indicates that symptoms started during sleep and recurred several times during the day. These symptoms suggest:

1. brain tumor.
2. migraine.
3. cluster headaches.
4. tension headaches.

NCLEX Client Need: Physiological Integrity, Basic Pathophysiology

10. The nurse providing care to a 60-year-old patient with trigeminal neuralgia identifies that pain is the priority problem. The nurse anticipates:

1. assessing the level of pain based on facial expressions.
2. administering an anticonvulsant class of medication.
3. placing warm cloths on the face.
4. preparing the patient for surgery.

NCLEX Client Need: Physiological Integrity, Basic Care

Critical Thinking Questions

Scenario A

Jack Thompson, age 36 years, had a seizure while walking down the hall at work. He fell to the ground and demonstrated jerking motions of his body.

1. What type of seizure is this most likely to be?
2. What observations should be made if he has another seizure?
3. How would you care for Mr. Thompson after the seizure is over?
4. If Mr. Thompson is diagnosed with epilepsy, what patient teaching will he need?

Scenario B

Part I

Bob Foster is a 77-year-old retired teacher who complained of a severe headache during dinner and then slumped over the table, unconscious. He was rushed to the hospital, and a tentative diagnosis of CVA was made.

1. What diagnostic tests might be appropriate for Mr. Foster?
2. What emergency care could you have given Mr. Foster if you had been present at dinner?

Part II

Mr. Foster's diagnostic tests indicate a subarachnoid hemorrhage from a ruptured aneurysm. He is comatose; his pupils are equal and reactive to light; and he responds to pain with decorticate posturing, opens his eyes at random, and seems to be paralyzed on the right side.

1. What are the priorities of care for Mr. Foster?
2. If Mr. Foster survives, what potential complications might he experience if he has had an intracerebral hemorrhage?

Scenario C

Janice Pringle, age 19 years, has been experiencing headaches more frequently over the past 6 months. She comes to the student health center on her college campus to seek help. This headache is really bad and she is nauseated.

1. What subjective and objective assessment data would you gather regarding this young lady and her headaches?
2. What are your priorities of care for Janice?
3. What interventions would you suggest at this time?

CHAPTER 24

Care of Patients With Peripheral Nerve and Degenerative Neurologic Disorders

Objectives

Theory

1. Compare and contrast the pathophysiology of Parkinson disease and myasthenia gravis.
2. Examine treatments for Parkinson disease.
3. Discuss the nursing care needed for a patient with Parkinson disease.
4. Explain why multiple sclerosis might be difficult to diagnose.
5. Illustrate the differences between Huntington disease and amyotrophic lateral sclerosis.
6. Recognize the signs and symptoms of myasthenia gravis.
7. Compare and contrast the complications of Parkinson disease with those of myasthenia gravis.

Clinical Practice

8. Teach a newly diagnosed patient about the medications for Parkinson disease.
9. Teach a patient about the diagnostic tests that might be ordered if multiple sclerosis is suspected.
10. Write a nursing care plan for a patient with myasthenia gravis who is hospitalized with a respiratory infection.
11. Summarize a home care plan for a patient with multiple sclerosis.
12. Choose a nursing care plan for a patient with Guillain-Barré syndrome.

KEY TERMS

bradykinesia (brā-dē-kī-NĒ-zē-ă, p. 554)

chorea (kă-RĒ-ă, p. 565)

demyelination (dē-MĒ-ĕ-lĕ-nā-shūn, p. 560)

diplopia (dī-PLŌ-pē-ă, p. 565)

hyperesthesia (hī-pĕr-ĕs-THĒ-zē-ă, p. 563)

Parkinson Disease

Parkinson disease (PD) is named after James Parkinson, who first described the syndrome in 1871. PD is considered a major health problem because of its crippling effects. It is a progressive disorder, beginning rapidly at first and then advancing more slowly. It affects more men than women and occurs most commonly after age 60 years. Approximately 5 million people in the world are affected with PD, and about 50,000 people in the United States are diagnosed with PD each year.

Etiology

The specific cause of PD is unknown, but it involves degeneration of the dopamine-producing neurons in the substantia nigra of the midbrain and the presence of Lewy bodies (cytoplasmic inclusions). Genetic susceptibility and environmental toxins appear to play a role. A history of head trauma increases risk (Jankovic, 2014). The most common type of PD is **idiopathic**—that is, the primary or specific cause is not known. Secondary PD can be drug induced, especially by reserpine-type antihypertensives such as methyldopa, phenothiazines, some tranquilizers such as the butyrophenones (e.g., haloperidol [Haldol]), some antiemetics, methamphetamine, and a few other drugs. These drugs block the uptake of dopamine at the receptors in the brain cells, and so may induce PD symptoms. Pesticide and herbicide exposure is largely implicated as a cause of PD.

Pathophysiology

PD affects the extrapyramidal system, in particular the motor structures in the basal ganglia. This is the part of the brain that controls balance and coordination. The basal ganglia are gray matter that is scattered throughout the white matter of the cerebrum beneath the cerebral cortex. Stimulation of the basal ganglia causes muscle tone in the body to be inhibited and allows refined voluntary movements. Two neurotransmitters accomplish this action: dopamine and acetylcholine (ACh) (see Table 21-4 for the action of the common neurotransmitters). ACh-producing neurons transmit excitatory messages throughout the basal ganglia. Dopamine inhibits the function of these neurons to allow for control of voluntary movement (Figure 24-1). There is usually a balance between these neurotransmitters. The degenerative changes in the basal ganglia that occur in PD lead to a decrease in dopamine. The ACh-secreting neurons remain active, creating an imbalance between excitatory and inhibitory neuronal activity. The excessive excitation of neurons prevents a person from controlling or initiating voluntary movements.

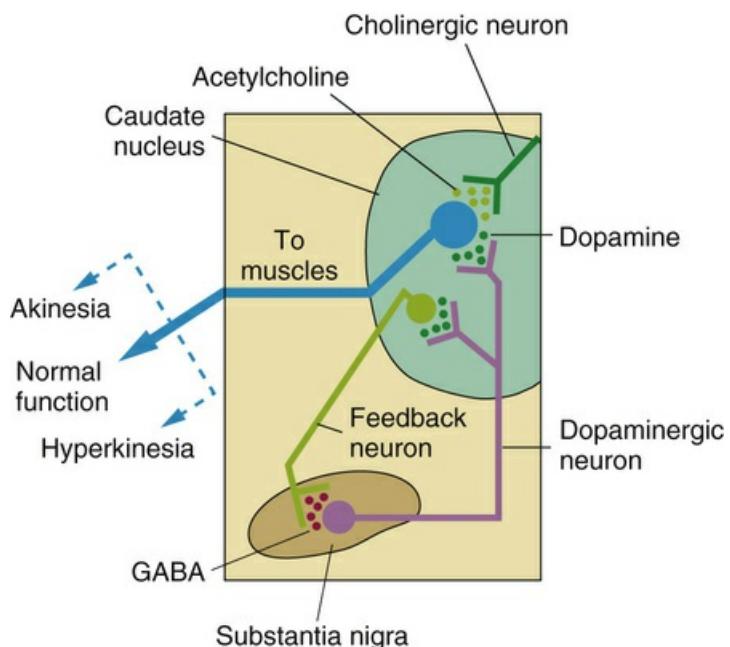

FIGURE 24-1 Dopaminergic synaptic activity is mediated by dopamine. Cholinergic synaptic activity is mediated by acetylcholine. A balance between the two kinds of synaptic activity produces normal motor function. A relative excess of cholinergic activity produces akinesia and rigidity. A relative excess of dopaminergic activity produces involuntary movements. GABA, Gamma-aminobutyric acid. (From Lewis SL, Heitkemper MM, Dirksen SR, et al: *Medical-surgical nursing: Assessment and management of clinical problems*, ed. 8, St. Louis, 2011, Mosby.)

Signs and Symptoms

The onset of PD is gradual and may involve only one side of the body initially. A triad of symptoms is characteristic of PD: tremor, bradykinesia, and rigidity. The first, *tremor*, occurs when the body is at rest, decreases when there is voluntary movement, and is absent when the patient is asleep. The tremor is most often a “pill-rolling” motion of the thumb against the fingers (a circular rubbing of a finger or two as if rolling a piece of string or fuzz into a “pill”). When the patient experiences stress and emotional tension, the tremor becomes more pronounced.

Bradykinesia (a condition that causes slow movement and speech) produces poor body balance, a characteristic gait, and difficulty initiating movement. The gait is shuffling, with short steps that become quicker (Figure 24-2). There is decreased swinging of the arms when walking. A foot may drag or may be stiff, producing a limp. Earlier in the disease process, the patient may lean slightly to one side, propel forward uncontrollably, or fall backward. In advanced stages there is a stiff, bent-forward posture when walking.

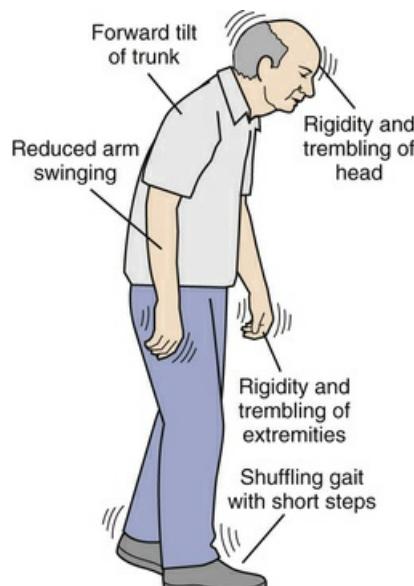

FIGURE 24-2 Parkinson disease causes abnormalities of movement. Movements are jerky in nature.

The third symptom is **rigidity** affecting the skeletal muscles and contributing to postural changes and difficulty in movement. Postural changes affect coordination and balance. The face becomes blank or masklike in appearance with little or no expression. Speech becomes low in tone, monotonous sounding, and slow; enunciation becomes difficult because of the decreased dopamine and the excitatory response from the increased ACh. Drooling may occur. The patient may experience decreased tearing, constipation, incontinence, excessive perspiration, heat intolerance, and decreased sexual ability. PD does not usually affect intellect; however, a percentage of patients do develop a dementia similar to that of Alzheimer disease. Mood disturbance does occur, and depression is a problem. Stress tends to make symptoms worse.

Think Critically

A patient comes into the clinic complaining about hand tremors and “stiffness” of the joints that started recently, excessive sweating, and some urinary incontinence. You notice that his gait is

abnormal. What would be a priority question you would ask him as you start history taking?

Diagnosis

The characteristic symptoms of the disease are used to diagnose the disorder. Laboratory tests usually reveal findings within normal ranges. However, magnetic resonance imaging (MRI) scans of the brain may be performed to rule out other neurologic disorders. Single-photon emission computed tomography (SPECT) can display the reduced uptake of dopamine (Figure 24-3).

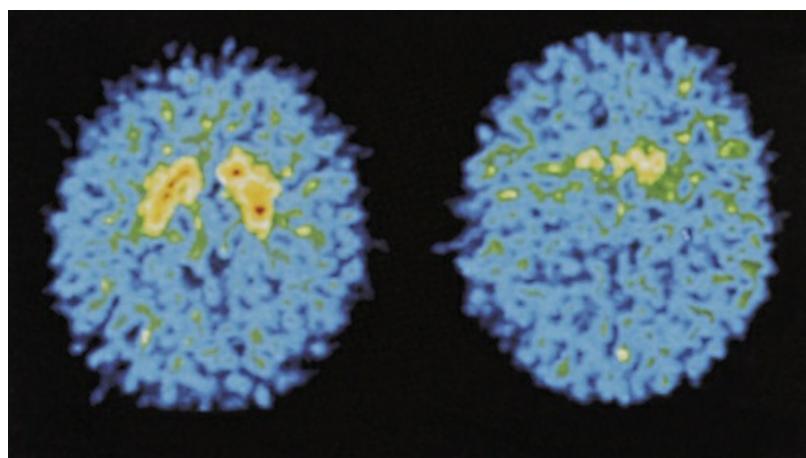

FIGURE 24-3 Positron emission tomography scan showing reduced uptake of dopamine in a patient with Parkinson disease. (From Perkin DG: *Mosby's color atlas and text of neurology*, St. Louis, 2002, Mosby.)

Treatment

Treatment of PD usually includes drug therapy, physical therapy, and considerable emotional support. Currently, medications for PD all involve controlling levels of dopamine. Drug therapy aims to provide dopamine to the basal ganglia and thus reduce symptoms. Anticholinergics, dopamine agonists, and monoamine oxidase inhibitor (MAOI) drugs are used to control symptoms. MAOIs block the metabolism of dopamine, leaving more dopamine in circulation. Deep brain stimulation (DBS) is a surgical procedure used to treat many of the neurologic debilitating symptoms associated with PD ([National Institute of Neurological Disorders and Stroke \[NINDS\], 2014](#)). This procedure does not destroy tissue (as did previous PD surgeries) but serves to block transmission from certain targeted brain areas. Successful treatment usually involves a combination of these therapies.

Safety Alert

Caution When Administering Monoamine Oxidase Inhibitors

When a patient with PD has been prescribed selegiline (an MAOI), caution him against eating foods containing tyramine, such as aged cheeses, anything fermented, smoked fish or meat, yeast extract, some imported beers, Chianti wine, dietary protein supplements, and soy sauce. Administering meperidine to someone taking an MAOI can cause **hyperpyrexia** (excessive elevation of temperature) and possible death. Many drugs interact adversely with MAOIs, and the health care provider or pharmacist should be consulted before a patient takes any other drug with an MAOI.

In the early stages of the disease when disability is not evident, selegiline (Eldepryl), a drug that increases dopamine's action, may be given. When disability is present, L-dihydroxyphenylalanine (L-dopa, or levodopa) or a combination of levodopa and carbidopa (Sinemet) is given. Sinemet is given in increasing doses until control of the symptoms is achieved; however, side effects can be

troublesome (Box 24-1). Various drugs are used either alone or in combination with L-dopa (Table 24-1).

□ Complementary and Alternative Therapies

Supplements Helpful for Parkinson Disease

Nutritional supplements that help slow the progression of PD include the enzyme NADH (nicotinamide adenine dinucleotide, 10 mg); coenzyme Q-10 (100 to 200 mg); phosphatidylserine (200 to 300 mg); and the antioxidants ester-C (1000 mg twice a day), vitamin E as mixed tocopherols (400 mg), and alpha-lipoic acid (100 mg twice a day). Health care providers sometimes prescribe these supplements in addition to the treatment medications.

❑ Think Critically

What would be appropriate nursing interventions for a patient who is beginning to experience dysphagia?

Box 24-1

Nursing Implications for Drugs Commonly Used for Parkinson Disease

When Giving a Drug for Parkinson Disease

- Pay close attention to dosage amount, because therapy is individualized to each patient.
- Check other medications patient is receiving for potential interactions with the antiparkinsonian drug, contraindicating administration of the drug.
- Administer the drugs as close to the time ordered as possible to maintain a consistent blood level of each drug.
- Carbidopa-levodopa may cause many neurologic disturbances, including psychiatric problems; discuss any onset of new symptoms that occur with the provider.
- Administer anticholinergic medications with meals to decrease gastrointestinal irritation.
- Selegiline may increase the side effects of carbidopa-levodopa. If this occurs, seek an order to decrease the dosage.
- Monitor for effectiveness of each drug by observing for a decrease in symptoms, such as tremor, rigidity, or drooling; assess for decrease in side effects of carbidopa-levodopa when anticholinergic drugs are given for that purpose.
- Continually assess the patient for worsening of symptoms that may result from disease progression, side effects of medication, or failure of medication.

Regarding Possible Side/Adverse Effects of the Drug

- Monitor patients taking carbidopa-levodopa, amantadine, bromocriptine, or pergolide for orthostatic hypotension and urinary retention.
- Assess patients who are taking carbidopa-levodopa for excessive or inappropriate sexual behavior.
- Bromocriptine may cause changes in mental status; report observed changes.
- Amantadine and pergolide may cause insomnia and should not be administered at bedtime.

- Many of these drugs can cause nausea, dyspepsia, and abdominal pain.
- Anticholinergics are contraindicated in patients with acute narrow-angle glaucoma.
- Anticholinergics cause dry mouth and constipation; increase fluids to 3000 mL/day; treat constipation as needed per orders; add fiber to diet.
- Monitor blood pressure and pulse during initiation and adjustment of anticholinergic medication; report tachycardia.
- Consult pharmacology book or drug insert for specific side effects of each particular drug.

Teaching for Patients Taking Antiparkinsonian Drugs

- Selegiline may cause dizziness; warn patient to move cautiously during initiation of therapy.
- Orthostatic hypotension causes dizziness and can precipitate falls; it is important for the patient to allow the blood pressure to stabilize in a sitting position before standing, to rise slowly, and to ensure balance while holding on to something when standing before walking.
- Carbidopa-levodopa will turn the urine dark.
- Ropinirole (Requip) may cause drowsiness; advise patient not to operate machinery or drive until adjusted to the drug.
- When taking a catechol-O-methyltransferase (COMT) inhibitor, it is important to have liver function checked regularly.
- Constipation is a problem with the anticholinergic drugs; increases in dietary fiber, plenty of fluid, and exercise can help control constipation; bowel movement frequency should be monitored to prevent impaction.
- Adjustment of dosages and combination of medications that will control symptoms with the fewest side effects may take weeks or months to accomplish.

Table 24-1
Drugs Commonly Used for Patients With Parkinson Disease

DRUG CLASSIFICATION	USE
Antiparkinsonian/Adrenergic	
Levodopa (L-dopa)	Decrease presence of tremor, rigidity, and bradykinesia and improve motor function
Levodopa-carbidopa (Sinemet)	
Bromocriptine mesylate (Parlodel)	
Pergolide (Permax)	
Pramipexole (Mirapex)	
Ropinirole (Requip)	
Apomorphine (Apokyn)	
Antiviral	
Amanitadine (Symmetrel)	Decreases presence of rigidity, bradykinesia
Anticholinergic	
Trihexyphenidyl (Artane)	Decrease tremor
Biperiden (Akineton)	
Benztropine (Cogentin)	
Monamine Oxidase Inhibitor (MAOI)	
Selegiline (Eldepryl, Carbex)	Decrease presence of tremor, rigidity, and bradykinesia and improve motor function
Monamine Oxidase Inhibitor B (MAOI-B)	
Rasagiline (Azilect)	Blocks breakdown of dopamine; initial monotherapy or as adjunctive therapy to levodopa
Catechol-O-Methyltransferase (COMT) Inhibitor	
Tolcapone (Tasmar)	Slow the breakdown of dopamine, thereby prolonging the action of levodopa
Entacapone (Comtan)	

Surgical Treatment

Stereotactic neurosurgery may be performed if the drug therapy fails to relieve a patient's PD symptoms. In one such procedure the area in the thalamus that is causing the involuntary movements is destroyed. Microsurgical procedures such as pallidotomy improve rigidity and bradykinesia ([WebMD, 2010](#)).

DBS uses electrode implants to provide electrical shocks that control tremors by blocking them. The device that delivers the shocks can be adjusted as the patient's symptoms change or worsen

(Hauser, 2014). There has been considerable success with DBS, but it is expensive: approximately \$10,000 for the implant unit and another \$8000 every few years for battery replacement. However, it has become the treatment of choice because it does not destroy brain tissue and it is reversible (Hauser, 2014).

Depression is common among patients with PD, but most respond well to a selective serotonin reuptake inhibitor (SSRI) antidepressant.

Complications

Dysphagia may develop, and mobility becomes severely limited as the disease progresses. Problems of immobility occur (see Chapter 9). Constipation, urinary incontinence, and insomnia are also common.

❖Nursing Management

■ Assessment (Data Collection) and Nursing Diagnosis

A thorough history is gathered and a physical examination is performed for patients who have or are suspected to have PD. [Nursing Care Plan 24-1](#) contains the common problem statements/nursing diagnoses, expected outcomes, and specific interventions for a patient with PD.

☒ Focused Assessment

Data Collection for a Patient With Symptoms of PD

Gather data regarding history by asking the following questions:

- Have you ever had a head injury, meningitis, encephalitis, or cerebrovascular disorder?
- Have you ever been exposed to metals, pesticides, or carbon monoxide for extended periods?
- What medications do you take? (Particularly important are major tranquilizers such as haloperidol [Haldol], phenothiazines, reserpine, methyldopa, and amphetamines.)
- Do you have a problem with fatigue?
- Have you noticed excessive salivation and problems handling secretions?
- Do you have any trouble swallowing?
- Have you been steadily losing weight?
- Do you experience constipation or urinary incontinence?
- Do you sweat excessively?
- Do you have difficulty initiating walking or other movements? Do you fall frequently?
- Has your dexterity decreased? Has your handwriting deteriorated?
- Do you have insomnia?
- Do you experience pain or cramping?
- Do you have mood swings? Are you depressed? Do you have hallucinations?

Points to cover in physical examination:

- Presence of drooling

- Ability to swallow
- Facial expression or lack thereof
- Presence of ankle edema
- Evidence of postural hypotension
- Presence of tremor at rest; pill-rolling movements
- Rigidity of body and jerky movements of extremities
- Slow start, then quick short steps when ambulating; shuffling gait with bent-forward posture
- Difficulty stopping once ambulating

Assignment Considerations

Feeding a Dysphagic Patient

UAP should not be assigned to feed dysphagic patients if at all possible. If an aide must be used to help feed a patient with dysphagia, be certain that suction is turned on and at hand and that the aide has been trained in helping a dysphagic patient to eat. Remind the UAP that the patient should be positioned as upright as possible, to give small bites, to wait for that bite to be swallowed before offering another one, and not to rush the patient. Coaching the patient to drop the chin when swallowing helps prevent choking.

Nursing Care Plan 24-1

Care of a Patient With Parkinson Disease

Scenario

Henry Merkel, a 63-year-old man, is admitted to your unit because of increasing incidence of falling. He is diagnosed with Parkinson disease. He is beginning to have trouble swallowing and his speech has slowed. He has a tremor in his left hand and upper extremity.

Problem Statement/Nursing Diagnosis

Altered nutrition/*Inadequate nutrition due to dysphagia.*

Supporting Assessment Data

Subjective: "I can't chew and swallow very well."

Objective: Difficulty chewing; difficulty getting food to go down.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will not aspirate food.	Monitor swallowing during drug administration and meals to assess degree of swallowing difficulty.	Allows assessment of swallowing ability.	Swallowing pills one by one without problem. No choking or difficulty during meal as long as eats slowly.
	Keep suction equipment at hand to remove pooled secretions and prevent aspiration; turn on before meal.	Readies suction and allows removal of secretions.	Suction on and at hand during meals.
	Maintain upright position for drug administration and meals.	Gravity helps food go down to the stomach and helps prevent aspiration.	Sitting fully upright for medications and meals.
	Provide semisoft foods and thickened liquids for diet.	Semisoft foods and thickened liquids are easier to swallow.	Has a semisoft diet. Thickener used for liquids.

Problem Statement/Nursing Diagnosis

Potential for injury/*Risk for injury related to abnormal posture, rigidity, bradykinesia, and difficulty in initiating movements.*

Supporting Assessment Data

Subjective: "I seem to have trouble with balance. I've fallen four times this month."

Objective: Rigidity of joints, jerky movements, shuffling gait, stooped posture.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will ambulate safely. Patient will maintain joint mobility and muscle strength.	Physical therapist to work with patient on joint mobility, muscle strengthening, and ambulation.	Physical therapy helps to decrease rigidity and muscle weakness.	Physical therapist is working with the patient. Patient is performing prescribed exercises with spouse's help.
	Administer antiparkinsonian medication as ordered. Monitor for side effects and effectiveness of medication.	Decreases tremor, rigidity, and bradykinesia.	Receiving ordered medications with no signs of side effects as yet. Rigidity slightly improved.
	Provide cane or walker if necessary.	Assistive device promotes safety.	Using walker when ambulating.
	Teach to perform active ROM exercises bid.	Techniques improve gait and movement.	Performing ROM exercises bid.
	Teach to walk as if over an imaginary line and to rock back and forth to initiate movement.		Physical therapist is coaching the patient in how to walk.

Problem Statement/Nursing Diagnosis

Potential for injury/*Risk for injury related to eating difficulties and inadequate food intake.*

Supporting Assessment Data

Subjective: "I haven't had much appetite lately and I've choked on food a few times."

Objective: Slight drooling, weight down 4 lb this month.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will not aspirate food.	Obtain consultation with speech therapist for swallowing studies.	Detects dysphagia.	Consultation with the speech therapist is ordered.
	Reinforce teaching regarding methods to be used for swallowing.	Various maneuvers can assist with correct swallowing and prevent choking.	Teaching plan is in place and teaching is ongoing.
	Obtain consultation with dietitian.	Assists with nutritional problems.	Dietitian will come tomorrow.
	Offer six small meals per day.		Offering between-meal small snacks.
	Serve hot meals on warming tray and do not rush patient with eating.	Keeps food warm while patient rests during meal.	Reheating food as needed during meal.
	Offer nutritional supplements between meals if needed.	Increases caloric intake.	Taking a protein shake in the afternoon.
	Administer anticholinergic medication as ordered.	Decreases drooling.	Medication is showing effect in decreased drooling.
	Monitor for side effects and effectiveness of medication; observe for urinary retention.	Identifies side effects patient experiences.	No urinary retention or other side effect as yet.
	Increase fiber intake and increase fluids to 3000 mL/day to prevent constipation.		Drank 2800 mL today. Fiber in diet increased.

Critical Thinking Questions

1. What are the side effects of Sinemet?
2. What would you suggest be done around the house to help prevent falls?

bid, Twice daily; *ROM*, range-of-motion.

■ Planning, Implementation, and Evaluation

Nursing care focuses on preventing complications of PD, drug therapy, enhancing voluntary movement, and safety. Constipation is a problem and requires the addition of fiber to the diet and an increase in fluids to at least 3000 mL per 24 hours. Grasping coins or other objects may help decrease tremors, because it is an intentional action. Walking may be improved by having the patient think about imaginary lines across the pathway on which to walk. Imagining stepping over something helps prevent "freezing" when walking. Teach the patient to consciously assume correct posture. Not using a pillow when resting helps prevent flexion of the spine. Learning to sleep prone also is beneficial for posture correction. The physical therapist will institute an exercise program to help the patient maintain muscle function and promote joint mobility.

Remember that patients with PD need extra time to finish tasks. A warming tray can be used to keep food hot during meals so that the patient can take rest periods while eating. Considerable patience and understanding are necessary to help the patient deal with the frustration of deteriorating body control and inability to do things that he formerly could easily do. Degeneration of cognitive skills occurs in the late stages of PD.

Falls are common, and safety is a major factor. Using a cane or walker will increase stability and decrease the incidence of falls. Leg braces or foot braces may help to maintain balance. Loose carpets should be removed from the home. Grab bars should be installed in the shower and tub; a raised toilet seat should also be installed. Patients with tremor must be cautioned against carrying

hot liquids, because spills may cause burns. [Chapter 21](#) discusses measures to help with the problems typical of many neurologic disorders. Patient and family teaching is an important part of nursing care for patients with PD.

Patient Teaching

Patients With Parkinson Disease

Patients may benefit greatly from tips on how to cope with the illness. Be sure to keep individual teaching sessions to a minimum to avoid fatigue.

Aids for Daily Living

- Using adjustable tables may help reduce arm fatigue and increase comfort by providing increased support and stabilizing the arms.
- Reacher bars may be helpful in pulling items off of shelves.
- Household chores such as folding laundry may provide gentle exercise.
- Music can provide relaxation, or motivation for exercise.

Healthy Eating

- Take an adequate amount of time to be able to eat comfortably and without rushing.
- Eating foods high in fiber and getting adequate fluids can prevent problems with constipation.

To Prevent Drooling or Salivating

- Sit upright when eating.
- Close your lips and keep your chin up.
- Swallow often.
- Use a straw when drinking to strengthen the muscles of the lips, mouth, and throat.

Writing Tips

- Use big strokes when writing and use lined paper.
- Use a larger pen or marker and change writing position often.
- Try changing to a different pen if your hand tires.

Balance

- Change positions slowly.
- When turning around, do not pivot. Move forward and slowly walk in a circle.
- A sturdy, single cane with a wide rubber tip may help maintain balance.

Exercise

- Avoid moving quickly.
- Avoid moving in a backward direction.
- Be aware of shuffling: stop and check that your posture is upright before continuing.

- Look ahead, not down.

Evaluation includes gathering data about the results of the interventions implemented. Next, determine whether the expected outcomes are being met. If progress toward the outcomes is not occurring, revise the care plan.

Multiple Sclerosis

Etiology

Multiple sclerosis (MS) is a chronic inflammatory disease that causes demyelination in the central nervous system (CNS). The most common type of MS is characterized by periods of remission and exacerbation. Another type is progressive without remission periods. The cause of MS is not known, but it is believed that an environmental factor (bacteria, virus, or chemical) combined with a genetic predisposition for the disease is responsible. MS is considered to be an autoimmune disease, in which the immune system attacks healthy CNS tissue.

There are four clinical progressions of MS (Table 24-2). There is no cure. The disease is most common in people of northern European ancestry. It affects females two to three times more frequently than males. Symptoms typically appear between 15 and 50 years of age but can occur at any age. A genetic factor can be involved; the disease is sometimes seen in more than one family member. It is estimated that there are more than 400,000 people with MS in the United States and 2.3 million around the world (Pietrangelo & Higuera, 2015).

Table 24-2
The Four Clinical Progressions of Multiple Sclerosis

TYPE OF PROGRESSION	CHARACTERISTICS AND CLINICAL COURSE
Relapsing-remitting (most common type)	Clearly defined relapses of acute worsening neurologic function. Partial or complete recovery occurs in remission period.
Primary progressive	Slow but almost continuous worsening, with occasional plateaus and temporary minor improvements.
Secondary progressive	Initial period of relapsing-remitting disease followed by a steadily worsening course. May or may not have occasional relapses, minor remissions, or plateaus.
Relapsing-progressive	Disease steadily worsens from onset, but there are clear acute relapses with or without recovery. Disease progresses between relapses.

Pathophysiology

Lymphocytes and macrophages infiltrate the central nervous system; immunoglobulin G (IgG) levels increase in the cerebrospinal fluid (CSF), indicating a humoral response with B-cell activation. T cells become reactive to a single myelin protein. Myelin is a protective sheath that insulates axons and assists impulse transmission. Axons transmit electrical impulses from one neuron to the next. In patients with MS, plaques form along the myelin sheath, causing inflammation. When myelin is eroded by inflammation and replaced by scar tissue (**demyelination**), nerve impulses cannot travel along the damaged neurons (Figure 24-4). Thus the muscles served by the affected nerves do not receive the impulses they need to perform in a well-coordinated and useful manner. When inflammation subsides, some remyelination occurs, but it is often incomplete, and nerve transmission is not normal.

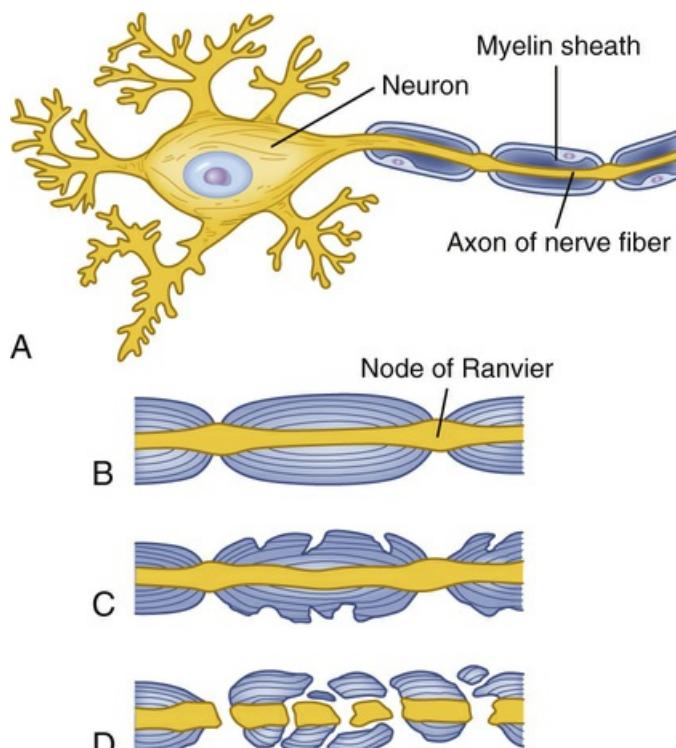

FIGURE 24-4 Effects of multiple sclerosis. **A**, Normal nerve cell with myelin sheath. **B**, Normal axon. **C**, Myelin breakdown. **D**, Myelin totally disrupted; axon not functioning. (From Lewis SL, Dirksen SR, Heitkemper MM, et al: *Medical-surgical nursing: Assessment and management of clinical problems*, ed. 9, St. Louis, 2014, Mosby.)

Signs and Symptoms

Clinical signs and symptoms reflect the pathologic changes that occur as a result of inflammation and subsequent scarring of myelin covering the nerves. MS typically follows a course of unpredictable flare-ups that are followed by periods of partial or complete remission. The very nature of the disease affects a patient's life in terms of ability to make a living, maintain satisfying interpersonal relationships with family and friends, and maintain a positive self-image.

Because the disease can affect any CNS tissue, symptoms can be unpredictable and vary from person to person. The more common manifestations of MS are as follows:

- *Motor dysfunction* can include weakness or paralysis of limbs, trunk, and neck; diplopia caused by oculomotor weakness; and spasticity of the muscles.
- *Sensory dysfunction* may include numbness, tingling, burning, and painful sensations; patchy or total blindness or blurring of vision in one or both eyes; dizziness; ringing in the ears; and hearing loss.
- *Problems of coordination* include ataxia (unsteady gait), intention tremor of limbs and eyes, slurring of speech, and dysphagia (difficulty swallowing).
- *Mental changes* usually are limited to depression and cognitive problems such as impaired judgment, decreased ability to solve problems, and memory loss, which occur late in the disease.
- *Fatigue* is a characteristic of MS and often is worsened by heat (e.g., a hot shower, hot weather, or high humidity may induce or worsen symptoms).
- Other problems that occur late in the disease are related to urinary and bowel incontinence and altered sexual function: loss of male and female self-esteem, physical impotence in men, and diminished sensation in women.

The neuromuscular dysfunctions characteristic of MS are unique to each person and can vary greatly from time to time in the same person. Symptoms may disappear for a while.

Diagnosis

No laboratory test will definitively establish a diagnosis of MS, although most patients have elevated IgG levels in their CSF and oligoclonal bands (bands of IgG produced by electrophoresis of the CSF). An MRI study usually shows characteristic white matter lesions scattered through the spinal cord and/or brain, which confirms the diagnosis of MS. However, the clinical signs and symptoms presented by a patient usually are sufficiently characteristic of the disorder to allow the neurologist to make a diagnosis that the patient possibly or probably has MS. The clinical manifestations of the disease reflect the extent to which inflammation and scarring of the myelin have occurred (Figure 24-5). Diagnosis may take several years, occurring only after a second attack.

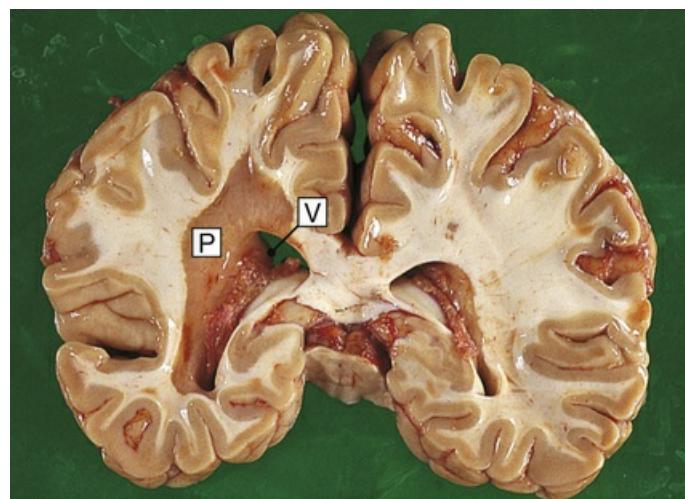

FIGURE 24-5 Chronic multiple sclerosis. Demyelination plaque (*P*) at gray matter–white matter junction and adjacent partially remyelinated shadow plaque (*V*). (From Stevens A, Lowe J: *Pathology: Illustrated review in color*, ed. 2, London, 2000, Mosby.)

Treatment

There has been an enormous amount of success with treatment from biologic response modifier drugs, such as interferon beta-1b (Betaseron), which is effective for many ambulatory patients with relapsing-remitting MS. It is given by injection. It reduces MS attacks by one third and decreases the number of severe attacks. Disease-modifying drugs are very expensive and are used to prevent relapses. Acute attacks are treated with intravenous (IV) methylprednisolone for 5 days, followed by oral prednisone in tapering doses. Adrenocorticotropic hormone (ACTH) may be given for its ability to suppress immune system activity. Most therapeutic efforts are centered on supportive measures to maintain resistance to infection; reduce muscle spasticity; and manage specific symptoms, such as diplopia, speech disorders, muscle weakness, fatigue, and depression. The drug regimen is geared to each patient's symptoms. CNS stimulants may be prescribed to combat fatigue. Sometimes the antiparkinsonian drug amantadine (Symmetrel) is used for fatigue.

The following 10 medications have been approved by the Food and Drug Administration (FDA) for use in MS:

- Aubagio (teriflunomide)
- Avonex (interferon beta-1a)
- Betaseron (interferon beta-1b)
- Copaxone (glatiramer acetate)
- Extavia (interferon beta-1b)
- Gilenya (fingolimod)
- Novantrone (mitoxantrone)
- Rebif (interferon beta-1a)
- Tecfidera (dimethyl fumarate)
- Tysabri (natalizumab)

An exercise program is very beneficial for patients with MS to relieve spasticity and improve coordination (Harmon, 2011). Swimming provides considerable benefits, because exercising in water is less fatiguing than exercising out of water. Because of fatigue, it is often difficult to convince patients with MS to exercise.

In addition, the patient should be provided the support and physical and psychological means necessary to develop a positive and hopeful outlook. There is an understandable tendency to become depressed and pessimistic about the future when confronted with the realities of muscle weakness, incontinence, sexual impotence, and any combination of disabilities likely to be experienced during the course of MS. Antidepressants may be helpful. Disease-modifying agents can reduce disease activity, frequency of relapses, and possibly progression of multiple sclerosis.

Nursing Management

Assessment (Data Collection), Nursing Diagnosis, and Planning

A careful history can provide many clues to the possibility that the patient has MS. Testing extremity strength, looking for visual problems, and checking reflexes are part of the physical examination.

Problem statements are based on the assessment findings and may include:

- Fatigue due to improper transmission of neural impulses.
- Altered physical mobility due to muscle weakness, spasticity, or paresthesias (tingling or numbness).
- Altered self-care ability due to muscle spasticity and neuromuscular deficits.
- Altered urinary function due to sensory motor deficits.
- Altered sexual function due to neuromuscular deficits.
- Potential for altered skin integrity due to immobility.
- Altered family coping due to potential financial problems, changing roles, and fluctuating physical abilities.
- Decreased self-esteem due to loss of usual abilities and roles.

Specific NANDA-I diagnoses can be chosen from the NANDA-I list (see inside back cover).

Expected outcomes are written for each problem statement/nursing diagnosis specific to the individual's problems.

Implementation and Evaluation

Appropriate care for a patient with MS depends on the severity of the disease and the symptoms. Care is individualized for each patient. During the diagnostic phase, the patient and family need a great deal of emotional support as they realize there is no cure.

Ongoing care by an interdisciplinary team focuses on safety, prevention of complications, assistance with physical therapy, and emotional support. The patient should not be exposed to excessive heat or hot baths, which cause weakness to become much worse (Harmon, 2011). Care of the common problems of neurologic patients is covered in Chapter 21. The importance of proper nutrition with adequate fluids and fiber in the diet should be stressed to maintain proper bowel function and decrease the likelihood of urinary tract infections. Calcium and vitamin D should be included in the diet to help prevent osteoporosis that may result from the IV steroid treatments. Medications to decrease stomach acid and prevent ulceration from the steroids may be administered (histamine H_2 -receptor blockers or proton pump inhibitors).

Help the patient and family establish a consistent daily routine that will promote optimum levels of functioning for the patient. The routine should include daily physical exercise balanced by rest periods to prevent fatigue. Patient teaching involves:

- Education about the unpredictability of the disease and the need to prevent stress, infections, and fatigue to maintain independence as long as possible.
- Referral to the National Multiple Sclerosis Society and local support groups. (Additional information and local sources of help for the patient with MS and the family can be obtained at www.nationalmssociety.org or by writing to the National Multiple Sclerosis Society, 733 Third Avenue, 3rd Floor, New York, NY, 10017.)

Evaluation of care is based on whether the expected outcomes are being achieved. If they are not, the plan is revised.

Alzheimer Disease

Alzheimer disease, a form of dementia caused by pathologic changes in the brain tissue of the patient, is covered in [Chapter 47](#). Diagnosis is by history and examination, because the specific diagnostic changes can be detected only at autopsy. The cause of Alzheimer disease is unknown, and considerable research is in progress to better define this disease. Much of this research centers around ways to decrease A β protein in the brain ([Crystal, 2015](#)). Other research seeks to restore memory function by reducing plaque that has formed in the brain. In one recent study on mice, 75% had restored memory function when treated with a noninvasive ultrasound technique. Human trials are expected to be under way by 2017 ([Sciencealert, 2015](#)). Alzheimer disease can occur during middle age or during the later decades of life and causes devastation to the patient and family. The disease has a slow onset, progresses at varying rates of speed through several stages, and is eventually fatal. See [Chapter 47](#) for further information on Alzheimer disease.

Amyotrophic Lateral Sclerosis

Etiology and Pathophysiology

Amyotrophic lateral sclerosis (ALS), also called *Lou Gehrig disease*, is a progressive neuromuscular disease characterized by degeneration of the gray matter in the anterior horns of the spinal cord and the lower cranial nerves. After degeneration, electrical and chemical messages generated in the brain cannot reach the muscles to activate them. The incidence of ALS is 1 per 100,000 people. It most often occurs in people between the ages of 40 and 70 years and affects men more than women. Although some people with ALS can survive for many years, the disease usually progresses rapidly, resulting in death within about 3 years of the onset of symptoms.

Signs and Symptoms

One of the first clinical manifestations of ALS is weakness of the voluntary muscles, especially of the distal muscles of the extremities. Some patients may notice difficulty swallowing and speaking clearly because of oropharyngeal weakness. As the disease progresses, there is atrophy of the muscles. Until atrophy is complete, however, there may be spontaneous contractions or spasticity of the muscles and abnormal sensations (**paresthesias**), such as tingling or prickling. The patient also may report pain, which is probably caused by strain on weakened muscles.

Only the motor neurons are affected in ALS; therefore the patient remains mentally alert and does not have sensory impairment. Depression is relatively common as a result of the unrelenting progression of muscle weakness and atrophy. Death typically results from respiratory infection and dysfunction as weakness and atrophy of the respiratory muscles impede normal respiration and mechanisms to clear bacteria and secretions from the lungs.

Diagnosis and Treatment

There is no laboratory test to confirm a diagnosis of ALS; electromyelography in combination with muscle biopsy and a creatine kinase level provide data for positive diagnosis. Other neuromuscular disorders such as MS, myasthenia gravis, and progressive muscular dystrophy must be ruled out.

There is no cure for ALS. Eventually the muscle paralysis renders the patient totally dependent because of inability to move, swallow, speak, and, ultimately, breathe. The drug riluzole (Rilutek), a glutamate antagonist, has been shown to slow the progression in certain patients ([NINDS, 2014](#)). Ultimately impaired breathing requires a tracheostomy and mechanical ventilation.

Nursing Management

During the first contact with a patient with ALS, conduct a thorough neurologic assessment. As the disease progresses, periodic assessments can identify specific needs. Problem statements likely to be associated with ALS are those related to difficulty with respiration, all problems of immobility, dysphagia, impaired ability to communicate, pain, ineffective coping, and depression.

In the later stages of ALS, the patient and family will need more assistance and guidance to maintain some level of independence and comfort for the patient. Rehabilitation includes obtaining equipment and devices such as a walker, wheelchair, hospital bed, suction machine, and nasogastric or gastrostomy tube feeding supplies.

Because of the nature of the disease, the patient and family are likely to experience issues related to terminal illness, death, and the grieving process (see [Chapter 8](#)). Toward the end of life, the services of a visiting nurse or a hospice program can provide appropriate instruction and physical and emotional support.

Guillain-Barré Syndrome

Etiology and Pathophysiology

Guillain-Barré syndrome (GBS) is a relatively rare disease that affects the peripheral nervous system, especially the spinal nerves outside the spinal cord. It also can affect the cranial nerves. The cause of GBS is not known, but it usually follows a viral respiratory infection or gastroenteritis in adults within 10 to 21 days. In 1976 and again in 2009, a causal relationship was found between the swine flu vaccine and GBS ([NINDS, 2014](#)), and there have been a few cases of GBS in recipients of meningococcal conjugate vaccine. Authorities believe that the disease is a cell-mediated immunologic response preceded by stimulation from a viral infection, trauma, surgery, viral immunizations, HIV, or neoplasm of the lymphatic system. Cytomegalovirus and Epstein-Barr virus are two viruses that have been linked to GBS.

Pathologic changes include demyelination, inflammation, edema, and nerve root compression. These changes bring about the paresthesia, pain, and progressive, ascending paralysis typical of the syndrome. Autonomic nervous system dysfunction with alterations in both sympathetic and parasympathetic systems may occur, causing orthostatic hypotension, hypertension, abnormal vagal responses, bowel and bladder dysfunctions, facial flushing, and diaphoresis. When the lower brainstem becomes involved, the cranial nerves are affected.

Signs and Symptoms

Objective and subjective symptoms of GBS include mild sensations of numbness and tingling in the feet and hands, followed by muscle pain, tenderness, and aching, especially in the shoulder, pelvis, and thighs. There is progressive muscle weakness, usually starting in the lower extremities and moving upward over 24 to 72 hours. However, it also can affect the cranial nerves and facial muscles first and move downward. Symptoms peak in about 14 days. Sensory loss can also occur but is not as common as motor loss. If respiratory function is affected, ventilatory support may be needed.

Pain is common and may be evidenced as paresthesias, muscular aches and cramps, and **hyperesthesia** (abnormal sensitivity to stimuli). Pain often is worse at night when there is less distraction in the environment.

Diagnosis

Diagnosing GBS is difficult, because its characteristic signs and symptoms are similar to those of several other diseases. Analysis of the CSF is helpful. Typically there is an elevated CSF protein content that tends to rise as the disease progresses, peaking in 4 to 6 weeks. The number of leukocytes remains within normal limits, as does CSF pressure. Electromyelography and nerve conduction studies show reduced conduction velocity. For the most part, the provider must depend on the clinical presentation to diagnose GBS.

Treatment

Medical treatment is mainly supportive. Within the first 2 weeks, plasmapheresis, in which the patient's plasma is removed and "washed" to remove antibodies, hastens recovery in some patients and decreases the time ventilatory support is needed. The use of IV immune globulin (IVIG) to hasten recovery is also effective ([NINDS, 2014](#)).

Nutritional support via tube feedings may be required because of dysphagia. If paralytic ileus (halt to bowel peristalsis) occurs, parenteral nutrition will be necessary.

Clinical Cues

Signs and symptoms of paralytic ileus are absence of bowel sounds, abdominal pain, and considerable abdominal bloating with lack of passage of stool.

❖ Nursing Management

■ Assessment (Data Collection), Nursing Diagnosis, and Planning

Assessment is the most important aspect of care during the acute stage. Monitor progression of ascending paralysis; assess respiratory function carefully; and assess gag, corneal, and swallowing reflexes closely. Monitor arterial blood gases and oxygen saturation. Observe vital sign trends and watch for orthostatic hypotension and cardiac dysrhythmia, which can indicate the degree of autonomic nervous system dysfunction.

Problem statements depend on the degree of nervous system involvement but may include:

- Altered gas exchange due to disease progression affecting respiratory nerves.
- Altered physical mobility due to paralysis of muscles from disease progression.
- Potential for injury due to dysphagia.
- Altered nutrition due to dysphagia and inability to feed self.
- Acute pain due to paresthesias, muscle aches and cramps, and hyperesthesia.
- Altered self-care ability due to inability to use muscles to accomplish activities of daily living.
- Fear due to seriousness of disease and unknown outcome.
- Altered communication due to paralysis of speech muscles or intubation.

Specific NANDA-I diagnoses can be chosen from the NANDA-I list (see inside back cover).

Expected outcomes must be written for each problem statement. Overall goals of care are:

- Maintain adequate ventilation.
- Control pain adequately.
- Prevent damage from aspiration.
- Maintain communication.
- Maintain adequate nutritional status.
- Return patient to normal function.

■ Implementation and Evaluation

There are three phases of GBS: the acute phase, the static phase, and the rehabilitation phase. Each demands different kinds of monitoring and intervention. During the **acute** phase, the goals are to sustain life, prevent complications related to immobility, and promote rest and comfort. Respiratory problems are particularly troublesome and may require suctioning, tracheostomy care, artificial ventilation, and other life-support measures.

Vital signs must be checked frequently. Alterations in the autonomic nervous system can cause drastic changes in blood pressure, particularly hypotension. Cardiac arrhythmias are also common, and the patient is continuously monitored.

The paralysis and loss of control that occur with GBS come on so suddenly and are so overwhelming that the patient becomes very frightened. Because the course of the disease usually extends for months with a very slow recovery, the patient begins to have feelings of hopelessness, despair, and isolation.

The **static** phase is a kind of plateau the patient reaches 1 to 3 weeks after the onset of the illness. During this time the motor loss and paresthesias no longer progress, and the patient's condition becomes somewhat stabilized; he gets no better but no worse. This phase can last from a few days to months.

Think Critically

What problems requiring specific nursing interventions would you expect to encounter for a patient with GBS who is now stable but has paralysis of the lower extremities and paresis of the upper extremities?

During the static phase, nursing care is concentrated on preventing complications of immobility and helping the patient deal with his feelings of anger, depression, and anxiety. Exercises are usually begun but are limited to passive and gentle range-of-motion and stretching exercises. There must be a balance of rest and exercise and no sudden changes in posture or position, in case blood pressure suddenly drops.

Meticulous skin care is essential because of immobility. Monitoring for thrombophlebitis is

important, because this is a common complication. Elastic stockings or sequential compression devices are applied to the legs, along with anticoagulant therapy, to try to prevent thrombophlebitis.

Clinical Cues

Signs of thrombophlebitis are warmth, swelling, and pain in the extremity. Temperature may be elevated.

The final phase, **rehabilitation**, is one of gradual recovery. The patient may become elated over the change in his condition and must be prevented from overexertion, which can lead to a relapse. As muscle function returns, the level of exercise and activity is slowly increased ([Andary, 2014](#)). It may take up to 2 years for maximal improvement with return to normal functioning. Approximately 80% to 90% of patients have little residual deficit.

Poliomyelitis and Postpolio Syndrome

Poliomyelitis destroys the motor cells of the anterior horn of the spinal cord, the brainstem, and the motor strip located in the frontal lobe. It is caused by a virus and can be prevented by immunization with the Salk (killed virus) or Sabin (attenuated live virus) polio vaccine. It is rare in the United States where immunization is given in childhood, but outbreaks still occur in other parts of the world. Some people who have had poliomyelitis develop postpolio sequelae or postpolio syndrome. A new onset of weakness, pain, and fatigue may occur in people who had the disease more than 30 years ago. Disability may be temporary or permanent. Treatment is geared toward making lifestyle modifications to preserve energy and physiologic function. Swimming in warm water has been found to promote comfort and help maintain flexibility.

Huntington Disease

Huntington disease or Huntington chorea is a rare, genetically transmitted degenerative neurologic disorder characterized by abnormal movements (**chorea**). It is accompanied by a decline in intellectual capacity and emotional disturbances. Signs of Huntington disease usually become evident during the fourth or fifth decade of life but may occur earlier. Women and men are equally affected. The disorder is progressive and causes disability and then death within 15 to 25 years after signs appear. Death is from neurologic degeneration affecting all body systems. Genetic transmission is by an abnormal gene on the short arm of chromosome 4. It is an autosomal dominant disorder, meaning that the children of a person who has the disease have a 50% chance of inheriting it. If a child does not inherit the disease, the gene is not passed on to the next generation.

A person with Huntington disease progresses from being fidgety and restless to a state of constant movement (chorea). Voluntary movement deteriorates until the patient is completely incapable of independent movement. Intellectual decline causes depression, suspiciousness, and eventual dementia. There is no specific test for the disease, but genetic testing can determine the possibility of it developing; there is no known treatment to alter its course.

Myasthenia Gravis

Etiology and Pathophysiology

Myasthenia gravis (MG) literally means “grave muscle weakness.” The disease is a chronic disorder. Skeletal muscles, respiratory muscles, and muscles enervated by cranial nerves are affected. The muscular weakness can be so mild that it causes a minor inconvenience or so severe that it is life-threatening because of its effect on the muscles used for breathing and swallowing.

Between 80% and 90% of patients with MG have an autoimmune disease in which circulating autoantibody is directed against the postsynaptic ACh receptors at the neuromuscular junction (the point at which nerve impulses are transmitted to muscle tissue) (Davis, 2014). The antibody reduces the number of functional receptor sites and restricts the neuron uptake of ACh. As a result, nerve impulses are not transmitted and the muscle cannot contract properly. Other types of antibodies are present in the remaining patients with MG.

There is a suggested connection between overgrowth of the thymus gland tissue and MG. Associations between MG and hyperthyroidism, treatment with D-penicillamine, interferon alfa, and bone marrow transplantation also exist.

Signs and Symptoms

Symptoms of MG include **diplopia** (double vision), difficulty chewing and swallowing, and ptosis (Figure 24-6). The patient's voice tends to be hoarse or nasal in quality, and voice volume decreases toward the end of a sentence. Severe muscle weakness that improves with rest is the primary symptom of the disorder. Any of the skeletal muscles might be involved; intestinal, bladder, and heart muscles are not affected.

FIGURE 24-6 Ptosis (drooping upper lid) characteristic of the muscle weakness of myasthenia gravis. (Courtesy Heather Boyd-Monk and Wills Eye Hospital, Philadelphia, PA.)

Ocular myasthenia may occur first and be demonstrated by diplopia and ptosis. In a small percentage of patients the disease progresses no further. If cranial nerves become more involved, bulbar myasthenia occurs, with facial and oropharyngeal muscle weakness causing a blank facial expression and a smile resembling a snarl. Swallowing and speaking become difficult. Further progression to generalized myasthenia involves the muscles of the neck, shoulders, limbs, hands, diaphragm, and abdomen. The disease does not affect the level of consciousness. Muscles are strongest in the morning and become weaker with activity. Respiratory muscle weakness may require mechanical ventilation.

Diagnosis

Diagnosis is established by history and physical examination. A Tensilon test may be ordered to confirm the diagnosis. Two divided injections of edrophonium (Tensilon) are administered; a marked increase in muscular strength is noted within 1 minute of the second injection if the patient has myasthenia gravis. The first injection is a test dose to determine whether the patient will have an adverse reaction to the medication. Atropine is kept on hand to reverse the effects of the Tensilon if necessary. A blood test for antibodies to ACh receptors is ordered. Electodiagnostic testing is performed to check muscle function. A chest radiograph and chest computed tomography (CT) will be ordered to check the thymus gland.

Treatment

There are two main modes of therapy; the choice depends on the severity of the symptoms. In milder cases the provider may manage the disease by dealing with the specific symptoms, rather than trying to induce a remission of the disease. In more severe cases, efforts are made to manage the underlying cause of the symptoms by inducing remission.

Because 80% to 90% of patients with MG have autoantibodies against ACh receptors, plasmapheresis (plasma exchange) can be an effective treatment for patients in crisis. It is particularly helpful in restoring muscle function when a patient is dependent on a ventilator. The purpose of the plasma exchange is to remove the circulating autoantibodies from the patient's blood. This mode of therapy may bring clinical improvement in some patients, but it is not a cure for MG.

Anticholinesterase therapy is the primary treatment for MG. Acetylcholine must be present at the point where nerve impulses are transmitted to the muscle for sustained repetitive muscle contraction to occur. Anticholinesterase agents inactivate acetylcholinesterase, a substance that prevents accumulations of ACh at the neuromuscular junction. Anticholinesterase agents temporarily increase muscle strength by allowing ACh to work, but they do not cure the problem. Two drugs commonly used as anticholinesterase agents are neostigmine (Prostigmin) and pyridostigmine (Mestinon). Pyridostigmine is more commonly used because it can be taken orally. Corticosteroids and immunosuppressant drugs such as azathioprine (Imuran), rituximab (Rituxan), or cyclophosphamide (Cytoxan) may be used to suppress the immune response. IVIG infusion is sometimes prescribed.

The dosage of anticholinesterase drugs is precisely calculated for each patient. The aim is to achieve a delicate balance between too much and too little ACh at the neuromuscular junction. Stress can quickly alter a patient's need for ACh; hence overmedication or undermedication can occur rather suddenly. Unfortunately, the symptoms of too much medication are quite similar to those of too little medication, so it is often difficult to adjust the dosage correctly.

Another method of treatment is to remove the thymus gland, which decreases the antibody production. Treatment with IVIG for 5 days may produce a favorable response for 30 to 60 days.

❖ Nursing Management

■ Assessment (Data Collection), Nursing Diagnosis, and Planning

The severity of MG is assessed by asking about the degree of fatigue, what body parts are affected, and how severe the problem is. Observe for ptosis of the eyelid and inquire about diplopia. Knowledge of the disorder should be determined, and the patient's coping abilities assessed. Assessment of respiratory function is a top priority. Assess muscle strength of the face, swallowing, speech volume and clarity, and cough and gag reflexes. Check the strength of the shoulder muscles and of the limbs.

☒ Clinical Cues

When assessing the status of a patient with MG, have the patient look up at the ceiling. Watch to see whether the eyelids start to move downward. This is often an early sign of the disease or that the medication is insufficient.

Problem statements will depend on the severity of the disease and may include:

- Altered breathing pattern due to diaphragm and intercostal muscle weakness.

- Altered airway clearance due to weakness of intercostal muscles and impaired cough and gag reflexes.
- Potential for injury due to difficulty swallowing, weakness of bulbar muscles.
- Altered nutrition due to impaired swallowing ability.
- Altered activity tolerance due to fatigue and muscle weakness.
- Altered communication due to intubation or weakness of larynx, mouth, and pharynx muscles.
- Decreased self-esteem to inability to maintain usual roles and lifestyle.

Specific NANDA-I diagnoses can be chosen from the NANDA-I list (see inside back cover).

Expected outcomes are written for each problem statement based on the specific problem the patient is experiencing.

Patient Teaching

Patients With Myasthenia Gravis

Use your anticholinesterase medication correctly:

- Take the drug with food or fluid.
- Take the drug 45 minutes before meals to permit maximum effect for chewing and swallowing. ☺
- Adjust drug dosage and times of administration as instructed according to your individual pattern of weakness and daily activities.
- Do not take over-the-counter or other prescribed medications without the approval of your health care provider or pharmacist.
- Report signs of cholinergic crisis to the health care provider quickly.
- Modify the diet for ease of chewing and swallowing; soft foods are easier to consume.
- Eat slowly in a calm environment and take small bites.
- Balance rest and activity throughout the day.
- Figure out ways of conserving energy while doing usual activities.
- Compensate with extra rest during periods of extra stress, illness, hormone swings during menstruation, and environmental temperature extremes.
- Wear a medical alert bracelet or necklace at all times; carry a card in your wallet stating that you have myasthenia gravis and list contact numbers for next of kin or significant other.
- Be aware of the signs and symptoms of myasthenic crisis and report them immediately.

Implementation and Evaluation

Infection, surgery, and other physical and emotional stresses can precipitate a myasthenic crisis and cause hospitalization. During the crisis, frequent monitoring is essential. The patient's ability to swallow and breathe on his own can be seriously compromised. Suctioning, tracheostomy, and artificial ventilation may be necessary to maintain life until the crisis is over.

Education of the patient and his family must include instruction about the nature of the illness and the adverse effects of emotional upsets, respiratory infections, and similar stresses. Care focuses on the neurologic deficits and their effect on daily activities. Rehabilitation goals include education and support for the patient and family so that the patient remains as independent as possible.

Because he can become critically ill and need immediate medical attention at any time, a patient with MG should at all times wear a medical alert emblem that identifies him as having the disease. The patient, as well as members of the family and the nurses who care for him in the hospital or at

home, should know the symptoms of overdosage of anticholinesterase medication. The symptoms of myasthenic crisis caused by underdosage of anticholinesterase agents, a precipitating illness, or stress factors are equally important to know (Box 24-2). If any of these symptoms occurs, the provider should be notified immediately.

Think Critically

What immediate action would you take if you found your patient in cholinergic crisis?

Box 24-2

Signs and Symptoms of Cholinergic Crisis and Myasthenic Crisis

Cholinergic Crisis

- Generalized weakness within 1 hour of the dose
- Dyspnea and increased bronchial secretions
- Poor tongue control producing difficulty in chewing
- Difficulty swallowing and excessive salivation
- Restlessness, anxiety, and irritability
- Diaphoresis
- Abdominal cramps, nausea or vomiting, or diarrhea

Myasthenic Crisis

Increase in myasthenia gravis symptoms after failure to take drug as prescribed or after a precipitating illness or increased stress:

- More difficulty swallowing
- Diplopia
- Ptosis
- Dyspnea

Notify the provider immediately if these signs and symptoms appear.

In addition to problems related to anticholinesterase drugs, patients with MG also can experience exaggerated and bizarre effects from a variety of drugs. These include steroids and thyroid compounds; sedatives and respiratory depressants, such as morphine; tranquilizers, such as the phenothiazines; many antibiotics; beta blockers; and some cardiac drugs, such as verapamil, procainamide, chloroquine, and quinidine. Because so many drugs are potentially dangerous to a patient with MG, it is imperative that you ensure that the provider ordering a medication is aware that the patient has MG. **Always check each drug the patient is to receive for interactions and contraindications.**

Restless Leg Syndrome

Restless leg syndrome (RLS) is a sensory-motor disorder that may affect up to 15% of the population, women more often than men ([Harvard Medical School, 2012](#)). It is marked by an uncontrollable urge to move the legs, more often in the evening, and its cause is unknown. However, there does appear to be an underlying genetic component. RLS is classified as primary (which usually occurs before the age of 40 years) and secondary (occurring after the age of 40 years). The latter is a more sudden onset and has been associated with anemia; Lyme disease; rheumatoid arthritis; chronic obstructive pulmonary disease (COPD); hypothyroidism or hyperthyroidism; fibromyalgia; and deficiencies of iron, folate, vitamin B₁₂, or magnesium ([Feuz, 2013](#)).

Three drugs have been approved for treating RLS: pramipexole (Mirapex) and ropinirole (Requip), which are dopamine agonists, and gabapentin enacarbil (Horizant), an adaptation of gabapentin, which is an antiseizure medication. Nurses should monitor medications closely and monitor patients taking dopamine agonists for orthostatic hypotension.

RLS is a frustrating complication for patients, but many benefit from available treatment. Foster an encouraging environment and provide education about the syndrome.

Community Care

After leaving the hospital, patients with neurologic problems often are cared for in long-term care facilities, rehabilitation programs, outpatient clinics, and the home. Nurses who work in long-term care facilities must be confident in caring for patients with PD, because a large percentage of residents in these facilities have this disorder. Nurses who work with patients who have neurologic deficits that cause some degree of immobility must constantly try to prevent the complications of immobility and to achieve as high a level of function for their patients as possible.

Because older adult patients often have more than one chronic illness, it is essential that nurses be knowledgeable about medication interactions and side effects. Each patient's medications must be continually assessed for possible adverse effects and side effects, as well as for data indicating that each medication is producing a sufficient therapeutic effect to warrant continued administration. A close working relationship with the pharmacist can assist you in judging these matters.

Collaborative care between the pharmacist, nurse, nurse aides, physical therapist, social worker, and others who interact with the patient is needed to provide the best plan of care for these patients who require complex care.

Home care nurses interact with entire families and need to continually offer support as the difficulties of learning to live with someone who has a neurologic deficit are met. Family roles often are altered and strained, and the period of adjustment for the patient and family is lengthy. It often is difficult for the family to cope with the personality changes that occur in patients with degenerative neurologic disorders. Referral to community support groups is often helpful for both the patient and the family members.

Get Ready for the NCLEX® Examination!

Key Points

- The characteristic triad of symptoms of PD is tremor, bradykinesia, and rigidity.
- Treatment of PD is with drug therapy (see [Table 24-1](#)), physical therapy, and emotional support.
- When drug therapy for PD fails, surgical treatment may be warranted.
- MS is a chronic inflammatory disease that causes demyelination of axons in the CNS (see [Table 24-2](#)).
- Common manifestations of MS are motor dysfunction, sensory dysfunction, problems of coordination, mental changes, fatigue, bowel and bladder problems, and altered sexual function.
- MS is treated with biologic response modifier drugs and drugs to treat the problems caused by the disease.
- Alzheimer disease is a form of dementia and is covered in [Chapter 47](#).
- ALS is a rare but devastating disease that usually results in death within 3 years after diagnosis.
- ALS affects the motor neurons and causes weakness of the voluntary muscles.
- Nursing care for patients with ALS focuses on preventing complications and dealing with the problems the disease has caused, particularly immobility, dysphagia, inability to communicate, pain, and depression.
- GBS affects the peripheral nervous system and the cranial nerves.
- GBS is a cell-mediated immunologic response to a stimulus from a viral infection, trauma, surgery, viral immunization, HIV, or neoplasm of the lymphatic system.
- GBS usually causes an ascending paralysis and considerable pain.
- Nursing care for GBS is directed at maintaining adequate ventilation, nutrition, and supportive care for immobility and activities of daily living.
- Postpolio syndrome is the reappearance of polio symptoms many years after the initial polio illness.
- Huntington disease is a genetic disease characterized by chorea.
- Huntington disease causes a decline in intellectual capacity, emotional disturbances, and total dependence, with death occurring in 15 to 20 years.
- MG is an autoimmune disease affecting the neuromuscular junction.
- MG is chronic and is manifested by fatigue and muscular weakness (both symptoms improve with rest).
- Ptosis, diplopia, a weak nasal-quality voice, a blank expression, and a smile resembling a snarl are signs and symptoms of MG.
- MG may affect the intercostal muscles and the diaphragm, causing inadequate respiration.
- Anticholinesterase therapy is the common treatment for MG.
- Nurses must know the signs of overdosage of anticholinesterase drugs.

Review Questions for the NCLEX® Examination

1. The provider discusses the treatment options with a patient newly diagnosed with PD. The patient asks, "What will happen to me?" An appropriate response would be:

1. "You seem worried. Let's talk about your concerns."
2. "Your provider can fully explain your condition."
3. "You will be all right."
4. "We all eventually get there."

NCLEX Client Need: Psychosocial Integrity, Therapeutic Communication

2. During a neurologic examination, a patient demonstrates difficulty initiating movement. The steps are short with quick cadence. Arm swings are decreased with subsequent steps. The clinical findings are referred to as:

1. muscle atrophy.
2. akinesia.
3. rigidity.
4. tremors.

NCLEX Client Need: Physiological Integrity, Pathophysiology

3. A nurse observes a nursing assistant feed a dysphagic patient. Which action by the nursing assistant indicates a need for further instruction and guidance?

1. The wall suction is turned on and readily available.
2. The patient is propped up with one pillow.
3. The food is cut into small, bite-size pieces.
4. The nursing assistant coaches the patient to drop the chin.

NCLEX Client Need: Physiological Integrity, Basic Pathophysiology

4. A 45-year-old patient newly diagnosed with MS asks about his prognosis for the future. Teaching about the future might include stating:

1. "The condition is a progressive neurologic disease, and you will

likely end up using a wheelchair or scooter. You might start equipping your house to be wheelchair accessible.”

2. “With the new immune-modifying drugs available as treatment, you will not even be able to tell you have the disease.”
3. “MS may begin with exacerbations and remissions, but it will eventually develop into a progressive disease, affecting your entire neurologic system and, thus, your whole body.”
4. “The condition is a periodic demyelination of the central nervous system, often with periods of remissions and exacerbations. It is a manageable disease, and there are many patients who live active and rewarding lives. Use of the new immune-modifying agents will help reduce exacerbations.”

NCLEX Client Need: Psychosocial Integrity, Coping Mechanisms

5. A patient is admitted for progressive muscle weakness in the lower extremities. The patient complains of tingling and numbness in the hands. The patient recovered from the flu a week ago. Which intervention(s) should be anticipated in the care of this patient? (*Select all that apply.*)

1. Medication for pain and discomfort
2. Immediate need for physical therapy exercise
3. Possible need for ventilatory assistance
4. Need for airway suctioning
5. Administration of muscle relaxants

NCLEX Client Need: Physiological Integrity, Basic Care

6. A female patient with MG is admitted with dyspnea and increased bronchial secretions, difficulty swallowing, abdominal cramps, and diaphoresis. The probable cause of these symptoms is _____.

NCLEX Client Need: Physiological Integrity, Basic Pathophysiology

7. Thirty seconds after the administration of edrophonium (Tensilon), the patient is observed to have slowed heart rate, sweating, and cramping. An appropriate nursing action would be to:

1. start chest compressions.
2. notify the provider.

3. administer atropine.
4. give pyridostigmine (Mestinon).

NCLEX Client Need: Physiological Integrity, Pharmacological Therapies

8. The nurse reinforces pharmacy instructions regarding safe use of pyridostigmine (Mestinon), an anticholinesterase, by a patient newly diagnosed with MG. Which statement indicates a need for further teaching?

1. "I need to take the medication after meals on a full stomach."
2. "I can adjust the drug dosage and times depending on daily activities."
3. "I shouldn't take over-the-counter medications without provider approval."
4. "I should balance rest and activity throughout the day."

NCLEX Client Need: Physiological Integrity, Pharmacological Therapies

9. The priority nursing assessment of a patient with MG would be to:

1. determine the degree of fatigue.
2. assess the level of knowledge regarding the disease.
3. monitor the adequacy of respiratory function.
4. check the patient's swallowing, speech, and protective reflexes.

NCLEX Client Need: Physiological Integrity, Basic Care

10. Injury is a possible problem statement for patients with RLS. Which nursing intervention(s) would help prevent injury? (*Select all that apply.*)

1. Educate the patient about daytime drowsiness, possibly severe, that may occur with the treatment for RLS. The patient should not drive or operate machinery until reaction to treatment is determined.
2. Apply leg braces for the patient at night.
3. Advise the patient to rise slowly to a standing position from a

sitting or lying position.

4. Install grab bars in the shower and tub.

NCLEX Client Need: Safe and Effective Care Environment, Safety and Infection Control

Critical Thinking Questions

Scenario A

Guillermo Perez had a bout of the “flu” about a week ago. Today he noticed he was having trouble walking. When he got home from an errand, he had trouble pulling his sweater over his head. His wife brought him to the emergency department.

1. Which neurologic problem within this chapter do you think he might have?
2. What might be done to establish a diagnosis?
3. What would be a top priority in his care at this time?
4. What further problems do you think could occur?

Scenario B

Mrs. Jones seems less animated than she has been over the past several months. Her husband tells you she has fallen three times since her last office visit. You notice that she seems more stooped over and her movements are “jerky.” The health care provider examines her and, after a thorough history and physical, tells the couple that he thinks Mrs. Jones has PD. He prescribes Sinemet for her.

1. What can you anticipate that Mr. and Mrs. Jones will need to be taught?
2. What are the potential complications of PD?

Scenario C

A fellow student in your clinical group confides that she has MG. She takes Mestinon for control of the disease.

1. What factors could cause her symptoms to worsen?
2. What might happen if she forgets to take her medication before reporting for her clinical rotation?

Scenario D

A man comes to the clinic complaining of difficulty enunciating, having tingling and prickling in the extremities, and having increased difficulty walking. After diagnostic testing it is determined that he has ALS.

1. What is the focus of interdisciplinary care?
2. What is the prognosis for the patient?

UNIT VIII

Sensory System

OUTLINE

Chapter 25 The Sensory System: Eye and Ear

Chapter 26 Care of Patients With Disorders of the Eyes and Ears

CHAPTER 25

The Sensory System

Eye and Ear

Objectives

Theory

1. Determine ways in which nurses can help patients preserve their sight and hearing.
2. Identify signs and symptoms of eye and ear problems.
3. Compare tests and examinations used to diagnose eye and ear disorders.
4. Select nursing activities associated with assessing the eye and ear.
5. Use the nursing process for patients with disorders of the eye or ear.

Clinical Practice

6. Provide teaching for a patient who is to undergo tests for a vision problem.
7. Perform focused assessments for disorders of the eyes and ears.
8. Assist visually impaired patients to find resources to maximize their vision.
9. Instruct a spouse in ways to effectively communicate with a hearing-impaired partner.

Anatomy and Physiology of the Eye

Structures of the Eye

- The eyeball is spherical in shape and 2 to 3 cm in diameter (Figure 25-1).

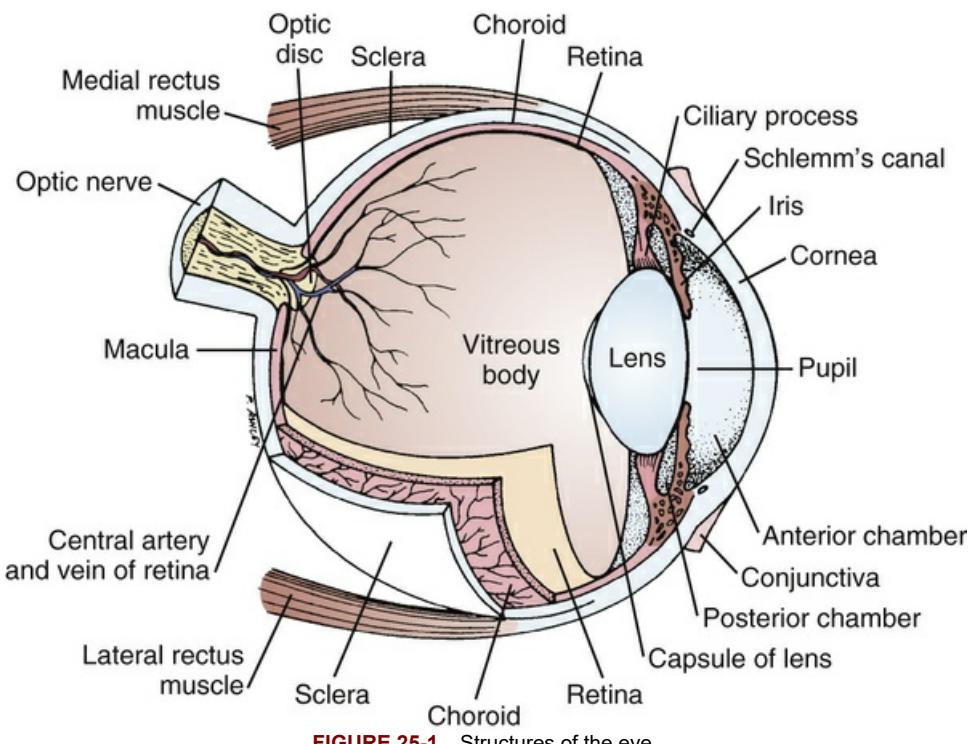

FIGURE 25-1 Structures of the eye.

- The sclera, which is part of the wall of the eyeball, is opaque white and covers the posterior five sixths of the eyeball.
- The transparent cornea is part of the wall of the eyeball and covers the anterior one sixth of the eyeball.
- The choroid is part of the middle layer of the eyeball. It is a highly vascular layer containing brown pigment located between the sclera and the retina.
- The ciliary body is part of the middle layer of the eyeball and contains finger-like ciliary processes that produce aqueous humor. The ciliary body helps change eye shape for near and far vision.
- The iris is the third part of the middle layer of the eyeball; it is the colored portion of the eye and is a doughnut-shaped diaphragm with the pupil as the central opening. The iris contains two groups of smooth muscles that constrict and dilate the pupil to regulate the entrance of light.
- The biconvex, transparent lens, together with the suspensory ligaments and the ciliary body, forms a partition that divides the interior of the eyeball into two chambers. The anterior chamber between the lens and the cornea is filled with aqueous humor. The posterior chamber, between the lens and the retina, contains vitreous humor.
- The suspensory ligaments connect the ciliary body to the lens.
- The retina is the inner layer of tissue of the eyeball and is found in the posterior portion of it. The retina contains several layers. The layer with rods and cones acts as the receptor for light images.
- The optic nerve carries messages from the nerve cells in the retina to the brain.
- The optic disc is formed by the axons of the ganglion cells of the retina.
- The macula lutea is a yellow spot just lateral to the optic disc that allows for visual detail.
- The fovea centralis is the area of the retina that produces the sharpest image.

- The eyelids are composed of skin, connective tissue, and conjunctiva. The conjunctiva is a thin mucous membrane that lines the eyelid and covers the anterior portion of the eyeball, except for the cornea.
- Eyelashes line the edge of the eyelid.
- Sebaceous glands are situated with the eyelashes.
- The lacrimal glands are located in the upper outer area above the eyes. The lacrimal ducts and canals carry tears from the eye to the nose.
- Six muscles attach to the eyeball and allow for movement. The muscles come from the bones of the orbit and insert on the outer layer of the eyeball.

Functions of the Eye Structures

- The bony orbit protects the eyeball.
- The eyelashes help trap foreign particles, keeping them from landing on the eyeball.
- The eyelids protect the eyes from foreign matter and help distribute moisture on the eye surface.
- The sebaceous glands secrete an oily fluid that lubricates the lids.
- Blinking of the eyelid 6 to 30 times a minute stimulates the lacrimal glands to produce tears.
- The lacrimal gland secretes tears that moisten, lubricate, and cleanse the surface of the eye. Tears contain an enzyme that helps destroy bacteria and prevent infections.
- The transparent cornea allows light to hit the lens. It assists with the bending of light rays (**refraction**), so that the rays will hit the retina in the right location for images to be transmitted to the brain.
- The choroid's brown pigment absorbs excess light rays that could interfere with vision.
- The ciliary processes secrete aqueous humor that helps maintain the shape of the anterior chamber; it also nourishes the structures in this part of the eye. The aqueous humor assists with refraction of light onto the retina. **The amount of aqueous humor present determines the internal pressure of the eye.** The aqueous humor is reabsorbed by the blood vessels located at the junction of the sclera and the cornea.
- Muscles in the iris control dilation and constriction of the pupil.
- The suspensory ligaments connected to the ciliary body and lens allow light to focus on the lens and retina, which is necessary for close vision.
- The retina's rods and cones are photoreceptors for light and color. The nerves of the retina transmit the images perceived to the brain.
- The optic nerve conducts nerve impulses from the retina to the brain.
- Visualization of the optic disc provides information about the pressure within the eye and within the skull. When intracranial pressure gets higher, the optic disc appears "swollen" or "choked."
- Visual impulses travel along the optic nerve to the optic chiasma just anterior to the pituitary gland; at this point some of the axons cross over to the other side. Images from the medial portion of the left eye and from the lateral portion of the right eye are carried by the right optic tract. Images from the medial portion of the right eye and from the lateral portion of the left eye are carried by the left optic tract ([Figure 25-2](#)). Images are conducted to the visual cortex in the occipital lobe of the brain.

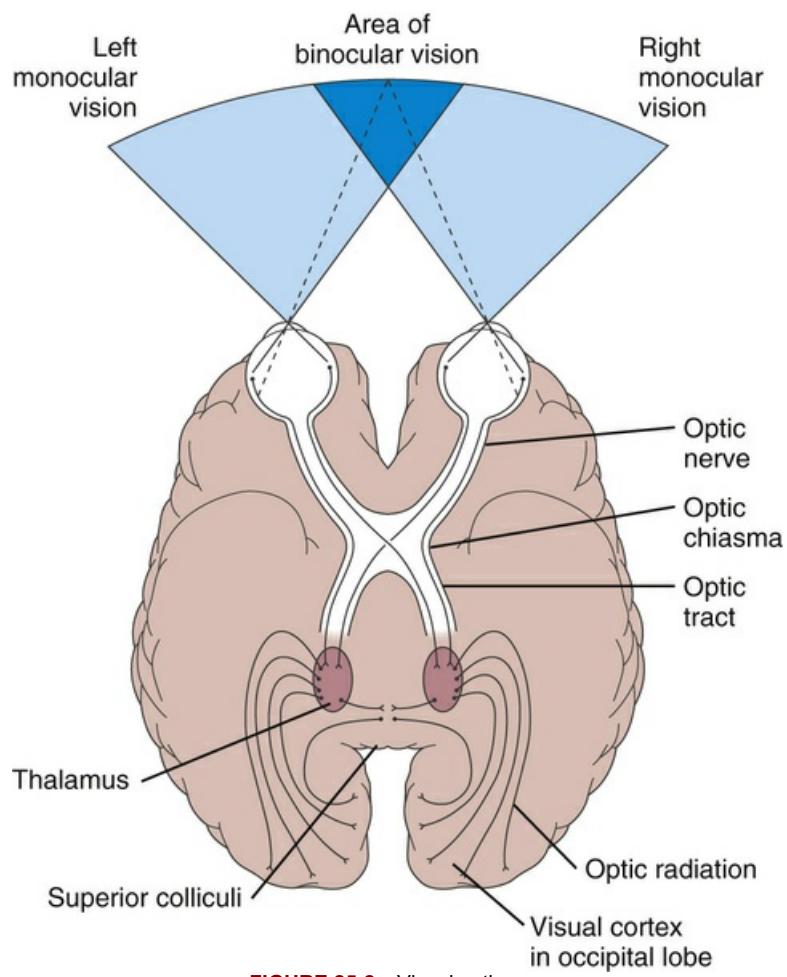

FIGURE 25-2 Visual pathway.

- Six muscles control movement of the eyeball. [Table 25-1](#) lists these muscles and the nerves that control them.

Table 25-1
Muscles of the Eye

MUSCLE	CONTROLLING NERVE	FUNCTION
Extrinsic (Skeletal) Muscles		
Superior rectus	Oculomotor (CN III)	Elevates eye or rolls it superiorly and toward the midline.
Inferior rectus	Oculomotor (CN III)	Depresses eye or rolls it inferiorly and toward the midline.
Medial rectus	Oculomotor (CN III)	Moves eye medially, toward the midline.
Lateral rectus	Abducens (CN VI)	Moves eye laterally, away from the midline.
Superior oblique	Trochlear (CN IV)	Depresses eye and turns it laterally, away from the midline.
Inferior oblique	Oculomotor (CN III)	Elevates eye and turns it laterally, away from the midline.
Intrinsic (Smooth) Muscles		
Ciliary	Oculomotor (CN III); parasympathetic fibers	Causes suspensory ligament to relax, so lens becomes more convex for close vision.
Iris, circular muscles	Oculomotor (CN III); parasympathetic fibers	Decreases the size of the pupil to allow less light to enter the eye.
Iris, radial muscles	Sympathetic fibers from spinal nerves	Increases the size of the pupil to allow more light to enter the eye.

CN, Cranial nerve.

Adapted from Applegate EJ: *The anatomy and physiology learning system*, ed. 4, Philadelphia, 2011, Saunders.

Aging-Related Eye Changes

- Subcutaneous fat and tissue elasticity decrease, and the eyes appear to be sunken.
- **Arcus senilis**, an opaque ring outlining the cornea, sometimes results from the deposition of fatty globules ([Figure 25-3](#)).

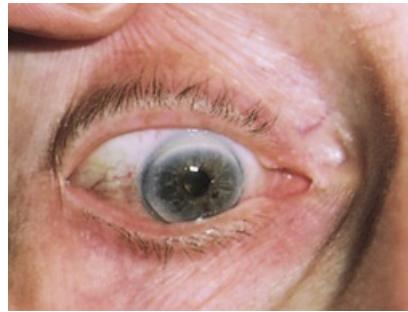

FIGURE 25-3 Arcus senilis, a white ring around the cornea. (From Swartz M: *Textbook of physical diagnosis: History and examination*, ed. 6, Philadelphia, 2009, Saunders.)

- The cornea flattens and develops an irregular curvature after age 65 years, causing astigmatism or making an existing astigmatism worse; vision becomes blurred. Cornea transparency also decreases.
- The sclera develops a yellowish tinge from fatty deposits; thinning of the sclera may cause a bluish tinge.
- The ability of the iris to dilate decreases, causing difficulty for the older person in going from a bright area into a darkened area.
- The lens of the eye changes after age 40 years, gradually losing water and becoming harder. Cataracts may form.
- The ciliary muscle has less ability to allow the eye to accommodate, a process responsible for the gradual extension of distance from the eyes at which an item to be read is held (**presbyopia**). This change usually begins around age 40 years.
- The farthest point at which an object can be identified decreases, and the visual field narrows.
- Pupil size becomes smaller, reducing the ability to see in dim light.
- Color discrimination decreases and may cause problems.
- Moisture secretion decreases, placing the eyes at greater risk for irritation and infection. This is especially common after age 70 years. Repeated episodes of **keratitis** (inflammation of the cornea) may seriously compromise vision and can lead to loss of independence.
- Eversion of the lower lid (**ectropion**) occurs because of loss of muscle tone and elasticity (**Figure 25-4**).

FIGURE 25-4 Ectropion. (From Albert DM, Jakobiec FA: *Principles and practice of ophthalmology*, vol. 3, Philadelphia, 1994, Saunders.)

- Decreased muscle tone and decreased elasticity may cause drooping of the upper lid to a point where it interferes with vision (**ptosis**).

The Eye

Eye Disorders

There are approximately 21 million visually impaired or blind people in the United States. Of those, 5.4 million are older than 65 years ([National Institute on Deafness and Other Communication Disorders \[NIDCD\], 2014](#)). There are two general kinds of patients with impaired vision: those who were born blind, and those who develop some degree of visual impairment later in life. This chapter focuses on the latter type of visually handicapped patient.

Eye disorders are caused by injury or disease or are disorders for which there is a genetic predisposition. Diabetes mellitus and hypertension contribute greatly to visual loss in the United States. Untreated glaucoma causes blindness. Macular degeneration is another major cause of impaired vision. It is now known that smoking has a direct link to the incidence of macular degeneration. Cataracts eventually cause blindness if they are not removed.

There are many new surgical techniques and medical treatments that offer hope for eyesight preservation to increasing numbers of people. Efforts also have been made to educate the public about eye care, prevention of eye disease, and periodic examinations to detect eye disorders in their earliest and treatable stages.

AIDS can cause blindness as a result of opportunistic infections. Ocular problems common in patients with AIDS are discussed in [Chapter 11](#).

Prevention

As health care providers, nurses share responsibility for preserving vision throughout the patient's life span. Three major nursing goals to promote good vision are:

- Health education to inform the general public about basic eye care
- Prevention of accidental injury to the eye
- Prevention of visual loss

Healthy People 2020 goals contain 10 objectives related^E to preventing vision loss and improving vision.

Basic Eye Care

To prevent eye strain, rest the eye muscles periodically when working at the computer, watching television, doing needlework, or performing any activity that demands intensive visual effort. If the eyes tire easily or if there is headache or burning, itching, or redness of the eyes, the eyes should be examined. Good nutrition is important to eye health, and certain nutrients such as lutein and zeaxanthin are especially beneficial to vision.

Nutrition Considerations

Vitamins and Antioxidants Beneficial to Vision

Vitamin A protects against night blindness, slow adaptation to darkness, and glare blindness. The carotenoids are the precursors for vitamin A and are found in green leafy and yellow vegetables. Carrots, greens, spinach, orange juice, sweet potatoes, and cantaloupe are rich sources of the carotenoids (Linus Pauling Institute, 2015). Lutein and zeaxanthin, both antioxidants, may help prevent macular degeneration and cataracts. They are found in yellow fruits and vegetables, red and purple fruits, and greens. Lutein is particularly high in tomatoes, carrots, broccoli, kale, spinach, and romaine lettuce. However, the National Eye Institute has removed beta carotene from its Age-Related Eye Disease Studies (AREDS) formulation, because the National Cancer Institute studies showed beta carotene supplementation may put subjects at a higher risk for lung cancer ([National Eye Institute, 2013](#)). Corn, cornmeal, kale, Japanese persimmons, and turnip greens have large quantities of zeaxanthin; corn contains the highest amount. Many vitamin supplements have added lutein to their formulation ([National Eye Institute, 2013](#)).

Normal secretions of the conjunctiva and tear glands should be sufficient to lubricate the eye and wash away small particles of dust. **Accumulations of purulent material or excessive tearing usually indicate the need for an eye examination.** Dry eye syndrome in people younger than 60 years could be symptomatic of underlying disease.

Older Adult Care Points

Older persons sometimes suffer from “dry eyes” as a result of decreased production of tears. This condition is treated by instilling “replacement tears,” which are commercial preparations or prescriptions of solutions similar in composition to real tears.

Adults with no risk factors should have a baseline eye examination at age 40, every 2 to 4 years from ages 40 to 54, and every 1 to 3 years from ages 55 to 64. After age 65, eyes should be examined by an eye specialist every 1 to 2 years (AAO, 2015). It is particularly important to test for glaucoma, because this disease usually is asymptomatic until damage to vision has occurred. People with a family history of glaucoma should be especially careful to have their eyes tested frequently for increased pressure within the eyeball, because this is the basic pathology of glaucoma, and the disorder tends to be hereditary.

Prevention of Eye Injury

Accidental injury to the eye is a major cause of diminished or total loss of vision. Adults should be cautioned to wear protective eyewear when engaging in sports such as racquetball and squash in which small balls travel at high speeds. Protective eyewear should be worn when using machinery that might cause debris to fly into the eye, such as lawn mowers, weed trimmers, sanders, or power saws.

The rate of occupational accidents has decreased since the establishment and enforcement of rules for wearing goggles and other protective devices by people working in a hazardous environment. The National Institute of Occupational Safety and Health (NIOSH) in Rockville, Maryland, provides information about eye safety and hazards in the workplace.

Cosmetics for the eyelids, eyelashes, and eyebrows can be a source of infection and allergy. Eye makeup should be discarded every 6 months to help prevent infection. Most dyes used for hair on the scalp are not intended for use on the eyelashes and eyebrows.

Saliva should not be used to moisten eye pencils, eye shadow, or mascara, because it may contain organisms that can cause eye infection. Eye cosmetics should be applied with a steady hand to prevent accidentally scratching of the cornea and eyelids. Cosmetics should never be shared, because this can transmit organisms.

Health Promotion

Danger Signals of Eye Disease

- Persistent redness of the eye. Infections and inflammations of the structures of the eye that are not treated may leave scars that can produce loss of vision.
- Continuing pain or discomfort, especially after an injury.
- Disturbance of vision. Although these symptoms may simply indicate a need for eyeglasses, blurred vision, loss of side vision, double vision, and sudden development of many floating spots in the field of vision may be symptomatic of more serious systemic diseases.
- Colored light flashes, or a feeling that a curtain has been pulled across the line of vision or a shade has been pulled down. This can indicate a retinal detachment and requires prompt attention.
- Crossing of the eyes, especially in children.
- Growths on the eye or eyelids or opacities visible in the normally transparent portion of the eye.

- Continuing discharge, crusting, or tearing of the eyes.
- Unequal size of the two pupils or distorted shape.

Prevention of Vision Loss

Diabetes mellitus and hypertension are chronic diseases that—when uncontrolled—may cause vision loss. Patients with these disorders are more susceptible to retinopathy. Nurses should encourage good control over these diseases.

Cultural Considerations

Latinos and Eye Disease

The Los Angeles Latino Eye Study found that Latinos had high rates of diabetic retinopathy and of open-angle glaucoma. The study interviewed and examined 6300 Latinos age 40 years and older from the Los Angeles area. Many of the Latinos involved in the study were found to have previously undiagnosed diabetes. Almost half of the individuals in the study who had diabetes had diabetic retinopathy. Seventy-five percent of Latinos with glaucoma were undiagnosed before participating in the study (National Eye Institute, 2010).

To help prevent infections that might cause corneal scarring and loss of vision, encourage people who experience an accident that causes a corneal abrasion to seek medical attention quickly. Promptly seeking medical attention when the eye is inflamed, is secreting purulent discharge, or is sore assists in treatment of infection that may cause a residual vision loss.

Think Critically

Can you identify four specific ways in which you might help prevent eye disorders among your relatives and patients?

Assessing patients for the presence of cataracts and recommending regular periodic eye examinations should be a part of every nurse's practice. Cataract removal can greatly improve vision. Screening for glaucoma reduces the incidence of blindness from that condition. Free screening clinics often are available in communities. Nurses can inform patients of when and where such screenings are available. The Tono-Pen is often used for such screenings. It is also used in the emergency department when a patient complains of symptoms that might indicate increased intraocular pressure ([Figure 25-5](#)).

FIGURE 25-5 The Tono-Pen is used to check intraocular pressure.

Nurses must be aware that there are many types of vision loss. Some may affect only one area of the field of vision in one eye, whereas others affect parts of the field of vision in both eyes. The degree of visual impairment varies greatly.

Diagnostic Tests and Examinations

Diagnostic tests are performed to test visual acuity, prescribe prescription lenses, inspect the interior of the eye, check intraocular pressure, and assess the health of the retinal blood vessels (Figure 25-6). Computed tomography, optical coherence tomography, and magnetic resonance imaging may also be used to diagnose eye disorders. Table 25-2 provides further information about diagnostic tests.

FIGURE 25-6 Slit-lamp ocular examination.

Table 25-2
Diagnostic Tests for Eye Problems

TEST	PURPOSE	DESCRIPTION	NURSING IMPLICATIONS
------	---------	-------------	----------------------

Ophthalmoscopy (retinoscopy)	To inspect the fundus (back portion) of the eyeball to detect abnormalities of the retina, macula, optic disc, and retinal vessels	The examiner uses an ophthalmoscope (see Figure 25-7) to focus light through the pupil onto the fundus.	The room is darkened before the examiner approaches the patient with the ophthalmoscope. Drops may be placed in the eye before this examination to dilate the eye and offer a wider area through which to view the fundus.
Visual acuity	To determine status of vision	The Snellen eye chart is used. It is placed 20 feet from the patient; first one eye is occluded, then the other eye is occluded. The person begins reading lines of letters that decrease in size. Visual acuity is expressed as a fraction for each eye. The numerator (first) figure indicates the distance between the patient and the chart. The denominator (second) figure expresses the distance at which the person with 20/20 vision could read the letters in the line correctly. Visual acuity of 20/20 in each eye is normal; vision of 20/200 (with correction) is legally defined as blindness.	Explain the procedure to the patient. Have the patient hold the occluding card close to the nose so that the entire eye is covered. Start with the third line. If the patient cannot read that, progress upward; if the line is correctly read, go to the next line down. Test the other eye. Record the findings.
Near vision test	To determine status of near vision	The patient is given a Jaeger Test Type card with different sizes of type on it. One eye is occluded while the patient reads the lines of type. Determination of vision status is made on the basis of what a person with normal vision can read.	Explain that this is a simple test of vision to determine whether there are any problems that might require further testing.
Visual fields test (confrontation test)	To examine the patient's visual fields, detecting problems with peripheral vision	The examiner faces the patient and asks her to look directly into his eyes. The examiner covers his right eye, and the patient covers her left eye. Then the examiner's finger is moved from an area outside of the peripheral vision into the line of vision. The patient should detect the finger about the same time as the examiner. The test is repeated with the other eye covered.	Explain the test to the patient and remind her to keep looking directly into your eyes.
Extraocular muscle function test	To test the function of the extraocular muscles	Ask the patient to hold her head still and to move her eyes to follow a small object such as a pen to each of the six cardinal points: right; upward and right; downward and right; left; upward and left; downward and left.	Observe for parallel eye movements and any deviation of movement. Nystagmus is a normal finding for the far lateral gaze. Record your findings.
Color vision test	To determine whether the patient has any color blindness	Use the Ishihara chart book, which shows numbers composed of dots of one color within an area of dots of a different color. Ask the patient what she sees on the page for each chart. Test each eye separately. Reading the numbers correctly indicates normal color vision.	Explain the purpose of the test. Tell the patient to tell you what number appears on the chart. Record your findings.
Refraction	To determine amount of lens correction necessary to restore person's vision to as near normal as possible with glasses	A series of glass lenses are placed in front of the patient's eyes to determine which lens provides the best vision correction. Each eye is tested separately.	A prescription for glasses will be written depending on the findings of the refraction test. The test may be performed for both near and far vision.
Intraocular pressure test	To determine the amount of pressure within the eye; aids in diagnosis of glaucoma	A tonometer is used to measure the pressure. This may be a handheld instrument, but it usually is a device that measures pressure by taking a reading while air is directed at the eye by a pneumotonometer. Another type of tonometer is the applanation tonometer. Normal intraocular pressure is 10-21 mm Hg.	Explain that this is a test to determine whether a patient might have glaucoma. More than one reading on different days is necessary to confirm a diagnosis of glaucoma. If a diagnosis of glaucoma is made, medication can be prescribed to help control the intraocular pressure and preserve vision.
Slit-lamp biomicroscopic examination	To examine the surface of the eye	A beam of light is reduced to a narrow slit that illuminates only a small section of the eye, allowing examination of a thin section of the eye structures at a time.	Explain that this device helps detect "floaters" in the vitreous humor, and abnormalities of the cornea and other structures of the eye. The eyes may be dilated with mydriatic drops for this test.
Topical dye (corneal staining)	To detect abrasions of the cornea or the presence of a foreign body on the cornea	Fluorescein dye drops are administered to the affected eye. The dye remains on the injured tissue or surrounds a foreign body. Such areas usually appear as green spots.	Explain the procedure and the rationale for the test. Warn that the drops may sting slightly for a few minutes. Give the patient a tissue to absorb the excess drops, because they may stain clothing.
Fluorescein angiography (retinal angiography)	To detect tumors of the interior of the eye and to help diagnose and measure the extent of retinopathy	An IV injection of sodium fluorescein is given. A short time later, photographs of the fundus are taken with a special camera.	An IV injection is necessary. A signed consent form is required to perform the procedure.
Electroretinography	To test the functional integrity of the retina; evaluates degeneration of the photoreceptor cells	Electrodes embedded into a contact lens are placed directly on the anesthetized eye. A light stimulus is introduced. The change in electrical potential of the eye caused by the flash of light is measured.	Instruct the patient that she must fixate on the target and not move her eyes during the test.
Optical coherence tomography (OCT)	To record images of retinal structures. To differentiate the anatomic layers within the retina and allow measurement of retinal thickness. To detect macular holes, epiretinal membranes, cystoid macular edema, and other pathologies	Focused beams of light are directed into the eye that scan the structural features of the retina. A cross-sectional image similar to a topographic map is produced.	The patient's eyes must be dilated. Tell the patient that she will be looking into a machine. The test takes 10-20 min.
Amsler grid test	To detect macular degeneration	Using a handheld card printed with a grid of black lines similar to graph paper, the patient fixates on a center dot and records abnormalities of the grid lines.	Test should be performed every week or two. Instruct the patient to record seeing wavy or missing lines or distorted areas.
Ultrasonography	To evaluate the characteristics of a lesion and its size and growth over time, or to determine the presence of a foreign body	A probe is placed directly on the eyeball. Sound waves are transmitted into the eye, bounce back off the various tissues, and are collected by a receiver and amplified on an oscilloscope screen.	Explain the procedure to the patient.

IV, Intravenous.

❖Nursing Management of Eye Problems

The nursing care of patients with severe visual handicaps demands a special awareness of the unique problems encountered by someone who has either a partial or a total loss of vision. You must be sensitive to these patients' special needs. Patient education is especially important to these patients' acceptance of their visual disorder, their participation in diagnostic and therapeutic measures, and their adjustment to their new surroundings when they are hospitalized or admitted to a long-term care facility.

■ Assessment (Data Collection)

All nurses should be able to perform a basic eye examination, inspecting the eye for signs of redness or discharge and checking visual acuity with a Snellen eye chart. Only nurses who have had special training are qualified to conduct a complete eye assessment (Figure 25-7). Significant data can be obtained by nurses who lack specialized education by taking an adequate history.

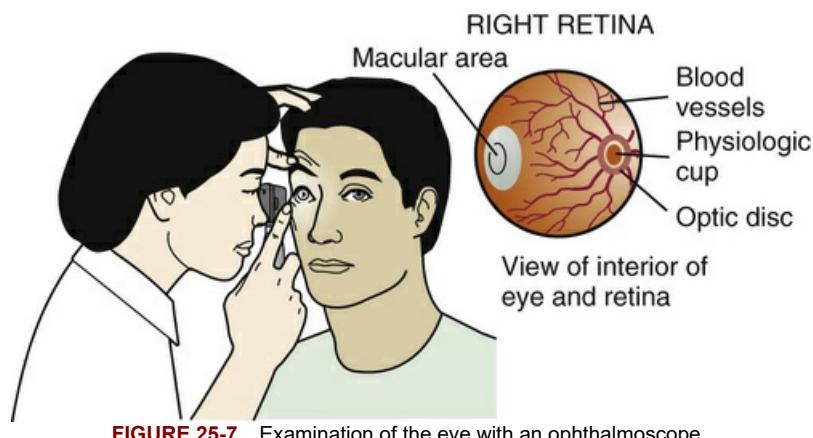

FIGURE 25-7 Examination of the eye with an ophthalmoscope.

History Taking

Many systemic diseases, including AIDS, hypertension, and diabetes mellitus, secondarily affect the eye and its functions. In the general assessment of any patient, you should be aware of the more obvious indications of an ophthalmic pathology, whether it is primary or secondary.

A history of neurologic disorders should be noted. Neuromuscular diseases are especially likely to cause diplopia, blurred vision, or inability to move the eyes. Endocrine disorders that secondarily affect the eyes include thyroid disease and diabetes mellitus. Acute hyperglycemia can alter the shape of the lens and temporarily cause blurred vision. **Prolonged hyperglycemia can adversely affect the blood vessels of the retina, causing bleeding and leading to loss of vision.** Liver and kidney failure can produce pathologic changes in both neural and vascular structures within the eye. Retinal changes also can be caused by hypertension and atherosclerosis.

Some drugs are capable of producing either transient or permanent ocular changes that lead to disturbances in color vision and visual acuity and to the formation of cataracts, retinopathy, and glaucoma. Among common drugs that have possible ocular side effects are digitalis leaf, corticosteroids, indomethacin (Indocin), and sulfisoxazole (Gantrisin).

A family history of eye disorders can be significant, because disorders such as strabismus, retinitis pigmentosa, glaucoma, and cataracts tend to run in families, or follow a pattern of inheritance.

▣ Focused Assessment

Data Collection for Eye Disorders

The following questions should be asked when gathering history regarding an eye disorder:

- Have you noticed a change in your vision?
- Do you have any pain or discomfort in the eyes? Itching? Burning? Stinging? Excessive tearing or watering?
- Have you had any episodes of blurred vision? Double vision? A loss in the field of vision? Blind spots? Floating spots?
- Do you have difficulty with vision at night?

- Is there any pain in your eyes when you are in bright light?
- Do you have headaches in the brow area?
- Do you see halos around lights?
- Have you ever injured an eye in any way?
- Do you experience frequent reddening of the eye (conjunctivitis)?
- Do you ever experience discharge or sticky matter in the eye?
- Do you find that your lids are crusty when you awaken?
- Do your eyes feel dry? Do you frequently use eyedrops?
- Do you wear contact lenses? Use glasses?
- What medications do you take regularly?
- Is there any history of glaucoma in your family?
- Have you ever been told you have diabetes? Hypertension?
- When did you have your last eye examination?
- **For those patients who have a previous visual loss:** How do you cope with your loss of vision?

Sometimes patients are not aware of gradual changes in vision, but have noticed that they have had more minor accidents lately, seem to be more easily fatigued, or are less interested in doing things that once gave them pleasure, such as sewing or some other hobby.

Physical Examination

Observe the patient's eyes and eye area for redness of the conjunctiva, swelling of the eyelids or in the periorbital space, excessive tearing, change in visual acuity, secretions and encrustations on the eyelids, abnormal position of the eyelid, and **exophthalmos** (protrusion of the eyeball).

Abnormalities of lid position are described in [Table 25-3. Xanthelasma](#), or soft, raised, yellow areas, sometimes appear on the eyelid after age 50 years ([Figure 25-8](#)). Signs and symptoms of selected eye diseases are listed in [Table 25-4](#). In addition to the more obvious signs of eye disease, visual impairment also can be assessed by noting the patient's head, hand, and eye movements. Tilting the head to one side to improve vision could mean that the patient has double vision or that one eye is much stronger than the other. Squinting could mean poor vision. Shading the eyes with the hands may indicate an increased sensitivity to light (**photophobia**).

Table 25-3
Abnormalities of Lid Position

ABNORMALITY	CAUSES	SYMPTOMS	TREATMENT
Entropion: Inversion of lid margin; eyelids are turned inward toward eyeball so that lashes rub against eyeball	Scarring and contraction of skin near eyelid (cicatricial entropion) or aging of skin with laxness of tissues supporting the lid and contraction of orbicularis muscle (spastic entropion)	Pain, tearing, redness, and corneal ulceration caused by lid margin and eyelashes rubbing against cornea	Splinting the lid, using a pressure patch, or taping lid into everted (turned outward) position Surgical correction by tightening musculature and evertting lid margin
Ectropion: Eversion or outward turning of the lower lid	Aging and laxness of skin and muscle tissues, facial paralysis, edema of conjunctiva lining the lid, or contraction of scar tissue	Irritation of palpebral conjunctiva, spilling of tears down the cheeks because of a blocked outlet, irritation of skin of cheeks, symptoms of conjunctivitis	Usually responds to patching of the eye Surgical correction necessary if paralysis of orbicularis muscle is permanent or if there is severe scarring and contraction of skin near the lid
Ptosis: Drooping of the eyelid so that it partially or completely covers the cornea	Congenital weakness of the levator superioris muscle or long-term presence of foreign body; one of first signs of myasthenia gravis	Obvious drooping of eyelid If not corrected in infants, can lead to blindness because light rays cannot enter and stimulate development of the eye Patient may be observed tilting head back or raising eyebrows in an effort to see from under eyelids	Surgical correction Removal of foreign body, if that is the cause

FIGURE 25-8 Xanthelasma. (From Bolognia JL, Schaffer JV, Duncan KO, Ko CJ: *Dermatology essentials*, St. Louis, 2014, Saunders.)

Table 25-4

Clinical Signs and Symptoms of Selected Eye Diseases, Medical Treatment, and Nursing Interventions

DISEASE	SIGNS AND SYMPTOMS	MEDICAL TREATMENT AND NURSING INTERVENTIONS
Blepharitis: Infection of glands and lash follicles along lid margin	Itching, burning, sensitivity to light Mucus discharge and scaling; eyelids crusted, glued shut, especially on awakening Loss of eyelashes	Warm compresses to soften secretions; scrub eyelids with baby shampoo; stroke sideways to remove exudate and scales. Antibiotic eyedrops; systemic and topical antibiotics if skin is infected.
Chalazion: Internal stye; infection of meibomian gland	Astigmatism or distorted vision, depending on size and location of chalazion Small, hard tumor on eyelid	Chalazion may require surgical excision and antibiotics to prevent chronic state and cyst formation.
Hordeolum: External stye; infected swelling near the lid margin on inside	Sharp pain that becomes dull and throbbing Rupture and drainage of pus bring relief Localized redness and swelling of lid	Hordeolum usually resolves spontaneously. Warm compresses qid for 10-15 min to bring stye to a head and hasten rupture. Caution patient never to squeeze swelling, because this could spread infection; poor health status can predispose a person to recurrence of styes.
Conjunctivitis: Inflammation of the conjunctiva; "pink eye" is a specific type caused by chemical irritants, bacteria, or virus	Varying degrees of pain and discomfort Increased tearing and mucus production Itching; sensation of a foreign body in the eye	Depends on type of infecting organism; antibiotic eyedrops and ointments. Special care when handling infective material.
Keratitis: Inflammation of the cornea	Varying degrees of pain and discomfort Photophobia; blurred vision if center of cornea is affected	Depends on specific causes; could be allergy, microbes, ischemia, or decreased lacrimation. Most superficial lesions are self-healing. Antibiotic eyedrops or ointment used for bacterial infections. Steroids can reduce inflammation and discomfort; however, herpes infection can rapidly worsen keratitis unless an antiviral agent is given simultaneously. Patient is encouraged to use good personal hygiene, frequent hand hygiene.
Corneal abrasion or ulceration	Moderate to severe pain and discomfort aggravated by blinking History of trauma, contact lens wear	Change or discontinue use of contact lens. Teach patient proper way to insert, remove, and care for contact lens. Caution patient not to moisten lens with saliva.

qid, Four times daily.

Observation of the patient's ability to move the eyebrows and eyes can be helpful in diagnosing nerve damage. Inability to raise the eyebrows indicates damage to the facial nerve. Movement of the eyeball to direct the gaze is controlled by six muscles, which are controlled by three cranial nerves: the oculomotor nerve (third cranial), the trochlear nerve (fourth cranial), and the abducens nerve (sixth cranial) (see Table 25-1).

Nursing Diagnosis

Problem statements/nursing diagnoses are based on the data obtained from assessment. The LPN/LVN collaborates with the RN in formulating the nursing care plan and selecting the problem statements. Problem statements commonly used for patients with eye disease are:

- Potential for injury due to decreased visual field.
- Fear due to visual loss.
- Inadequate home maintenance ability due to impaired or lost vision.
- Potential altered activity due to visual limitation.
- Insufficient knowledge for instilling eyedrops properly.

Specific NANDA-I nursing diagnoses may be chosen from the NANDA-I list (see inside back cover).

■ Planning

Expected outcomes for these problem statements might be:

- Patient will compensate for decreased visual acuity and not suffer sensory deprivation.
- Patient will not experience injury.
- Patient will verbalize decreased fear as treatment begins to help condition.
- Patient will seek assistance with home maintenance within 7 days.
- Patient will explore other means of diversion than reading and watching television.
- Patient will demonstrate proper instillation of eyedrops and will verbalize the schedule for the eyedrops.

When a patient is visually impaired, plan extra time to assist with personal care, to allow the patient to perform as much self-care as possible. The instillation of preoperative eyedrops is a very time-consuming nursing task (Box 25-1). Plan for this when creating the work plan for the shift. Hands must be washed before and after instilling eyedrops. Often an eye patch must be removed and a new one placed after instilling eye medication. Planning also must incorporate patient teaching on the administration of medication, self-care instructions for a patient with glaucoma, and postoperative instructions.

Box 25-1

Instillation of Eyedrops and Eye Ointment

Check the medication label and be certain which eye is to receive the medication. Follow the “Six Rights” of medication administration. Perform hand hygiene and apply gloves.

Eyedrops

- Remove the cap and place it on the table on its side or upside down.
- With the patient sitting or reclining, ask the patient to look up at the ceiling and tilt the head slightly toward the eye receiving the drop.
- With a tissue beneath the fingers, retract the lower lid downward, exposing the conjunctival sac.
- Stabilize the eyedrop container above the eye and drop the designated number of drops directly into the conjunctival sac. Do not place drops on the cornea. Block the entrance to the lacrimal gland by placing a finger over it.
- Carefully replace the cap on the container without contaminating the dropper tip.
- Ask the patient to close the eyelids gently and move the eyes from side to side under the lids to distribute the medication.

Eye Ointment

Ointment is sometimes used rather than drops to aid in the process of treating rough, dry eyes and introduce moisture to the surface of the eye. Also, ointment may include antibiotics.

- Remove the cap from the tube and set it down on the table upside down.
- Expose the conjunctival sac.
- Apply a thin ribbon of ointment along the entire length of the conjunctival sac.
- To end the ribbon, twist the tube with a lateral movement of the wrist without touching the eye.
- Recap the tube.
- Ask the patient to gently close the eyelids and roll the eyes around under the lids to distribute the medication.

■ Implementation

Many eye problems require eyedrops or ophthalmic ointment applied to the eye several times a day. A new contact lens delivery system is being tested to dispense a glaucoma drug directly to the surface of eye in a time-release manner. The lens stays on the eye for 1 month. A prototype is in trials (Ciolino et al, 2014).

Nursing Interventions for Visually Impaired Patients

Individuals with impaired sight must make considerable adjustments. People who have lost their eyesight may experience hopelessness and despair. Patients who are visually impaired go through stages of grief in much the same way a dying person does. A different lifestyle must be learned, but it is not necessarily less meaningful.

When communicating with these patients, remember that the person has a vision impairment; she is not deaf. Speak normally. Speak to the person and identify yourself as you enter the room, and do not touch her until after you have spoken to her—this prevents startling or frightening the patient if she did not hear you enter the room. Ensure that she is oriented to the room and can easily locate the call bell.

Prevention of accidents is an important part of the care of a blind person. Aside from the physical effects of bumping into objects or falling over them, a person who is visually impaired also may experience a loss of self-confidence and security if movement is not safe and independent. Doors should be kept closed or left completely open. They must never be left ajar. Always return things to their places when working in the room. If it is necessary to move any object in the room, ask for the patient's consent, and state the object's new location. When you leave the room, tell the patient that you are going. This will prevent her from becoming frustrated by resuming a conversation, only to find that no one is there. When ambulating with a patient with a visual impairment, lead with the patient holding your arm as she follows.

Pity is neither expected nor appreciated by people with visual impairments. They want to be treated as other people and would prefer to ask for your help when they need it rather than have you do everything for them. If you are assigned to the care of a patient with a visual impairment, determine the amount of assistance the patient needs and wants by asking. Do not assume that the person is helpless, but do not neglect the patient when help is needed.

When a patient who is visually impaired is admitted, she will require special orientation to the room and surroundings. If there is total blindness, describe the size of the room and the placement of furniture, using the bed as the focal point. An ambulatory patient can be walked around the room and to the bathroom to develop familiarity with the location of the commode, bath, and sink. As with any patient, explain how to locate and use the call system, the radio, and the telephone (if there is one at the bedside).

Most patients prefer to feed themselves, if at all possible. However, it usually is necessary to set up the meal tray of patients who are visually impaired, using the "clock" method for placement of food on the plate. The patient is told what food is in which area (e.g., "The potatoes are at 2 o'clock."). Setting up the meal tray includes opening containers of milk and juice, pouring coffee or tea, and cutting meat into bite-sized pieces, unless the patient is accustomed to doing these things.

■ Assignment Considerations

Assisting Visually Impaired Patients

If a CNA or UAP is assigned to help feed, ambulate, or care for a patient who is visually impaired, be certain that the person understands what the visual impairment is and whether one or both eyes are affected. Ask that the aide announce his presence with a knock on the door and speak before touching the patient. Review how to feed a blind patient and how to assist with ambulation. Gently remind the CNA or UAP that the patient is blind and not deaf, unless deafness is also a patient problem.

Do not give a person who is visually impaired a straw or drinking tube unless you are asked to, because it may be awkward to use. If you must feed the patient all of a meal, work slowly and calmly. Indicate about hot and cold foods on the tray, and alternate dishes rather than feeding all of one thing before offering another. Avoid talking too much, thus forcing the patient to either stop

eating or answer you with a mouth full of food. Whenever possible, help the patient select finger foods such as sandwiches and raw fruit or vegetables from the menu. The goal is to help the patient maintain dignity and self-respect while meeting her personal needs.

If a guide dog is present, do not interfere with it or pet it while it is working. Do not feed the dog; let the patient feed it at the appropriate time. Be sure the dog is near the bed on its own mat. Ask if the mat may be on the side of the bed that the staff are less likely to use.

Think Critically

Can you think of three specific ways in which you can assist a blind patient who is admitted to the hospital to maintain as much independence in this setting as possible?

Evaluation

Evaluation is based on reassessing data and determining whether expected outcomes have been met. This is an ongoing process. Some questions to be asked when gathering data for evaluation include: Is the patient compliant with the use of eye medications? Is an infection resolving? Is vision improving? If interventions have not been effective in helping the patient achieve expected outcomes, the plan of care should be altered.

Community Care

Nurses in all settings should be conscious of eye safety for themselves and those around them. Public education about using sunhats, visors, and dark glasses when outdoors to protect the eyes from ultraviolet A and B (UVA and UVB) rays is another function of all nurses.

Nurses working in home care often find that patients have not had eye care in many years; prescriptions have not been changed, and their quality of vision has decreased. Arrange for referral to an appropriate agency to set up an eye examination when the patient cannot. Glaucoma testing should be encouraged every 2 to 3 years for all adults older than 40 years.

Anatomy and Physiology of the Ear

Structures of the Ear

- The external ear consists of the pinna (auricle) and the canal (auditory meatus). The pinna is the fleshy part of the ear situated on the side of the head (Figure 25-9).

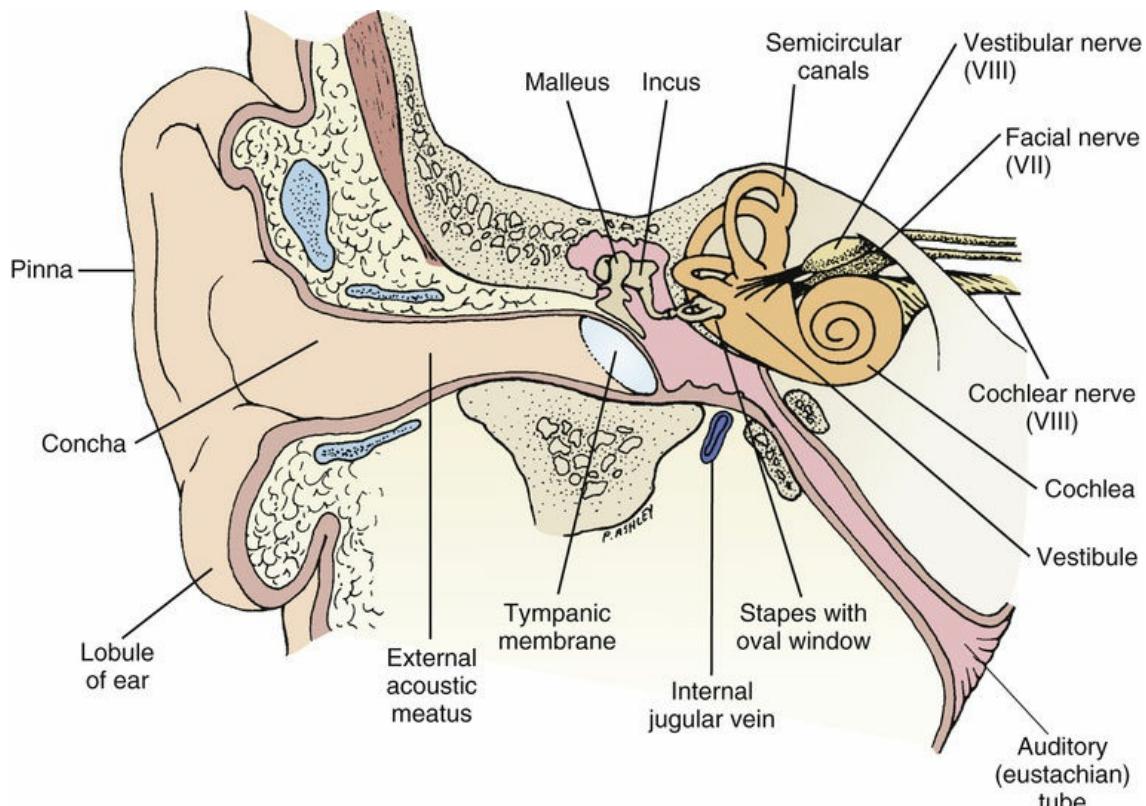

FIGURE 25-9 Structures of the ear.

- The auditory meatus is a tube approximately 2.5 cm long that extends from the pinna to the tympanic membrane.
- The meatus is lined with numerous hairs and glands that secrete a waxy substance called **cerumen** (earwax).
- The middle ear contains the auditory bones (ossicles) and opens into the eustachian tube.
- The auditory ossicles are three small bones: the malleus (hammer), the incus (anvil), and the stapes (stirrup).
- The malleus attaches to the tympanic membrane.
- The stapes attaches to the oval window.
- The incus links the malleus and the stapes.
- The tympanic membrane (eardrum) separates the middle ear from the external ear.
- The eustachian tube connects the middle ear with the throat.
- The oval window and the round window connect the middle ear to the inner ear.
- The inner ear is divided into the vestibule, the semicircular canals, and the cochlea.
- The inner ear contains a bony labyrinth with a membranous labyrinth lining; the inner ear is located in the temporal bone of the skull.
- A clear fluid, endolymph, fills the membranous labyrinth.
- The cochlea contains the organ of Corti, which is composed of sound receptors.

Functions of the Ear Structures

- The pinna collects sound waves and channels them into the auditory meatus.
- The hairs and cerumen in the canal help prevent foreign objects from reaching the tympanic membrane.
- The tympanic membrane vibrates when sound waves hit it; the sound vibrations are conducted to the malleus.
- The bones of the middle ear transmit the sound vibrations to the inner ear. The malleus transmits them to the incus, and the incus transmits sound vibrations to the stapes. The stapes transmits the sound vibrations to the oval window, which transfers the motion to the fluid in the inner ear.
- Fluid motion in the inner ear stimulates the sound receptors in the cochlea and the organ of Corti.
- The organ of Corti transmits impulses to the cochlear branch of the vestibulocochlear nerve (cranial nerve VIII). This nerve carries the impulses to the medulla oblongata, the thalamus, and then to the temporal lobe of the brain, which contains the auditory cortex.
- The eustachian tube helps equalize pressure in the middle ear.
- Receptors responsible for equilibrium (balance) are located in the inner ear, within the bony vestibule and at the base of the semicircular canals.
- Impulses from the equilibrium receptors are transmitted to the brain via the vestibular branch of the vestibulocochlear nerve (cranial nerve VIII). The cerebellum is important in mediating the sense of equilibrium and balance.

Age-Related Changes in the Ear

- Cerumen becomes harder, containing less moisture, and its buildup within the ear may contribute to a hearing loss in the low-frequency range.
- The tympanic membrane loses elasticity.
- The joints between the auditory bones become stiffer; the stiffness interferes with the transmission of sound waves but is not clinically significant by itself.
- There is a gradual loss of the receptor cells in the organ of Corti after age 40 years.
- The number of nerve fibers in the vestibulocochlear nerve decreases, contributing to hearing loss and sometimes affecting balance and equilibrium.

The Ear

Approximately 36 million adults in the United States have some degree of hearing loss ([National Institute on Deafness and Other Communication Disorders, 2014](#)). The number has risen dramatically in the past three decades. Approximately 15% (26 million) of Americans between the ages of 20 and 69 years have high-frequency hearing loss caused by exposure to loud sounds. Social withdrawal is common when hearing becomes severely impaired. The inability to hear causes difficulty with communication. Approximately 2 in 1000 babies born in the United States have some form of congenital hearing problem. After age 75 years, about 47% of the population has some degree of hearing loss. It is believed that the trend of playing very loud music—causing damage to the acoustic nerve—will result in considerably more hearing loss in the coming decades.

Health Promotion

Coping With Hearing Loss

The sooner a person with a hearing loss obtains and learns to use a hearing aid, the greater the hearing improvement. The brain is better able to integrate the hearing aid transmissions when hearing has not been impaired for a very long time. Encourage individuals with any hearing loss to be tested and to try a hearing aid if one is recommended. The person should be told that there is an adjustment curve with new hearing aid use, and it often takes several trips back to the hearing aid center for minor adjustments to the instrument to be made. It also takes practice in using the aid to achieve better hearing.

There are two types of hearing loss related to problems in the ear: **sensorineural** and **conductive**. Approximately 80% of hearing loss is caused by a disorder of the hearing nerve (**sensorineural loss**). Conductive hearing loss is caused by a problem transmitting sound impulses through the auditory canal, the tympanic membrane, or the bones of the middle ear. Causes of sensorineural and conductive hearing impairment are listed in [Box 25-2](#).

Box 25-2

Common Causes of Sensorineural and Conductive Hearing Loss

Conductive Loss

- Obstruction by impacted cerumen
- Infection with labyrinthitis
- Otosclerosis
- Trauma and scarring of the tympanic membrane
- Congenital malformation of the outer or middle ear

Sensorineural Loss

- Presbycusis
- Heredity with congenital loss
- Ototoxic drugs
- Loud noise exposure

- Tumor (acoustic neuroma)
- Ménière disease
- Severe infection such as measles, mumps, or meningitis
- Rubella in utero

Arteriosclerosis can cause decreased blood flow to the otic nerve (eighth cranial nerve), resulting in sensorineural hearing loss. This often contributes to hearing loss in older adults.

A loss of hearing—like a loss of sight—burdens its victims with physical, emotional, psychosocial, and financial problems. Hearing allows for communication with others in everyday conversations, in the classroom, and in business transactions. Without the ability to hear, one can be deprived of many of the joys and pleasures of life: music, drama, exchange of ideas, and the thousands of sounds in one's environment. Because hearing warns one of danger, an inability to hear can cause anxiety and fear. Adults who have a hearing deficiency might lose jobs and alienate friends because of their communication handicap. Nurses must learn ways to help prevent hearing loss and to assist patients who already have such a loss.

Inner ear disorders can cause problems with balance. Dizziness, vertigo, and ataxia can greatly interfere with an individual's ability to work or to perform usual activities of daily living.

Accidental injury and fractures from falls may occur.

To understand the problems affecting the ear, it is necessary to recall the ear's normal structure and functions.

Hearing Loss

Causes and Prevention

A glance at the causes of hearing loss listed in [Box 25-2](#) will help identify some of the ways nurses can help prevent hearing loss. Not all cases of hearing disability can be prevented, but education of the general public about causes of hearing loss can reduce its incidence. *Healthy People 2020* includes many objectives to prevent hearing loss and improve hearing among the American public. Adequate treatment of severe ear infections helps preserve hearing. Loud noise is a major cause of sensorineural hearing loss, and the use of headphones or earbuds contributes considerably to hearing damage ([Table 25-5](#)) (National Institute on Deafness and Other Communication Disorders, 2010b). A large amount of hearing loss is the result of employment-related exposure to loud and continuous noise. Active and retired military personnel are experiencing hearing loss from exposure to loud noises. Veterans are 30% more likely to have severe hearing impairment (SHI) than nonveterans ([MMWR, 2010](#)).

Table 25-5
Range of Sounds Audible and Hazardous to the Ear

LEVEL IN DECIBELS (dB)	EXAMPLE
0	Lowest sound audible to the human ear
30	Quiet library, soft whisper
40	Living room, quiet office, bedroom away from traffic
50	Light traffic at a distance, refrigerator, gentle breeze
60	Air conditioner at 20 feet, conversation, sewing machine
70	Busy traffic, noisy restaurant; at this decibel level, noise may begin to affect hearing if exposure is constant
Hazardous Zone for Hearing Loss	
80	Subway, heavy city traffic, alarm clock at 2 feet, factory noise; these noises are dangerous if exposure to them lasts for more than 8 hr
90	Truck traffic, noisy home appliances, shop tools, lawn mower; as loudness increases, the "safe" time exposure decreases; damage can occur in 8 hr
100	Chain saw, stereo headphones, pneumatic drill; even 2 hr of exposure can be dangerous at this decibel level; with each 5-dB increase, the safe time is cut in half
120	Rock band concert in front of speakers, sandblasting, thunderclap; the danger is immediate; exposure of 120 dB can injure ears
140	Gunshot blast, jet plane; any length of exposure time is dangerous; noise at this level may cause actual pain in the ear
160	Rocket launching pad; without ear protection, noise at this level causes irreversible damage; hearing loss is inevitable

Adapted from Lewis SL, Heitkemper MM, Dirksen SR, et al: *Medical-surgical nursing: Assessment and management of clinical problem*, ed. 8, St. Louis, 2011, Mosby.

Hairpins, the ends of pencils, and other objects should never be used to relieve tickling or itching in the ear or to remove cerumen. Earwax normally moves on its own out of the ear canal to the outer ear, where it can be removed without danger of damaging the delicate lining of the ear canal or the tympanic membrane (eardrum). Obstructive cerumen should be removed by using drops

that dissolve it or by a provider or nurse skilled in removing impacted cerumen. Foreign objects, such as beans, peas, and other organic substances, also should be removed by someone who is experienced and aware of the potential for ear damage.

Conductive hearing loss most often occurs from stiffening of the bones of the middle ear or from scarring of the tympanic membrane. Continued exposure to excessively high levels of sound can produce sensorineural loss called *noise-induced hearing impairment*. This condition is particularly likely to occur in industrial settings where machinery operation creates loud noise. The standards of the Occupational Safety and Health Administration (OSHA) require the wearing of ear protectors in such settings.

A more recent phenomenon is the potential damage to the inner ear caused by amplified music. **Sustained exposure to noise levels of 90 to 95 dB may result in hearing loss.**

Many drugs can be toxic to the inner ear. This is especially true if a very high dose of the drug is given or if it is given incorrectly. Commonly administered drugs that can be ototoxic are many of the antibiotics, nonsteroidal anti-inflammatory drugs, chemotherapy agents, and potent diuretics, such as furosemide (Lasix) (Box 25-3). Aspirin and other salicylates can produce loss of hearing of high frequencies and ringing in the ears (**tinnitus**).

Box 25-3

Ototoxic Drugs and Environmental Chemicals

Ototoxicity (ear poisoning) is caused by drugs or chemicals that damage the inner ear or the vestibulocochlear nerve. There are more than 200 drugs that cause toxicity. The vestibulocochlear nerve sends balance and hearing information from the inner ear to the brain. Ototoxicity may result in temporary or permanent disturbances of hearing, balance, or both. Environmental chemicals can be toxic from inhalation of fumes or powder residue or from skin contamination.

Drugs That May Cause Ototoxicity

Antibiotics

(Family history may increase susceptibility; may cause permanent damage.)

- Tobramycin
- Gentamicin
- Streptomycin
- Kanamycin
- Amikacin
- Neomycin
- Netilmicin
- Dihydrostreptomycin
- Erythromycin (IV)
- Vancomycin
- Chloramphenicol
- Minocycline
- Capreomycin
- Dibekacin
- Etiomycin

Antineoplastic Drugs

(May cause permanent damage.)

- Cisplatin
- Carboplatin
- Bleomycin
- Nitrogen mustard

Loop Diuretics (IV)

(Usually temporary damage.)

- Furosemide
- Torsemide
- Bumetanide
- Ethacrynic acid

Salicylates

(Usually temporary damage.)

- Aspirin

Nonsteroidal Anti-inflammatory Drugs

(Usually temporary damage.)

- Ibuprofen
- Naproxen sodium

Quinidine Derivatives

(Usually temporary damage.)

- Quinidex
- Atabrine
- Plaquenil
- Quinine sulfate
- Mefloquine
- Chloroquine

Environmental Chemicals

- Metals (lead, mercury, gold, arsenic)
- Aniline dyes
- Toluene
- Carbon monoxide
- Trichloroethylene

- Xylene
- Povidone-iodine
- Nicotine
- Potassium bromate

IV, Intravenous.

Nurses should be aware of the potential for damage to the ear by potent drugs. Nonsteroidal anti-inflammatory drugs are more toxic in older adults and when used at maximum dosages over an extended period.

Older Adult Care Points

The older the patient, the greater the chance of ototoxicity occurring from analgesic medications, because many older patients have chronic conditions that cause chronic pain. Older adults' liver and kidneys generally have decreased function because of aging, so they cannot degrade and eliminate drugs as easily as those of younger people. This can cause drugs and drug metabolites to build up to toxic levels when medication is taken on a continuing basis.

Safety Alert

Dangers of Ototoxic Drugs

Know the toxic effects of the drugs you administer. Patients should be assessed frequently while receiving a potentially ototoxic drug. Any signs of ototoxicity, such as ringing in the ears, subtle changes in hearing ability, and difficulty in hearing, should be reported immediately. Ototoxicity commonly occurs because patients are taking more than one drug that can be toxic to the ear. Teach patients who are taking daily doses of aspirin or nonsteroidal anti-inflammatory drugs for arthritis or other chronic pain conditions to immediately report the signs of ototoxicity.

Diagnostic Tests and Examinations

Visual examination of the ear.

The two instruments most commonly used to examine the ear canal and tympanic membrane are the otoscope and the aural speculum. The otoscope is fitted with a light and a magnifying lens to facilitate inspection (Figure 25-10). The aural speculum is used with a special circular, slightly concave head mirror that has a hole in its middle. The head mirror is positioned so that the central hole lies in front of the examiner's eye. A source of light, such as a lamp, is placed behind the examiner so that it shines on the head mirror and is reflected into the ear.

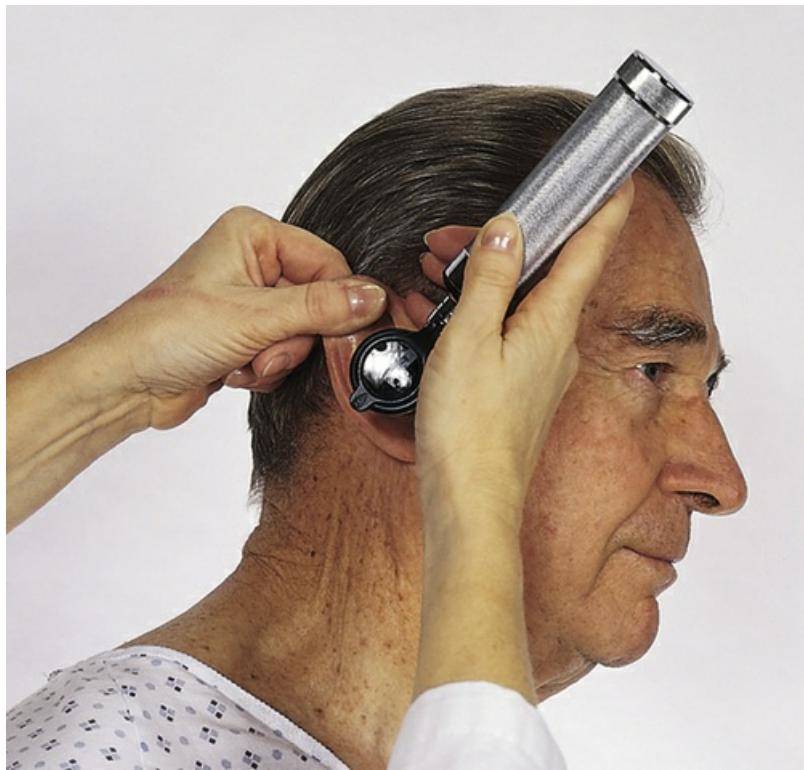

FIGURE 25-10 Examination of the ear with an otoscope. (From Jarvis C: *Physical examination and health assessment*, ed. 6, St. Louis, 2012, Saunders.)

The simple speculum can be modified by attaching a special tube and inflatable bag (pneumatic otoscope), thereby creating an airtight system. This allows the examiner to determine whether the tympanic membrane responds to positive and negative pressure. The normal eardrum moves in response to pressure. Healed perforations and scars on the eardrum can be seen when the tympanic membrane is moved.

A simple hearing test is the **whisper test**. The examiner stands behind the patient and whispers a question to the patient. If the patient hears the question, an answer is forthcoming. The examiner backs up a step and whispers another question, and so on.

Tuning fork tests.

Tuning forks measure hearing by air conduction or by bone conduction (Weber test and Rinne test). A tuning fork is activated by holding it by the stem and striking the tines softly on the back of the hand ([Table 25-6](#)).

Table 25-6
Diagnostic Tests for Ear Problems

TEST	PURPOSE	DESCRIPTION	NURSING IMPLICATIONS
Weber test	To determine loss of hearing in one ear or both	Tuning fork is struck, and then the handle is placed on the patient's forehead. Normal hearing or equal loss in both ears is demonstrated by hearing the sound in the middle of the head.	Explain purpose and procedure to patient.
Rinne test	To determine whether hearing loss is sensorineural or conductive	Tuning fork is struck, and then the handle is placed on the mastoid bone; the fork is removed and struck again and held beside the ear. The patient is asked in which position she heard the sound better or longer.	Explain procedure to patient.
Audiometry	To determine degree of hearing loss in each ear	Earphones are placed on the patient's ears and, with the use of an audiometry machine, the audiologist channels sounds of different decibels and pitch into one ear and then the other. The patient signals when she hears the tone.	Explain procedure to patient.
Caloric test	To check for alteration in vestibular function in each ear	With patient in a seated or supine position, each ear is separately irrigated with a cold and then a warm solution to determine vestibular response. Normal response is nystagmus, vertigo, nausea, vomiting, falling; decreased response indicates abnormality.	Explain procedure to patient; tell patient she may experience nystagmus, vertigo, nausea, and vomiting, but these will indicate a normal response.
Electronystagmography (ENG)	To assess for disease of vestibular system	Electrodes are placed near the patient's eyes. Caloric test is performed; movement of the eyes is recorded on a graph. Decreased response is abnormal.	Explain procedure and equipment to patient. Tell her that nausea, vertigo, etc. indicate a normal response.
Evoked-response audiometry (ERA); auditory brainstem response (ABR)	To determine abnormality of nerve pathways between eighth cranial nerve and brainstem	Electrodes are attached to the client's head in a darkened room; similar to EEG. Auditory stimuli are directed to the patient, and a computer is used to track and separate the auditory electrical activity of the brain from other brain waves.	Explain procedure and equipment to patient. Tell her the room will be darkened.
Magnetic resonance imaging (MRI)	To detect tumor of the eighth cranial nerve, acoustic neuroma	Huge electromagnet is used to detect radiofrequency pulses from the alignment of hydrogen protons in the magnetic field. A computer translates the pulses into cross-sectional images. Provides high-contrast views of soft tissue.	Explain to patient that her head will be placed in a machine that looks like a large tube. She will need to lie very still during the test; all metal must be removed before the test.
FTA-ABS blood test	To test for syphilis	Blood is drawn and sent to the laboratory for determination of presence of	Explain that a blood sample is needed.

| syphilis. Syphilis can cause problems with nerve transmission from the ear. |

EEG, Electroencephalography; FTA-ABS, fluorescent treponemal antibody absorption.

Test for nystagmus.

To test for **nystagmus** (involuntary rhythmic jerking of the eyes), hold a finger directly in front of the patient at eye level. The patient is asked to follow the finger without moving the head. Move the finger slowly from the midline toward the right ear about 30 degrees. Then the finger is moved back to the midline and then slowly toward the left ear about 30 degrees. The patient's eyes are watched for any jerking movements. Nystagmus other than at the extremes of lateral gaze is abnormal and may indicate an inner ear problem, intracranial tumor, or paralysis of an eye muscle.

Romberg test.

The Romberg test is a test of equilibrium. The patient stands with the feet together, the arms out to the sides, and the eyes open. Note the ability to maintain an upright posture without swaying. The patient is then asked to close the eyes, and posture is observed again. If the patient loses balance, it may indicate a problem with the inner ear or the cerebellum.

❖Nursing Management

■ Assessment (Data Collection)

Patients older than 60 years should always be assessed for hearing loss. If a patient has a known hearing impairment, Assess how the patient is coping with it. Hearing and balance are subjective problems and require a good history from the patient.

▣ Focused Assessment

Data Collection for Ear Disorders

Ask the following questions:

- Have you had any pain in the ear?
- Have you had a recent temperature elevation?
- Do you suffer from allergies?
- Do you have frequent upper respiratory infections?
- Have you ever been exposed to very loud noise? Do you work in an area that is noisy? Do you listen to loud music?
- Have you ever had a head injury?
- Do you scuba dive, hunt or shoot skeet, or fly in small airplanes?
- Do you ever have ringing, buzzing, or odd sounds in the ears?
- Do you feel your hearing ability has decreased? Do people you live with think that you do not hear as well as you used to hear? Do you frequently have to ask people to repeat things that have been said to you?
- Is there a history of hearing loss in your family?
- Have you ever had a really high fever?
- What medications are you taking regularly? Are there other medications that you have taken for an extended period in the past? Do you take aspirin?

- How do you clean your ears?
- Do you ever experience dizziness, vertigo, or loss of balance?

Diagnosis of infection requires an otoscopic examination. It should be noted that the color, texture, and amount of cerumen varies among individuals. In whites and African Americans cerumen tends to be moist and rust-brown colored. Native Americans and Asians have cerumen that is lighter in color and drier. Normally, the top of each pinna is aligned with the corner of the eye on each side of the head. Lesions on the pinna may indicate skin cancer, particularly in older adult patients. There should be no secretions other than cerumen from the ear. Ear pain may be referred from other parts of the head and neck and may occur from sinusitis, dental problems, or temporomandibular joint syndrome.

Focused Assessment

Physical Assessment of the Ear

- Compare the pinna from one side to the other for symmetry and placement.
- Palpate the pinna for the presence of nodules.
- Observe for the presence of lesions on the pinna.
- Check for drainage (**otorrhea**) from the ear; note color and odor.
- Observe the gait to detect any problem with balance.
- Observe for wavering when arising from a supine or seated position that might indicate dizziness or equilibrium problems.
- Observe for signs of bruising on the body from falls that may indicate problems with balance.
- Observe whether the person speaks in a voice louder than necessary.
- Observe whether facial expression indicates difficulty in understanding what is being said.
- Determine whether responses to statements are inappropriate.

Note: Someone qualified and experienced in using an otoscope should inspect the auditory meatus and the tympanic membrane.

The ears of older adults in long-term care facilities should be checked with an otoscope at regular intervals for cerumen. Many long-term care residents have a correctable hearing loss related to impacted cerumen. Cerumen can be removed by using cerumen softener drops, and then irrigating the external ear canal ([Figure 25-11](#)).

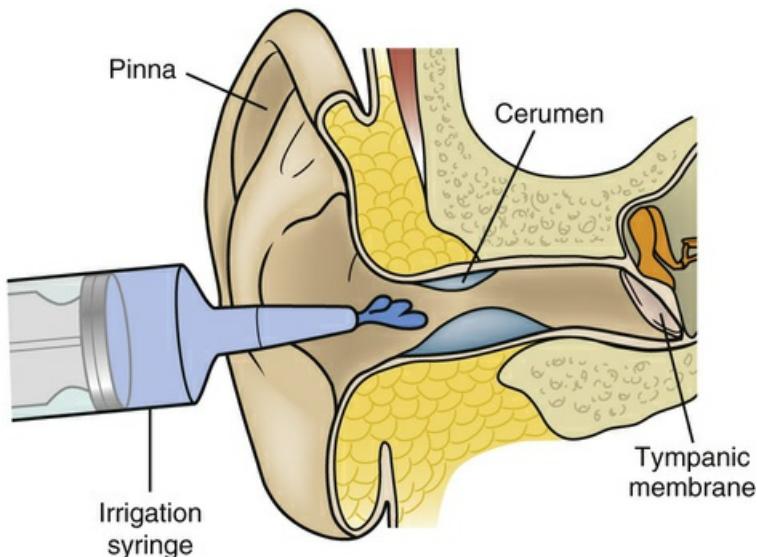

FIGURE 25-11 Irrigating the external ear canal. Warm water is used to remove cerumen and debris from the canal. Aim the stream of water above or below the impaction to allow back pressure to push it out rather than farther down the canal.

Nursing Diagnosis and Planning

Problem statements/nursing diagnoses are chosen considering the assessment data (Table 25-7). Specific NANDA-I diagnoses can be chosen from the NANDA-I list (see inside back cover). General goals for a patient with problems of the ear or hearing are:

- Promote knowledge to protect hearing
- Prevent infection and injury
- Promote effective communication
- Promote coping with hearing loss

Table 25-7

Common Problem Statements, Expected Outcomes, and Nursing Interventions for Patients With Ear Disorders

PROBLEM STATEMENTS	GOALS/EXPECTED OUTCOMES	NURSING INTERVENTIONS
Insufficient knowledge about preventing hearing loss	Patient will verbalize ways to prevent further hearing loss. Patient will be free of ear infection within 10 days.	If cerumen is obstructing the auditory canal, irrigate as ordered; warm the irrigation solution to body temperature. If infection is present, instruct regarding antibiotic medication and encourage to take entire prescription. Instruct in use of hearing aid if one is prescribed. Advise of ways to prevent further hearing loss: avoid loud noise or wear ear protectors; seek treatment immediately for signs of ear infection.
Pain due to ear inflammation	Pain will be controlled with analgesia within 8 hr. Pain will be resolved within 7 days.	Administer analgesics as ordered as needed. Warm analgesic eardrops to room temperature before administration. Have patient rest head on heating pad turned on "low" setting if this seems to decrease pain.
Altered communication ability due to hearing loss	Patient will assist in choice of methods to improve ability to communicate. Patient will try hearing aid for 2 wk if there is an indication that this device would help hearing.	Plan with patient the best way to communicate so that instructions and information are comprehended; explore tone of voice, level of volume, distance from patient when speaking, writing out communication, etc. Establish a routine procedure to confirm patient's understanding. Refer for evaluation by audiologist. Encourage daily use of hearing aid if one is prescribed. Explain that time and adjustments are necessary to obtain the optimum result. Give praise for efforts to use hearing aid.
Anxiety due to impaired safety or inability to perform well at work because of hearing loss	Patient will explore methods of maintaining safety within 2 wk. Patient will verbalize ways in which assisted hearing devices might assist in performance in the work environment.	Encourage verbalization of fears. Use means to enhance communication. Advise of assisted-hearing devices, hearing aids, and availability of "hearing ear" dogs. Introduce means of learning alternative communication methods, such as sign language and speech reading. Explore methods of enhancing attention to visual cues of dangers in the environment (e.g., close attention to signal lights or observing others at street crossings). Discuss problems of communication in social settings and explore possible solutions (e.g., masking devices for use in crowds, having interaction with only one or two people at a time, avoiding noisy restaurants, or using hearing aid).
Potential for injury due to impaired equilibrium	Patient will verbalize methods to ensure safety within 3 days. Patient will not experience a fall or injury.	Administer medication for vertigo as ordered. Encourage a low-sodium diet. Instruct to change positions very slowly. Encourage to hold on to something solid or to someone when rising from a sitting to a standing position. If vertigo is present, instruct to not ambulate without assistance. Teach or reinforce vestibular/balance exercises as prescribed. Assist to identify any aura (presence of symptoms that precede an attack). Instruct to lie down and keep the eyes open and focused straight ahead when experiencing vertigo.
Altered self-care ability	Patient will verbalize ways to enhance safe self-care within 2 wk.	Describe measures to assist the person to adapt; refer to support groups and sources for information. Refer to community agencies and resources for the hearing impaired.

Potential for social isolation due to difficulty in communicating	Patient will establish an adequate social network within 2 mo.	Assist patient to consider possibilities for social contact despite hearing problems. Help patient obtain a telephone for hearing-impaired people. Encourage the use of e-mail, texting, and other social media for contact with friends and family and social interaction with others.
---	--	---

Expected outcomes are written for each problem chosen for the patient's care plan. The outcomes should be written in collaboration with the patient and other health team members. In addition to the nurse and provider, an audiologist, hearing aid specialist, and speech therapist may be involved in the patient's care. Both long- and short-term goals for the patient should be considered.

When a patient is severely hearing impaired, communication with the patient for treatments and activities of daily living may take longer than with patients who hear normally. Take this into consideration when creating the daily work plan. If the patient does not have adequate aids for hearing, Devise an acceptable method of two-way communication with the patient.

■ Implementation

Interventions for patients with a hearing or balance problem are geared toward patient education, treatment of infection, preoperative and postoperative care and instructions, measures for communication (Box 25-4), and referral to resources. The hearing aid must be cared for properly (Box 25-5).

Box 25-4

Communicating With a Person Who Is Hearing Impaired

- If the person uses a hearing aid, encourage its use and see that it is situated, turned on, and adjusted before beginning speaking.
- Be certain you have the person's attention before beginning speaking.
- Sit facing the person with the light on your face rather than from behind you.
- Ask permission to turn down the volume of or turn off the television or radio.
- The best distance for speaking to a hearing-impaired person is $2\frac{1}{2}$ to 4 feet. Place yourself on eye level with the person. Do not speak directly into the person's ear, because this prevents the person from obtaining visual cues while you are speaking.
- Do not smile, chew gum, or cover your mouth while speaking.
- Use short, simple sentences. If the patient does not appear to understand or responds inappropriately, state the message again using different words. Try to limit each sentence to one subject and one verb.
- Give the person time to respond to questions.
- Ask for oral or written feedback to make certain your message is understood.
- Avoid using the intercom system, because it may distort sound.

Box 25-5

Caring for a Hearing Aid

When a hearing aid does not work:

- Check that the switch is "on."
- Examine the ear mold for attached wax or dirt; clean the sound hole.
- Check the battery to see that it is inserted correctly.
- Check the connection between the ear mold and the receiver.

- Replace the battery. Batteries last an average of 12 to 14 days depending on type of aid.
 - Check placement of the ear mold in the ear; it should fit snugly.
 - Adjust the volume.
 - If all else fails, take the hearing aid to an authorized service center for repair.
- To clean the hearing aid:
- Turn the hearing aid off.
 - Wash the ear mold with mild soap and warm water; do not submerge in water.
 - Use a pipe cleaner or toothpick to gently cleanse the opening or short tube that fits into the ear.
 - Dry the mold completely before turning on the aid or before reattaching it to the hearing aid (if it is separate).

Instillation of Ear Medication

Eardrops may be prescribed to dissolve cerumen, relieve pain, or combat infection in the auditory meatus. The patient should be positioned in a supine lateral position so that the affected ear is uppermost. The medication should be at room temperature. Cold eardrops may cause discomfort or dizziness. For adults and children 3 years of age and older, the ear canal is straightened by drawing the pinna upward and toward the back of the head ([Figure 25-12](#)). For a child younger than 3 years, the pinna is pulled down and back. Following the “Six Rights” of medication administration, draw up the correct amount of medication. Insert the tip of the dropper into the external ear canal and instill the medication ([Box 25-6](#)). Place cotton in the external meatus to prevent the medication from escaping. Have the patient remain in the lateral position for 5 to 10 minutes.

FIGURE 25-12 Straightening the ear canal to instill eardrops.

Box 25-6

Instilling Otic Medication

- Follow the “Six Rights” of medication administration.
- Read the order carefully to determine which ear is to receive the medication.
- Position the patient supine and in the lateral position so that the affected ear is uppermost.
- Draw medication into the medicine dropper by depressing the bulb and letting it go.
- Straighten the ear canal by drawing the pinna upward and toward the back of the head. For children younger than 3 years, draw the earlobe slightly down and back.

- Insert the tip of the medicine dropper into the external ear canal and depress the bulb to dispense the medication. Withdraw the dropper.
- Place cotton in the external meatus to prevent the medication from escaping.
- Have the patient remain in the lateral position for 5 to 10 minutes.

Communicating With a Patient Who Is Hearing Impaired

A patient who is hearing impaired has unique problems of communication when in the hospital or long-term care facility. If she cannot hear well and misunderstands or misinterprets the voices and sounds in the unfamiliar surroundings, she is likely to be frustrated, fearful, and anxious. Unless a special effort is made to have frequent contact with the patient, social isolation may occur.

When speaking to a patient who is hearing impaired, sit at eye level facing the patient. Gain eye contact and speak slowly and enunciate clearly. When trying to communicate with a person who is hearing impaired, bear in mind that attempts to answer questions without fully understanding what is asked may occur. Past experience has taught many people with hearing loss that to ask for repetition of questions irritates people and causes them to think the person is stupid. **For this reason, many people who cannot hear well commonly smile and say “Yes,” when such an answer is either incorrect or inappropriate.** Another problem is that the individual may fill in parts of sentences with similar-sounding words. For example, the words “Knott’s Berry Farm” may be interpreted as “not very far.” Some guidelines to help patients who are hearing impaired and improve nurses’ ability to communicate are given in **Box 25-4**.

Think Critically

What three techniques of communication with a patient who is hearing impaired do you think would be the most helpful?

A piece of tape or note should be placed over the terminal on the intercom system that designates the room of a patient who is hearing impaired. This serves to remind the person answering the light to go to the patient’s room rather than try to talk over the intercom system.

Evaluation

Evaluation involves reassessment to determine whether the expected outcomes are being met. Determining whether hearing has improved is the criterion by which effectiveness of treatment is evaluated. Improvement is verified by audiology. Fading or resolution of dizziness and vertigo indicate that actions and treatments for these problems have been effective. Resolution of infection is determined by the appearance of the eardrum, absence of pain, and normal temperature.

Common Problems of Patients With Ear Disorders

Hearing Impairment

Hearing impairment ranges from difficulty in hearing certain ranges of tones or in understanding certain words to total deafness. Persons with sensorineural hearing loss typically have more difficulty hearing high-pitched tones than low-pitched ones; thus they commonly can understand the speech of men better than that of women. Another characteristic of sensorineural hearing loss is difficulty hearing softly spoken and poorly enunciated words. Speaking slightly louder to a person with sensorineural hearing loss may help, but it is especially important to speak slowly and clearly and to face the person when communicating with her. Because people with sensorineural hearing loss do not hear their own voices as well as a person with normal hearing, they tend to speak louder than necessary.

Assignment Considerations

Caring for a Patient Who Is Hearing Impaired

When assigning tasks for a patient who is hearing impaired to UAP and CNAs, remind them how

to effectively communicate with the patient: face the patient and obtain the patient's attention before speaking; speak slowly and enunciate clearly in a normal voice. If the patient wears a hearing aid, it should be in the ear and the patient should be reminded to turn it on before communication begins.

Hearing aids help some people with sensorineural hearing loss. Aids designed to amplify some pitches and block out others that do not need amplification are most helpful. Hearing aids are not always the answer to a problem of hearing loss, and for some people the most effective therapy is focused on rehabilitation to facilitate acceptance of the loss and learning of new ways to communicate despite some degree of deafness. Most hearing aid professionals and companies will offer a 30-day money-back guarantee on any hearing aid so that the patient can try it.

Clinical Cues

When a patient can benefit from a hearing aid, then the earlier it is obtained and used, the better the brain will adjust and the better the quality that can be achieved (Tonkin, 2014).

Central hearing loss occurs in the brain as a result of a pathologic condition above the junction of the eighth cranial nerve and the brainstem. Central hearing loss can result from a problem of transmission of stimuli in the brain, an inability to decode and sort signals received from one or both ears, or a failure in the transmission of sounds from one hemisphere of the brain to the other. Causes include brain tumors, vascular changes that suddenly deprive the middle ear of its blood supply, and cerebrovascular accidents.

Many people have a combination of two or more types of hearing impairment. Often there is a combination of sensorineural and conductive loss.

Think Critically

How would you work with a patient who is hearing impaired and is a candidate for a hearing aid, but adamantly refuses to consider trying one?

Dizziness and Vertigo

The sense of balance and equilibrium is governed by the vestibular system in the inner ear. Increases in fluid pressure in the inner ear, inflammations, and vascular disorders that interrupt blood supply to the cochlea can produce dizziness, loss of balance, and nausea and vomiting. These symptoms can range from mildly annoying to completely incapacitating and should always be assessed whenever a person has an ear disorder and loss of hearing. Ménière disease and labyrinthitis cause vertigo.

A patient who experiences dizziness and positional vertigo should be cautioned to avoid suddenly turning her head or making other movements that aggravate the vertigo. She should be told to call for assistance whenever she needs to move from her bed or chair. When helping the patient to her feet, move slowly and give her time to stand for a moment before beginning to walk. **Typically, patients with this kind of vertigo feel that the room is spinning around during an attack, and any motion exacerbates the sensation.** While the patient is having an attack of vertigo, she should lie in bed and remain as motionless as possible. Stabilizing her head with a pillow on either side may encourage immobility. Attacks can last from a few minutes to hours.

Medications to reduce motion sickness and nausea should be given precisely as prescribed. These are usually given every 3 to 4 hours or on a preventive basis **before** the patient's symptoms become severe. A series of head movements called *Epley maneuvers* or *Brandt-Daroff exercises* can be helpful.

When increased fluid pressure in the inner ear is suspected as the cause of dizziness, the provider may order a low-sodium diet and limit fluid intake. Patients with recurrent attacks of vertigo are encouraged to stop smoking if they are habitual tobacco smokers. Tobacco is vasoconstrictive and can affect the blood supply to the inner ear and nerves. **Stress may affect the frequency of attacks of vertigo in patients with inner ear disorders.** Teaching the patient effective coping mechanisms to handle stress or adding rest periods into the work schedule may be helpful.

Tinnitus

Ringing, buzzing, or other continuous noise in the ear (**tinnitus**) can be mildly annoying or so severe that it interferes with activities of daily living and prevents the patient from getting sufficient sleep and rest. Common causes of tinnitus include **presbycusis** (hearing loss associated with aging), constant exposure to loud environmental noise, inflammation and infection in the ear, otosclerosis, Ménière disease, and labyrinthitis. Systemic disorders such as hypertension and other cardiovascular disorders, neurologic disease (including head injury), and hyperthyroidism and hypothyroidism also can cause ringing in the ears. **Tinnitus may be one of the first symptoms produced by an ototoxic drug.** Symptoms of tinnitus are subjective, and diagnosis is by patient history.

Clinical Cues

Because of the overload of sensory input to the brain, a patient with tinnitus will become more fatigued than others when in a noisy location such as a social gathering or a restaurant. Family and friends should be informed of this situation.

Medical treatment begins with efforts to determine the underlying cause and treat it. When the cause cannot be found, symptomatic relief is tried. However, some cases of intractable tinnitus resist all modes of conventional therapy. Less traditional measures that have varying degrees of success include biofeedback training and "masking." Sometimes substances that increase circulation are helpful (Niacin). Benzodiazepines, such as diazepam (Valium) or chlordiazepoxide (Librium), seem to help some people. Oral Lipo-Flavonoid has provided relief for many patients with tinnitus.

Biofeedback training is especially helpful in those cases in which emotional stress and anxiety are believed to be the underlying causes of tinnitus. Through visual or auditory signals, the person learns to relax and exert some degree of control over her autonomic nervous system. This can lower blood pressure and pulse rate and relax muscles that are very tense.

Masking simply provides a low-level noise to block out, or "mask," the head noise heard by the person complaining of tinnitus. Some examples include playing soft music or a tape of sounds of nature, such as a waterfall, while the person is resting or sleeping; providing "white noise" in the working environment, using a hearing aid to amplify sound from the outside and overcome head noise; and wearing a special tinnitus instrument, which is a combination hearing aid and tinnitus masker for people who have both hearing loss and tinnitus. The therapeutic effect of masking is highly individualized. Some people find instant relief, some have partial abatement of the head noise, and some do not benefit from attempts to mask the sounds of tinnitus. Earplugs or ear protection should be worn when noise exposure cannot be avoided.

Rehabilitation for Hearing Loss

Specific measures to rehabilitate a patient with hearing loss depend on the age and aptitude of the patient. Adults who have acquired the skills of speech and language before their loss of hearing occurred are better able to pick up language cues and understand what is being said to them, and therefore should have fewer problems with communication by language.

Lip-Reading (Speech Reading)

Instruction in reading lips is one mode of therapy for patients who are hearing impaired, but it is not a remedy for all difficulties. Only about 60% of the sounds in the English language can be identified by watching the lips. Most experienced lip-readers do not catch more than half of the words spoken to them. Communication by lip-reading is enhanced by other nonverbal clues, such as facial expressions and hand gestures. Learning to lip-read is difficult. It requires at least average intelligence, exceptional language skills, excellent eyesight, and much persistence and patience.

Sign Language

Many people who are deaf learn to communicate with sign language. American Sign Language (ASL) is the third most commonly used language in the United States. There are online dictionaries for ASL and several websites that provide tutorials (see Online Resources). Most major hospitals have someone on staff who can act as an interpreter for ASL.

Hearing Aids

An evaluation by a reputable audiologist can lead to a prescription for a hearing aid designed to provide the best possible improvement of hearing. Hearing aids can improve hearing for a variety of types of hearing loss. For people who do not have a defect in the middle ear, a hearing aid can transmit amplified sound from the receiver through the eardrum to the inner ear. This is accomplished by amplifying sound waves transmitted by air conduction and bone conduction. There are many types of hearing aids on the market. Newer digital types can amplify the tones needed while masking other levels of noise. It takes time to adapt to the use of a hearing aid, and the audiologist must make repeated adjustments to the device to achieve optimum function.

The design of a hearing aid varies. Some are worn in the ear, others behind the ear, and still others are built into the frame of eyeglasses. Persons with binaural hearing loss (both ears are affected) must wear a hearing aid in each ear. Regardless of the type of hearing aid, it will have a microphone, an amplifier, a receiver, and a battery (Figure 25-13).

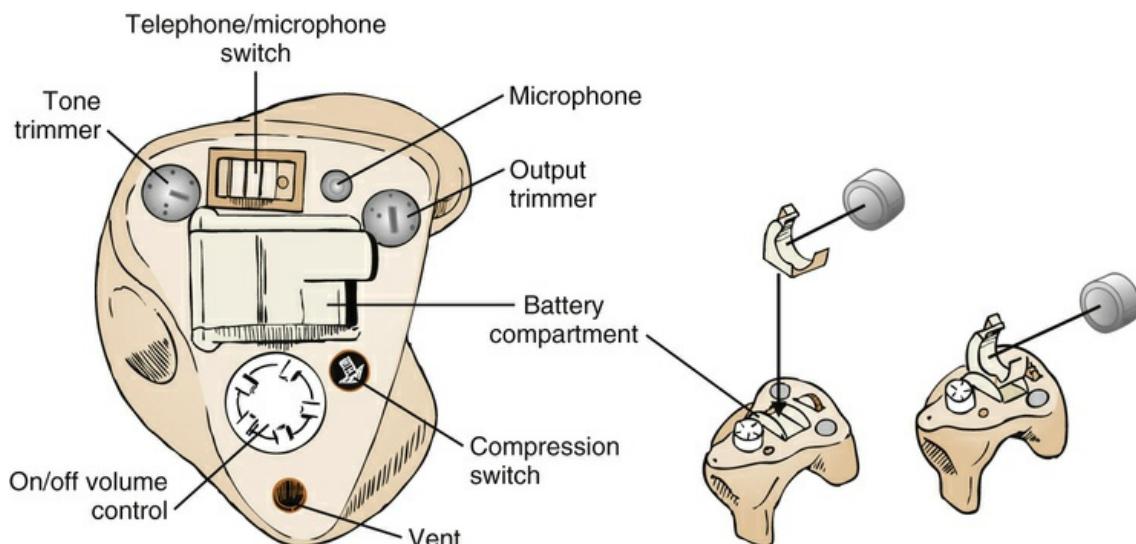

FIGURE 25-13 Parts of a typical in-the-ear hearing aid. (From Black JM, Hawks JH: *Medical-surgical nursing: Clinical management for positive outcomes*, ed. 7, Philadelphia, 2005, Saunders.)

The hearing aid should not be handled roughly or dropped. The ear mold can be cleaned with soap and water, but the other parts of the aid should not get wet (see Box 25-5). Hair spray can damage the microphone of a hearing aid. Regular servicing by a dealer can keep the aid in good working order. When an incapacitated patient has a hearing aid, you are responsible for the security of the hearing aid.

Recently implantable middle-ear devices have become available for those who have limited success with conventional hearing aids and have severe sensorineural hearing loss (Shohet, 2012). These are indicated for adults 18 years or older.

Cochlear Implant

Cochlear implants are now available for some patients who have no hearing at all. The device is a small computer that changes spoken words into electrical impulses that are transmitted via an implanted coil to the nerve endings in the cochlea. Success with the surgical implant varies considerably from one person to the next (Figure 25-14). Bone hearing devices and semi-implanted devices are under development. A speech therapist works with the patient once the cochlear implant is in place. Rush Limbaugh is one celebrity who has a cochlear implant in each ear.

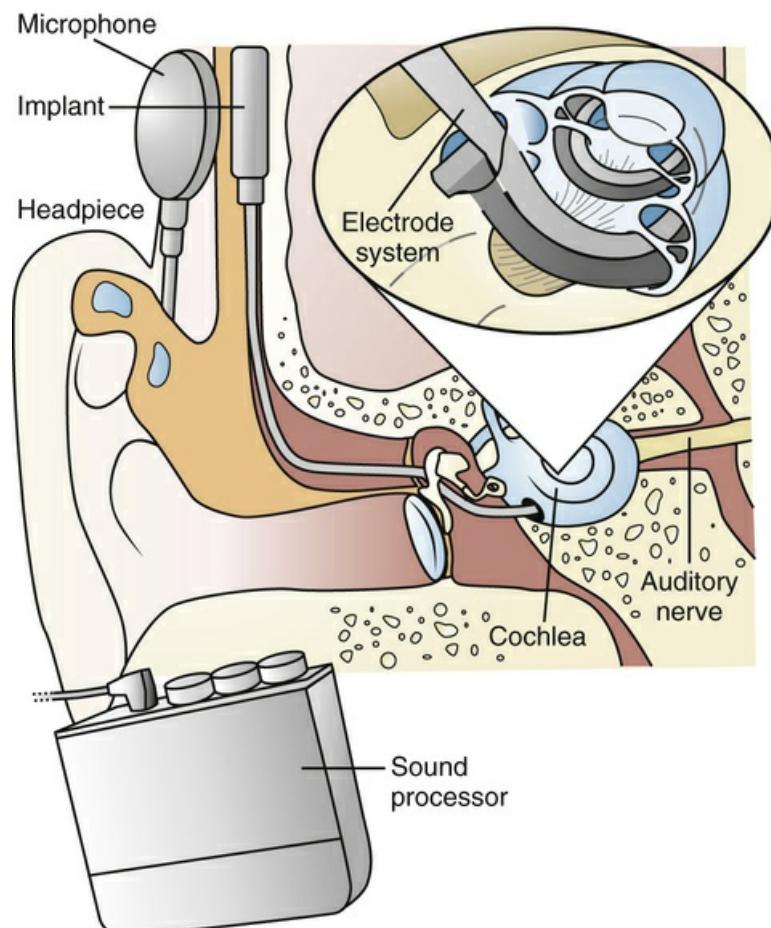

FIGURE 25-14 Cochlear implant.

Hearing-Assistive Devices

Many devices on the market use hearing aid technology. These devices assist people to hear telephone conversations, television, and sound systems, such as those in church or the theater. A telecommunication device for the deaf (TDD) is available. It is a combination typewriter and telephone and can be used to communicate with someone else who has a TDD or can be used to call a relay center that then communicates the message to the intended person. There are alarm clocks that activate a flashing light, smoke detectors that flash light, and doorbells and telephones that flash a light when a sound is produced. "Hearing ear" dogs are trained to alert their owners to particular sounds and to keep their owners safe when around traffic.

Community Care

Public education about the dangers of loud noise and music could do much to prevent thousands of people from becoming hearing impaired. Teaching people to seek prompt medical attention for symptoms of otitis media prevents damage to the tympanic membrane and preserves hearing ability.

Encouraging those with hearing impairment to have a thorough evaluation and to try a hearing aid could do much to improve the quality of their lives. There is little economic reason for refusing to **try** a hearing aid. Veterans should be told that the Veteran's Administration Health Clinics will perform hearing tests and supply a hearing aid. The Office of Vocational Rehabilitation may provide this service as well. Nurses in home care and in long-term care settings should frequently assess the function of the patient's hearing aid.

Older adults with arthritis or poor vision may have difficulty properly inserting the battery into a hearing aid. If the aid is not working, it may be that the battery simply is not inserted correctly.

Get Ready for the NCLEX® Examination!

Key Points

- Eye disorders are caused by injury, disease, or genetic predisposition.
- Everyone older than 40 years should have a complete eye examination.
- After age 65 years, an eye examination is recommended every 1 to 2 years.
- Control of diabetes mellitus and hypertension can help preserve vision.
- Obtaining a good history is important to data collection regarding vision.
- The tympanic membrane must be able to vibrate when sound is received for the sound waves to be transmitted to the middle ear.
- The bones of the middle ear transmit the sound waves to the inner ear.
- Sound is transmitted from the inner ear to cranial nerve VIII.
- Changes in the ear structures with aging may cause hearing impairment.
- Exposure to loud noise causes sensorineural hearing loss.
- A variety of drugs are ototoxic (see [Box 25-3](#)).
- There are several diagnostic tests and examinations for problems of the ear (see [Table 25-6](#)).
- Learning to communicate with people who are hearing impaired is important for nurses (see [Box 25-4](#)).
- Labyrinthitis and Ménière disease cause dizziness and vertigo.
- Decreasing stress often decreases dizziness and vertigo.
- Tinnitus is common with a variety of ear disorders.
- A variety of treatments are available to help patients with tinnitus; biofeedback and masking help many people.
- Lip-reading or speech reading is helpful to people with hearing impairments but is difficult to learn.
- Various types of hearing aids are available, but using one takes practice.
- Cochlear implants are available for patients who are totally deaf.
- Nurses should actively educate in the community about ways to prevent hearing loss.

Review Questions for the NCLEX® Examination

1. A nurse evaluates the visual acuity of a patient using the Snellen chart. Which statement is true regarding the use of the Snellen chart?

1. The chart is placed 40 feet away from the patient.
2. The patient reads the letters using one eye at a time.
3. The numerator (top number) indicates the smallest line that the patient could read.
4. The denominator (bottom number) refers to the patient's distance from the chart.

NCLEX Client Need: Health Promotion and Maintenance, Disease Prevention

2. While looking at a card with a geometric grid of identical squares, a patient is asked to focus on a central dot and to describe any distortions of the surrounding boxes. Which patient statement indicates a need for further diagnostic testing?

1. "I get dizzy staring at these boxes for so long."
2. "I am beginning to see color differences in the squares."
3. "I can see all the boxes surrounding the dot."
4. "There are wavy lines around the central dot."

NCLEX Client Need: Physiological Integrity, Reduction of Risk Potential

3. During a provider visit, a 65-year-old man complains of pain in his right eye associated with excessive tearing. The nurse notes that the eye is red with lashes rubbing against the cornea. A likely condition would be:

1. ptosis.
2. ectropion.
3. hordeolum.
4. entropion.

NCLEX Client Need: Physiological Integrity, Physiological Adaptation

4. Which nursing action(s) demonstrate(s) appropriate care of a patient who is visually impaired?
(Select all that apply.)

1. Introduce self before touching.
2. Speak slowly with a loud voice.
3. Keep the door ajar.
4. Ensure ready access to the call button for assistance.
5. Assist with feeding using the clock method.

NCLEX Client Need: Psychosocial Integrity, Sensory/Perceptual Alterations

5. When a patient is receiving Lasix for a problem with edema, which assessment relative to this drug is important to the patient's health?

1. Measuring the blood pressure
2. Determining whether the patient is nauseated
3. Inquiring about constipation
4. Checking for hearing loss

NCLEX Client Need: Physiological Integrity, Pharmacological Therapies

6. A nurse applies a vibrating tuning fork to the middle of a patient's forehead. What response would indicate normal hearing?

1. Hearing the sound in the back of the head.
2. Feeling a vibration but hearing no sound.
3. Hearing the sound in the middle of the head.
4. Feeling a vibration and hearing a sound in the temporal area.

NCLEX Client Need: Physiological Integrity, Physiological Adaptation

7. When administering eardrops to an adult, the nurse would:

1. draw the pinna upward and toward the front of the head.
2. draw the pinna upward and toward the back of the head.
3. pull the pinna downward and toward the front of the head.

4. pull the pinna downward and toward the back of the head.

NCLEX Client Need: Physiological Integrity, Basic Care

8. A patient returns 1 week after receiving hearing aids and states, "I guess I may as well return these—I just cannot get used to them." What is an appropriate nursing response? (*Select all that apply.*)

1. "Maybe a different type of hearing aid would be better for you."
2. "You have not been able to hear well for a long time. Adjusting to the way you hear the sound through a hearing aid may take quite a bit of time, but it will be worth it!"
3. "In order to adjust to the hearing aids, you must wear them most of the time. Are you able to keep them in most of the time, or do you spend most of your time without them?"
4. "My daughter adjusted to hers in just a few days. Something is not right here."

NCLEX Client Need: Psychosocial Integrity, Coping Mechanisms

9. When communicating with a patient who is hearing impaired, the nurse should: (*Select all that apply.*)

1. sit at eye level facing the patient.
2. use a slightly higher tone than usual.
3. enunciate clearly.
4. speak directly into the patient's ear.
5. use simple, short sentences.

NCLEX Client Need: Psychosocial Integrity, Therapeutic Communication

10. While ambulating, a patient with Ménière disease complains of dizziness and vertigo. An immediate nursing action would be to:

1. provide oxygen.
2. assist the patient to supine position.

3. administer nausea medication.

4. notify the provider.

NCLEX Client Need: Physiological Integrity, Physiological Adaptation

Critical Thinking Questions

Scenario A

Mr. Hartman comes to the ambulatory clinic because he “got something in my eye” while using the weed trimmer.

1. What type of examinations would you expect the health care provider to perform?
2. What would you teach Mr. Hartman about eye safety before he leaves?
3. What questions would you ask him about basic eye care while you are interviewing him before the provider sees him?

Scenario B

Mrs. Como is admitted to the hospital for management of her hypertension. She has had sensorineural deafness for several years, and it is much worse in her left ear than in her right. Her inability to hear well causes additional stress for Mrs. Como, and she is especially anxious about being in the hospital among strangers. Mrs. Como also suffers from tinnitus, which adds to her stress and inability to relax and rest. Tinnitus and the stress of not being able to hear adversely affect Mrs. Como's hypertension.

1. What evidence would you expect to find that would indicate that Mrs. Como has a hearing impairment?
2. What can the nurses do to improve communication with Mrs. Como and help allay her anxiety about being in the hospital?
3. Why could her hearing problem make her blood pressure rise?

Scenario C

Mrs. Martinez is scheduled for a cochlear implant and states that she “really doesn't understand” how the device works.

1. What should she be told?
2. What should she expect she will need to do after the cochlear implant surgery?

CHAPTER 26

Care of Patients With Disorders of the Eyes and Ears

Objectives

Theory

1. Review errors of refraction and their treatment.
2. Devise nursing care for a patient who is undergoing a corneal transplant.
3. Compare measures used to provide assistance after a chemical eye burn with measures for an eye injury with a foreign object.
4. Summarize the signs and symptoms of selected disorders of the eye and appropriate medical treatment and nursing interventions for each.
5. Plan nursing interventions for a patient having a scleral buckle or a cataract extraction.
6. Present aids and resources for people with vision loss.
7. Explore the effects of hearing or vision loss on an individual and his family.
8. Explain the signs and symptoms of selected disorders of the ear, appropriate medical or surgical treatment, and nursing interventions for each.
9. Compile aids and resources for people with impaired hearing or tinnitus.

Clinical Practice

10. Teach a patient with tinnitus or vertigo measures that may decrease the symptoms.
11. Provide appropriate preoperative care for a patient who is having eye surgery.
12. Properly administer eye medications to patients.
13. Teach a patient to properly administer ear medication.
14. Provide appropriate care for a patient after ear surgery.
15. Assist a patient to find resources for low-vision assistance.

KEY TERMS

- accommodation (ă-kōm-ō-DĀ-shūn, p. 597)**
astigmatism (ă-STIG-mă-tĭsm, p. 598)
drusen (drū-zĕn, p. 613)
enucleation (ē-nū-klē-Ā-shūn, p. 601)
exophthalmos (ěk-sōf-THÄL-mös, p. 599)
hyperopia (hī-pěr-Ö-pě-ă, p. 597)

myopia (mī-ō-pē-ă, p. 597)

nystagmus (nīs-tāg-mūs, p. 617)

photodynamic therapy (fō-tō-dī-nām-īk thēr-ě-pē, p. 613)

photophobia (fō-tō-fō-bē-ă, p. 602)

presbyopia (prēz-bē-ō-pē-ă, p. 597)

tympanoplasty (tīm-pă-nō-plăs-tē, p. 616)

Common Disorders of the Eye

Errors of Refraction

The most common visual defects are those of refraction. This means that light rays entering the eye are not “refracted,” or bent, at the correct angle ([Figure 26-1, A](#)) and therefore do not focus on the retina. Errors of refraction may be caused by a number of structural defects within the eyeball itself. For example, if the distance between the lens and retina is too short, the light rays focus behind the retina. This causes difficulty in seeing objects close at hand and is called *farsightedness* ([hyperopia](#)) ([Figure 26-1, B](#)).

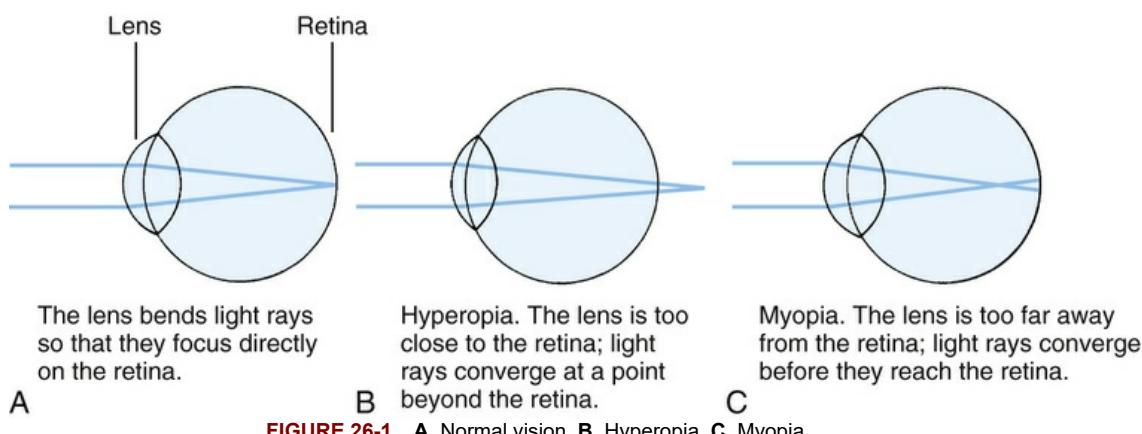

FIGURE 26-1 **A**, Normal vision. **B**, Hyperopia. **C**, Myopia.

If the opposite is true, and the eyeball is too elongated, the light rays will converge and focus in front of the retina. The individual then has difficulty seeing objects at a distance and is referred to as being *nearsighted*. *Nearsightedness* is called [myopia](#) ([Figure 26-1, C](#)).

Light rays from distant objects do not enter the eye at the same angle as light rays from near objects. When looking off into the distance and then quickly looking down at a book, the eyes must make an adjustment to the difference in the light rays entering the eye. This adjustment, which is called [accommodation](#), is accomplished by ciliary muscles and ligaments that change the shape of the lens, making it more rounded or flatter, thereby allowing light rays to fall on the retina ([Figure 26-2](#)).

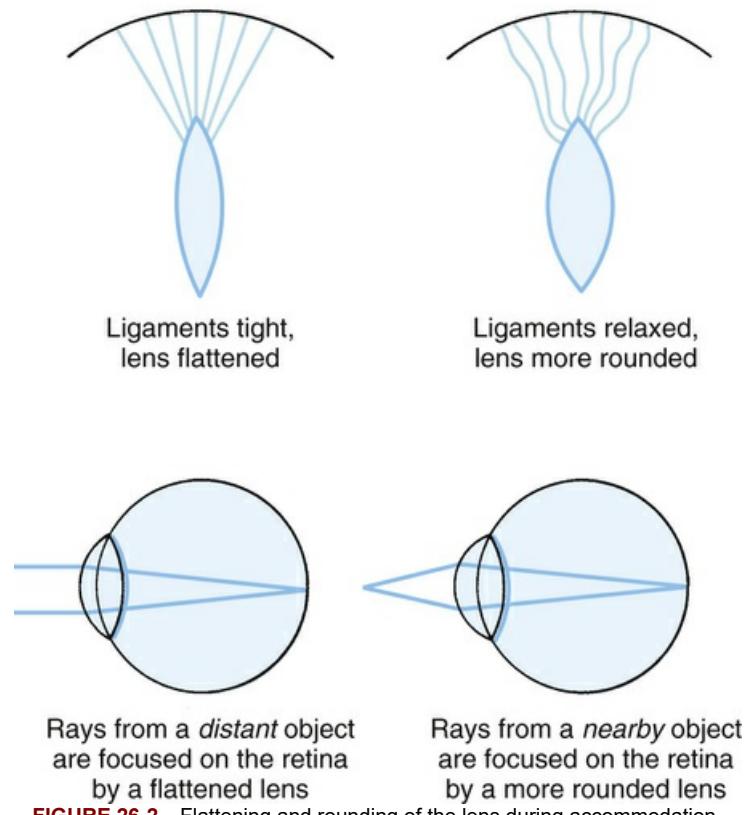

FIGURE 26-2 Flattening and rounding of the lens during accommodation.

With increasing age, the ciliary muscles become less elastic and cannot readily accommodate the needs of distant and near vision. Hardening of the ciliary muscles occurs in many people older than 40 years and is known as **presbyopia**. Bifocal glasses are usually prescribed for this condition because they allow for two sets of lenses in one pair of glasses, one for viewing distant objects and one for seeing close objects.

Astigmatism is a visual defect that results from a warped lens or an irregular curvature of the cornea; either condition will prevent the horizontal and vertical rays from focusing at the same point on the retina. Actually, very few people have perfectly shaped eyeballs, and thus there are very few who do not have some degree of astigmatism. If the astigmatism is very slight, the eye can accommodate for its imperfection by changing the shape of the lens. If there is a serious error of refraction, the eyes will tire very easily or the person will have defective vision because the eyes cannot change the shape of the lens enough to compensate for the abnormality.

Serious errors of refraction are treated with prescription eyeglasses or contact lenses that are fitted so that the light rays are brought into proper focus on the retina. In recent years, advances have been made in refractive surgery that permit correction of refraction problems for some people. Those who are nearsighted (myopic) can undergo one of three procedures. In photorefractive keratectomy (PRK), an excimer laser is used to remove a thin layer of tissue from the cornea. This corrects the excessive curvature of the cornea that is interfering with the proper focus of light rays through the lens. The preparation takes 30 minutes and the actual procedure takes less than a minute to perform; visual improvement is apparent within 3 to 5 days. Laser in situ keratomileusis (LASIK) is the most common procedure for nearsightedness in the United States. The middle layer of the cornea is reshaped with a laser after a very thin outer layer of the cornea is peeled back. The outer layer is replaced. Postoperative recovery is very rapid with little discomfort. The procedure takes about 10 to 15 minutes per eye and is performed as an outpatient procedure.

Radial keratotomy is used to correct both nearsightedness and astigmatism. Tiny cuts are made in the cornea that flatten it. It is another outpatient procedure. LASIK and PRK have mostly replaced this procedure.

Uveitis

The uveal tract consists of the iris, the ciliary body, and the choroid. Uveitis is inflammation of the

uveal tract. The cause is unknown; uveitis may result from allergens, trauma, infectious agents, or systemic disease (rheumatoid arthritis, herpes simplex, herpes zoster, or bacterial infection). Signs and symptoms are tearing; blurred vision; photophobia; aching around the eye; a bloodshot sclera; or a small, nonreactive, irregular pupil. Treatment involves resting the ciliary body with a cycloplegic drug. The pupil is dilated to prevent adhesions of the involved structures. Analgesics, antibiotics, and ocular steroid injections may be used. Cool or warm compresses are used for discomfort. Sunglasses should be worn to reduce photophobia. Low light indoors is advisable.

Dry Eye

Dry eye is a common condition in people over 40, especially in women after menopause. Because our population of older adults is growing, the incidence of dry eye is becoming more common. The symptoms of dry eye include tearing, soreness, and a gritty feeling in the eye. These symptoms can be treated with lubricating eye drops, but if the condition is left untreated it may lead to corneal ulcers.

Dry eye may be caused by a deficiency of tears, such as seen in Sjögren's disease (see [Table 12-2](#)), or it may be caused by evaporation, resulting from a dysfunction of meibomian glands that can be exacerbated by environmental conditions such as dust and wind ([Miller, 2013](#)).

Dry eye is managed by treating the underlying cause, such as meibomian gland dysfunction, and keeping the tear layer of the eye moist and functional. Patients with insufficient tears should use a solution of artificial tears that is most appropriate for their condition, including those containing sodium hyaluronate, which increases the stability of the tear film, and/or carbomer-based products that adhere to the ocular surface for an extended time. Studies have shown that carbomer-based products are more effective than artificial tears containing polyvinyl alcohol (PVA) ([Miller, 2013](#)).

Corneal Disorders

Keratitis

Keratitis is an inflammation of the cornea caused by irritation or infection. Patients who have had a stroke may develop irritation of the cornea because the eyelid does not close normally. Keratitis may occur in a comatose patient who is not receiving proper eye care. Some people with [exophthalmos](#) (protruding eyeballs) develop this disorder. Infection is common among those who wear contact lenses. The infecting agent may be in home-prepared saline solution used for cleaning the lenses. The eye becomes reddened, and there may be tearing, along with a feeling of grittiness or pain. Discharge from the eye may occur. Treatment of irritation is instillation of artificial tears. Infection is treated by a medication to kill the organism. Drugs may be given topically, subconjunctivally, or by intravenous (IV) infusion.

Corneal Ulcer

A corneal ulcer may occur from irritation, infection, or injury. The ulcer is cultured to determine whether there is a causative organism when there is no history of injury. Antibiotic medication is usually prescribed. Scarring from corneal ulcers or severe infection is treated by keratoplasty.

Corneal Transplantation (Keratoplasty)

Corneal transplants replace corneas that have been damaged by genetic disorders, trauma, ulcers, or disease such as keratitis (inflammation of the cornea); transplants help restore corneal clarity. Two types of procedures are available: a full-thickness keratoplasty (corneal transplant) and a lamellar keratoplasty, which replaces only a superficial layer of corneal tissue. The full-thickness keratoplasty restores vision in approximately 95% of patients ([Figure 26-3, A](#)). Corneas for transplantation are harvested from donor cadavers soon after death. The transplantation is performed with regional anesthesia. A new procedure, Descemet stripping endothelial keratoplasty (DSEK), replaces only the inside lining of corneal cells through a tiny incision. There are no sutures and the cells are held in place for the first 24 hours by an air bubble. Vision is improved in a matter of weeks. DSEK is used only when disease is limited to the endothelial surface. Artificial cornea transplantation studies are showing success in both adults and children; this procedure reduces the chance of rejection of human tissue.

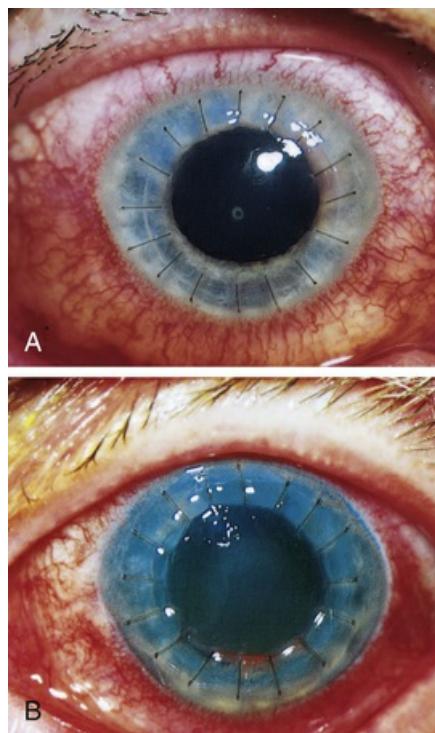

FIGURE 26-3 **A**, Keratoplasty (corneal transplant). **B**, Acute transplant rejection. (Courtesy Ophthalmic Photography at the University of Michigan, W.K. Kellogg Eye Center, Ann Arbor, Michigan.)

The patient must be “on call” to come for the transplantation, as it is unpredictable when a donor cornea will become available. The surgery is an outpatient procedure. The patient must realize beforehand that it takes 1 to 2 weeks before any improvement in vision is noticeable and that improvement will continue for several months. Because the cornea does not have an abundant blood supply, healing is very slow and is not complete for about 1 year. **Prevention of infection is extremely important.** Preoperative care is much the same as for other eye surgeries.

Safety Alert

Correctly Mark the Surgical Site

As part of the preoperative preparation, clearly mark the operative site, verifying verbally with the patient that the site is correct. Document that this was done in the medical record.

After surgery, the patient remains in recovery for 1 to 2 hours and then is discharged home. A pressure dressing and eye shield are applied in the surgical suite after the procedure and should be removed only by the provider the next day. The shield is then worn at night and when around small children or pets for at least a month. The pressure dressing helps keep the donor tissue in contact with the eyeball. Nursing actions focus on caring for the patient's disturbed visual sensory perception. Instructions regarding safety are provided before discharge. The patient may lie only on his back and nonoperative side postoperatively. Graft rejection is a possibility and is heralded by inflammation beginning near the graft edges (see *Figure 26-3, B*). This finding must be reported promptly. Should the first transplant fail, the procedure can be redone.

Sometimes an eye excimer laser is used to polish the cornea, restoring vision. A scleral lens has been developed. It is like an oversized contact lens that arches over the cornea. The space between the lens and the cornea is filled with artificial tears, providing lubrication, and thus the scleral lens fulfills the optical functions of the damaged cornea. These innovations may eventually make corneal transplants unnecessary for many people.

Older Adult Care Points

An older adult patient who is temporarily or permanently visually impaired may experience a loss of independence and a change in self-perception. This patient will need specific suggestions on ways to maintain independence. After an outpatient eye surgery, the person will need someone to help at home for a few days, at least.

Eye Trauma

Eye trauma occurs from accidents and from debris in the air. Not using safety goggles or glasses when sanding or operating weed trimmers and various types of power equipment accounts for most incidents of foreign bodies landing in the eyes ([Bashour, 2014](#)).

Removal of Foreign Bodies From the Eye

If the foreign body is not deeply embedded in the tissues of the eye, it can easily be removed by irrigation. Irrigation with clear, lukewarm water or sterile water or saline is used to remove a foreign body sticking to the cornea. Continuous irrigation can be done with small tubing, and a bottle of solution or an irrigating syringe or bottle can be used. Be very careful not to touch the eye with the tip of the irrigating device. Sometimes a speck of foreign matter on the cornea can be removed with a moistened, sterile cotton swab. Have the patient tilt the head back. Hold the eyelids open to prevent blinking ([Cao, 2013](#)).

If a foreign body is sticking out of the eye, no attempt to remove it should be made. Both eyes should be patched to prevent further eye movement, and the patient should be transported to the emergency department or to an ophthalmologist. If the patient continues to complain of a sensation that a foreign body is still in the eye after it appears to have been removed by irrigation, or complains of continuing pain, refer to a provider immediately, because there may be a corneal abrasion.

The provider will apply a stain to the eye to assess whether the cornea is abraded. If there is an abrasion, medicated ointment will be prescribed, and the eye will be patched ([Box 26-1](#)). The patient must be given instructions on how to instill the ointment. A thin line of eye ointment is applied from the inner canthus to the outer canthus along the lower eyelid inside the conjunctival sac ([Figure 26-4](#)). The patient closes the eyelid and moves the eyeball around in the socket to distribute the ointment. Excess medication is gently wiped away with a tissue, moving from the inner to the outer canthus. If an eye patch is not applied, the patient is warned that the ointment may blur vision for a while. A corneal abrasion is painful; a nonsteroidal anti-inflammatory drug may be used for discomfort.

Box 26-1

Applying an Eye Patch

- Perform hand hygiene, and cleanse the skin of the patient's forehead and cheek with a skin preparation solution or pad.
- Prepare strips of nonallergenic paper or other tape to secure the patch.
- Ask the patient to close both eyes and position the pad over the lid of the eye to be patched.
- Secure the patch by placing strips of tape diagonally over the patch from the cheek to the forehead. Use several strips of tape to ensure adhesiveness.
- After surgery, the shield is used for 2 to 6 weeks, depending on the surgeon's instructions.

For a Pressure Patch

- Use two eye patches. Fold the first one in half; place it over the closed lid and then place the other patch on top of the folded one. Apply tape as instructed previously.

For Sleeping

- A plastic or metal eye shield may be placed over the eye and secured to further protect the eye. In many cases, the patch can be left off when the shield is placed for sleeping.

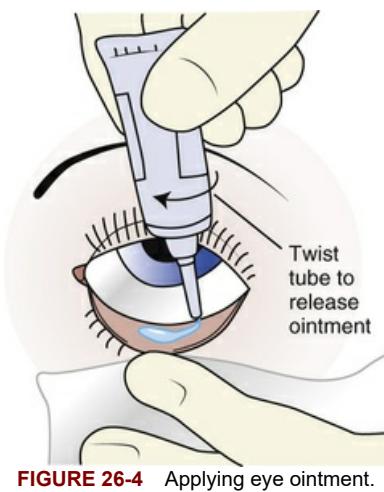

FIGURE 26-4 Applying eye ointment.

Chemical Burns

Chemical burns should be treated by lengthy, continuous irrigation. If available, an IV bag of normal saline is the preferred solution; otherwise, tap water will suffice. Place the patient supine with his head turned to the affected side. With gloves on, direct the stream of fluid to the inner canthus so that the stream flows across the cornea to the outer canthus, holding the lids apart with your thumb and index finger. Water should be lukewarm. At intervals, stop and have the patient close his eyes to move secretions and particles from the upper eye to the lower conjunctival sac; then begin again. Continue for 15 to 30 minutes. The patient should be seen by a provider as soon as possible. All commercial businesses where exposure to chemicals is a possibility must comply with Occupational Safety and Health Administration (OSHA) standards and have an eyewash station within the facility as close as possible to the area where chemicals are likely to be used (Randleman, 2013).

Enucleation

If the eye is too damaged by trauma to be salvaged or is irreparably damaged by disease or tumor, **enucleation** (removal of the eye) is performed. An implant is created to maintain the orbital anatomy while a matching artificial eye is created. The implant is sutured to the muscle structures. When the artificial eye is placed, the muscle attachments allow for coordinated eye movement.

Postoperatively, observe for signs of complications such as excessive bleeding, swelling, increased pain, elevated temperature, or displacement of the implant. Losing an eye is a devastating experience even when there has been a long period of painful blindness preoperatively. Understanding of the emotional effects and support of the patient are primary nursing responsibilities. The permanent prosthesis is placed about 6 weeks after the surgery.

Care of an artificial eye.

The procedure for cleansing and caring for an artificial eye is similar in many ways to the care of dentures. Both require basic principles of cleanliness, careful handling, and proper storage. An artificial eye is very expensive and must be handled very carefully.

The artificial eye is cleansed by hand (no cloth used) with gentle soap (mild hand soap or baby shampoo) and water, unless the patient, his family, or the provider directs otherwise. Keep it in a safe place to prevent damage. When the eye is to be reinserted, it should be cleansed again with soap and water and remain wet with water or contact lens solution. When inserting or removing the prosthesis, have the head over a padded surface. The patient's upper lid is lifted, and the eye is inserted with the notched end toward the nose. After the prosthesis is placed as far as possible under the upper lid, the lower lid is depressed, allowing the eye to slip into place.

Cataract

A **cataract** is opacity of the lens that produces an effect similar to one a person would experience when looking through a sheet of falling water (Figure 26-5). A cataract causes a blurring of vision because the lens, which is normally transparent, becomes cloudy and opaque.

FIGURE 26-5 Cloudy appearance of eye with cataract. (Courtesy Ophthalmic Photography at the University of Michigan, W.K. Kellogg Eye Center, Ann Arbor, Michigan.)

Etiology and Pathophysiology

Congenital cataracts are most commonly caused by maternal infection with rubella or *Toxoplasma gondii*. Cataracts typically occur as a result of aging and are found in people older than 50 years (adult-onset [senile] cataracts).

Traumatic cataracts may occur from a physical blow, extreme heat, or chemical toxins. Cigarette smoking increases the risk of developing cataracts. Heavy drinking also is implicated. Chronic use of corticosteroids predisposes to the development of cataracts.

Health Promotion

Cataract Prevention

Encouraging the habit of wearing sunglasses that protect from ultraviolet light and a hat when outdoors can help prevent the development of cataracts. Cumulative exposure to ultraviolet light is the greatest risk factor for cataracts ([UMM, 2014](#)).

Think Critically

What would you teach a person with rheumatoid arthritis about eye care, if that person is on corticosteroids most of the time?

Signs, Symptoms, and Diagnosis

In addition to the blurred vision that is typical of opacity of the lens, with cataracts there may be decreased color perception. Uncomplicated cataracts are usually painless, but the patient may have **photophobia** (intolerance of light). Assessment may reveal the following symptoms:

- Hazy, blurred, or double vision (**diplopia**)
- Increasing complaints about glare
- Increasing nearsightedness
- Complaints that colors are faded or appear yellowish or brownish
- Desire for increased light by which to read
- Difficulty with night vision
- Frequent need for eyeglass prescription change

The loss of vision associated with cataracts is progressive and sometimes is partially caused by secondary glaucoma. As an untreated cataract progresses, the lens of the eye becomes cloudy or milky white, then may turn yellow, and eventually may become brown or black (see [Figure 26-5](#)).

Diagnosis of a cataract is confirmed by examining the dilated pupil with a slit lamp, which enables the examiner to see opacities more clearly. Glaucoma should first be ruled out as a possible cause of the symptoms. Tonometry is used to determine intraocular pressure (IOP), or the fluid pressure within the eye. The Tono-Pen may be used for screening purposes.

Treatment

Cataract surgery is performed when the loss of vision greatly affects the quality of the person's life. The only effective method of treating cataracts is surgical removal of the affected lens with clear lens implantation; cataract surgery is the most commonly performed surgical procedure in the United States. Surgical techniques are (1) **extracapsular extraction**, in which the lens is removed along with the anterior portion of the lens capsule; and (2) **intracapsular extraction**, in which both the capsule and the lens are removed. Extracapsular extraction is most common because it allows an intraocular lens to be inserted inside the remaining capsule. Lenses are now available that allow for multifocal vision rather than monovision, in which vision is good at only one distance without glasses. One type of lens is hinged to the ciliary muscle, allowing for accommodation of vision for various distances ([Harvard Eye Associates, 2010](#)). If a monovision lens is chosen, vision is corrected for nearsightedness or farsightedness by the lens implant, and further correction of vision is achieved with regular eyeglasses or contact lenses. Vision is improved within 2 weeks and is usually fully recovered within 3 months of surgery ([Nursing Care Plan 26-1](#)).

Nursing Care Plan 26-1

Care of a Patient Undergoing a Cataract Extraction

Scenario

Mrs. Fort, age 79 years, is admitted to the outpatient surgery unit for extraction of a cataract of the left eye with lens implant. The vision in her right eye also is affected by a cataract, but the visual loss is not as severe in that eye. Mrs. Fort suffers from a crippling osteoarthritis of the hands, but her general health is good. She is well oriented, outgoing, and physically active. She lives alone in an apartment building for retired senior citizens. Her daughter and son-in-law live nearby and are in daily contact with her. Mrs. Fort has not been hospitalized since she was treated for pneumonia 20 years ago and she is concerned about what to expect preoperatively and postoperatively.

Problem Statement/Nursing Diagnosis

Insufficient knowledge/Deficient knowledge related to preoperative and postoperative procedures and care.

Supporting Assessment Data

Subjective: "I have never had surgery before."

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will verbalize preoperative routine activities and postoperative procedures and expectations.	Teach patient and daughter about eye medications to be used at home and how to instill them; how to dress and shield eye properly; how to remove bandage without contaminating eye.	To comply with instructions, teaching must occur on how to instill drops and how to dress and shield the eye and perform care needed.	Provided teaching for patient and daughter. Will ask for return demonstration before discharge. Left printed instructions.

Problem Statement/Nursing Diagnosis

Potential for injury/Risk for injury related to postoperative complications such as hemorrhage and increased intraocular pressure.

Supporting Assessment Data

Objective: Undergoing cataract extraction; hemorrhage and increased intraocular pressure are potential complications.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Intraocular hemorrhage will not	Teach signs and symptoms of complications that are to be reported to	Patient must know what to look for	Gave instructions and left printed list.

occur, and there will not be an increase in intraocular pressure.	provider immediately: increasing eye pain, purulent discharge, decreasing vision, fever or chills, increasing brow headache. Instruct to refrain from straining at stool; encourage to use milk of magnesia or stool softener to prevent straining as needed.	to report complications. Preventing the Valsalva maneuver will help prevent an increase in intraocular pressure.	Will ask for feedback before discharge. Verbalizes the ways to prevent raising intraocular pressure.
	Perform hand hygiene thoroughly before instilling eye medications or changing dressing; teach patient and daughter to wash hands before approaching eye area.	Aseptic techniques help prevent infection. Maintaining asepsis aids in protecting the surgical site from infection and prevents complications.	Patient and daughter state that they understand hand hygiene and aseptic techniques for postoperative eye care.
	Demonstrate how to put on eye shield for sleep.	Wearing a protective eye shield will protect the eye from bumps or scratches.	Instructed to clean the eye shield daily with 70% isopropyl alcohol.
	Instruct patient to avoid rapid or sudden movements and bending from the waist.	Bending from the waist increases intraocular pressure.	Instructed to crouch rather than bend at the waist and to avoid sudden movements.
	Instruct patient to take medication immediately for nausea and vomiting.	Quickly medicating for nausea may avert vomiting.	Instructions given and a written instruction sheet at bedside.
	Remind patient not to lie on affected side.	Sleeping on the affected side creates too much pressure on the eye.	Instruct to avoid sleeping on the operated side for at least 2 weeks.
	Encourage patient to seek assistance with ambulation while vision is blurred.	Walking alone with blurred vision increases risk for falls.	Instruct to seek assistance for ambulation.

Problem Statement/Nursing Diagnosis

Limited self-care ability/*Ineffective self-health management related to disabilities imposed by osteoarthritis.*

Supporting Assessment Data

Objective: Severe osteoarthritis of the hands with limited dexterity.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Assistance with administration of postoperative eye medications and eye care will be given by daughter.	Teach daughter techniques needed for postoperative eye care and give her a written schedule for that care.	Written instructions and a schedule reinforce the teaching and help care to occur on time.	Daughter observed care and administration of eye medications today; will demonstrate postoperative eye care when meds are next due.

Critical Thinking Questions

1. Why should one wait 5 minutes between instilling one type of eyedrop and the next type of eyedrop?
2. What is one of the most important things to teach someone who is to instill eyedrops or ointment postoperatively?

One technique for intracapsular cataract extraction (ICCE) uses **cryosurgery**, in which the lens is frozen by a supercooled probe and then removed.

Phacoemulsification, in which the tissue is pulverized and the debris is removed by suction, is often used for extracapsular cataract extraction (ECCE). These outpatient surgical procedures are performed under procedural sedation and local anesthesia. An intraocular lens implant is placed after cataract extraction. Postoperative care is covered later in this chapter.

Patient Teaching

General Care After Eye Surgery

Instructions for the patient and/or family caregiver:

- Always wash hands before instilling medication. Check the label of the container to be certain it is the right medication. Do not contaminate the applicator tip of the medication.
- Instill only the number of drops ordered; apply pressure at the inner canthus to prevent systemic absorption; close the eye gently (do not squeeze the eye shut).
- Change the eye patch dressing at least once a day; change as needed to keep the area clean.
- Follow the medication schedule prescribed by the provider exactly. (Send home a written schedule.)
- Maintain designated head position and activity restrictions.

- Report signs of complications: sudden, increasing pain in the eye, which can indicate hemorrhage; purulent drainage; decreasing vision; or signs of increased IOP, such as brow headache.
- Keep the follow-up appointment with the surgeon.
- Use caution to prevent getting water in the eye.
- Protect the eye during the day with glasses; use sunglasses for outside wear; wear a protective eye shield at night.

Nursing Management

The patient must be told that there is a period of visual adjustment after cataract surgery. The surgeon may prescribe miotic eyedrops after surgery to constrict the pupil and decrease the danger of lens dislocation. **Patient adherence to the schedule for postoperative medications is critical to prevent complications and promote healing.**

Think Critically

Can you identify patients who should be carefully assessed for signs and symptoms of cataract?

Glaucoma

Etiology

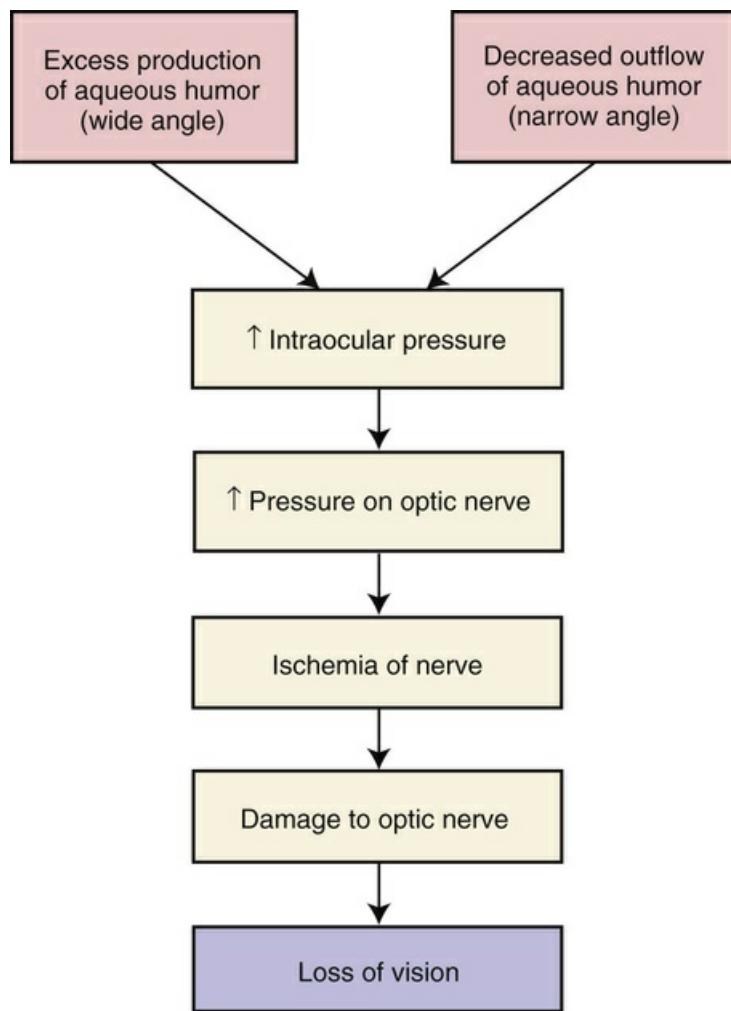

The term *glaucoma* comprises a complex group of disorders that involve many different pathologic changes and symptoms but have in common an optic neuropathy that damages the optic disc, causing atrophy and loss of peripheral vision. The neuropathy often is caused by increased IOP ([National Eye Institute, 2013](#)). Glaucoma may come on slowly and cause irreversible vision loss without presenting any other noticeable symptoms, or it may appear abruptly and produce blindness in a matter of hours. Glaucoma can be present at birth or can develop at any age. It can result from genetic predisposition, trauma, or another disorder of the eye. Glaucoma is commonly a manifestation of diseases and pathologies in other body systems. The amount of increased IOP that causes damage differs from one person's eye to another. **Blindness is preventable if the disorder is treated early.**

Think Critically

How can you include inquiries about family history or predisposing risk factors for glaucoma into your patient care?

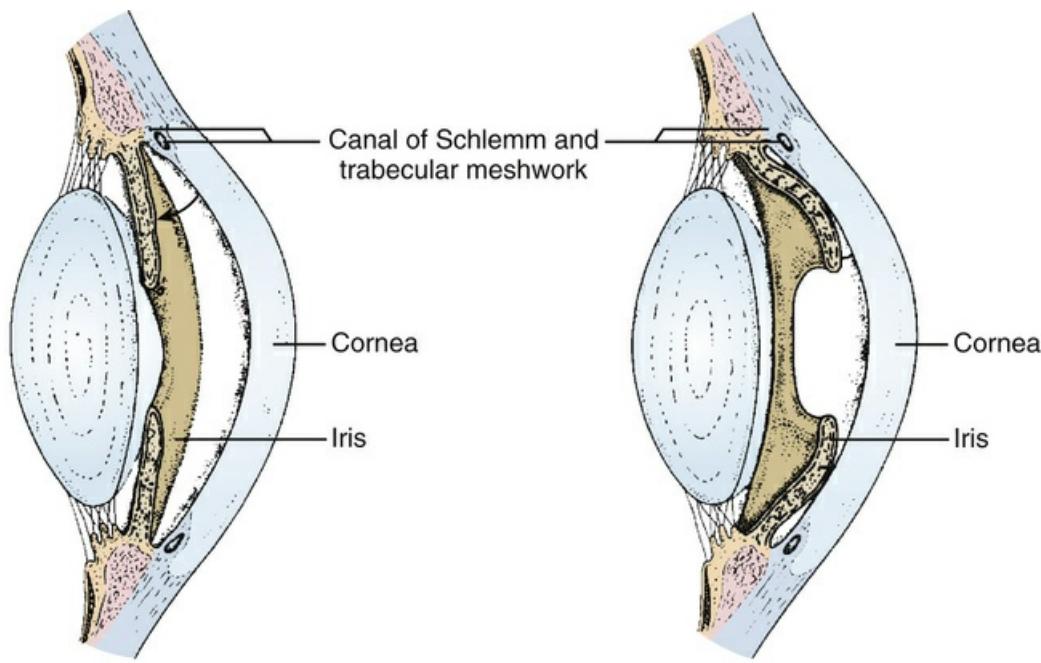

Pathophysiology

The IOP is determined by the rate of **aqueous humor** production and the outflow of the aqueous humor from the eye. Aqueous humor is produced in the ciliary body and flows out of the eye through the canal of Schlemm into the venous system ([Concept Map 26-1](#)). An imbalance may occur from overproduction by the ciliary body or by obstruction of outflow. Increased IOP greater than 22 mm Hg requires thorough evaluation. Increased IOP restricts the blood flow to the optic nerve and the retina. Ischemia causes these structures to lose their function gradually. **The vision impairment from damage to the optic nerve or retina is permanent.** Glaucoma may be secondary to eye infection, trauma, eye surgery, or ocular tumor.

CONCEPT MAP 26-1 Pathophysiology of glaucoma.

There are three types of glaucoma: narrow-angle or angle-closure (acute) glaucoma, open-angle (chronic) glaucoma (Figure 26-6), and associated or secondary glaucoma. The terms *narrow angle* (angle closure) and *open angle* refer to the angle width between the cornea and the iris. *Acute* and *chronic* refer to either the onset or duration of the problem. These two major types differ in their clinical signs and symptoms, treatment, and effects on vision. **Associated glaucoma** may occur with diabetes mellitus, hypertension, or extreme myopia or after retinal detachment.

Open-angle glaucoma
The angle between the iris and cornea is open, allowing outflow of aqueous humor through the canal of Schlemm and the trabecular meshwork

Narrow-angle glaucoma
The angle between the iris and cornea is constricted, blocking outflow of aqueous humor

FIGURE 26-6 Comparison of open-angle (wide, chronic) and narrow-angle (closed, acute) glaucoma. (From Lehne RA: *Pharmacology for nursing care*, ed. 5, Philadelphia, 2004, Saunders.)

Open-Angle Glaucoma

Signs and Symptoms

Open-angle, or chronic, glaucoma, in which there is no angle closure, is much more insidious and more common, occurring in about 90% of people with glaucoma. It often is an inherited disorder that causes degenerative changes in the aqueous humor outflow tracts. It may be caused by a mixture of factors of overproduction of aqueous humor and anatomic problems within the eye. It usually is bilateral and can progress to complete blindness without ever producing an acute attack. Its symptoms are relatively mild, and many patients are not aware that anything is wrong until vision has been seriously impaired.

Health Promotion

Danger Signals of Glaucoma

The National Society for the Prevention of Blindness lists the following symptoms as danger signals of open-angle glaucoma:

- Glasses, even new ones, that do not seem to clarify vision
- Blurred or hazy vision that clears up after a while
- Difficulty adjusting to darkened rooms, such as in movie theaters
- Seeing rainbow-colored rings around lights
- Narrowing of vision at the sides of one or both eyes

Encourage a complete eye examination if any of these signs is present.

Diagnosis

People at normal risk for glaucoma should be screened every 2 to 4 years before age 40, every 1 to 3 years from age 40 to 54, every 1 to 2 years from age 55 to 64, and every 6 to 12 months after age 65 (glaucoma.org, 2013). Those with high risk factors should be screened every 1 to 2 years after age 35.

People at high risk for glaucoma are:

- Those with diabetes
- African Americans (at least four times as many African Americans as non–African Americans have glaucoma-related blindness)
- Individuals with a family history of glaucoma

A commonly used screening technique for early detection of glaucoma is to measure IOP with an air tonometer. A puff of air is directed at the cornea, which causes a momentary indentation while a pressure reading is taken ([National Eye Health Education Program \[NEHEP\], 2014](http://National Eye Health Education Program [NEHEP], 2014)). The test is painless, and nothing but the air touches the eye. Verification of the diagnosis of glaucoma may require the use of a more complex instrument called an *applanation tonometer* (Figure 26-7). The cornea is flattened, and pressure is measured with a slit-lamp biomicroscope.

FIGURE 26-7 Applanation tonometer. (From Phipps WF, Monahan FD, Sands JK, et al: *Medical-surgical nursing: Health and illness perspective*, ed. 7, St. Louis, 2003, Mosby.)

Treatment

The initial treatment of choice for chronic (open-angle) glaucoma is medication rather than surgery. If drugs are not effective, or if they produce worrisome side effects, surgery is performed.

Drug therapy is intended to enhance aqueous humor outflow, decrease its production, or both by constricting the pupil (miotics) or by inhibiting the formation of aqueous humor (Table 26-1). Miotics cause blurred vision for 1 to 2 hours after use. Adjustment to dark rooms is difficult because of pupil constriction. Pilocarpine is available in an eye medication disk that resembles a contact lens. The disk is inserted into the conjunctival sac in a patient's lower eyelid, where it can remain for up to 7 days. The medication is slowly released. Use of the disk does not prevent the wearing of contact lenses. Diuretics may be prescribed to reduce the production of aqueous humor fluid. Not all diuretics reduce IOP, and a substitute should not be used for the specific drug prescribed.

Table 26-1**Drugs Commonly Used to Treat Eye Disorders**

CLASSIFICATION	EXAMPLES	ACTION/NURSING IMPLICATIONS
Drugs Used for Glaucoma		
Miotics	<i>Prostaglandin analogs:</i> latanoprost (Xalatan), bimatoprost (Lumigan), travoprost (Travatan)	Increase outflow of aqueous fluid through the ciliary muscle by relaxation of the muscle.
	<i>Unoprostone isopropyl (Rescula)</i>	
	<i>Cholinergics:</i> pilocarpine HCl (Isoptic Carpine), pilocarpine nitrate (Ocusert Pilo-20, Ocusert Pilo-40), carbachol (Miostat)	Constrict the pupil, promote outflow of aqueous humor, and reduce intraocular pressure. Reduce visual acuity in dim light; advise patient to avoid driving at night. Ocusert is placed in conjunctival sac and replaced weekly.
	<i>Cholinesterase inhibitors:</i> echothiopate iodide (Phospholine iodide), demecarium bromide (Humorsol)	Produce miosis, increase aqueous humor outflow, and decrease intraocular pressure. Avoid touching tip of bottle to eye; moisture may interfere with drug potency.
Carbonic anhydrase inhibitors	<i>Beta-adrenergic blockers:</i> timolol maleate (Timoptic), betaxolol (Betoptic), levobunolol (Betagan), metipranolol (OptiPranol), carteolol (Occupress)	Reduce production of aqueous humor, thereby reducing intraocular pressure. Betaxolol reduces intraocular hypertension. Monitor pulse and blood pressure during initiation of therapy. Blurred vision decreases with continued use. Use beta blockers cautiously in patients with a history of asthma.
	Acetazolamide (Diamox), dorzolamide (Trusopt), brinzolamide (Azopt)	Interfere with carbonic acid production, thereby decreasing aqueous humor formation and decreasing intraocular pressure. Taken orally or as eyedrops (Trusopt). When taken orally, these drugs have a diuretic action; observe for dehydration and postural hypotension. Monitor electrolytes. Confusion may occur in older adults. Check for interaction with other drugs patient is receiving.
Sympathomimetics	Epinephrine (Epifrin), dipivefrin (Propine), apraclonidine (Iopidine)	Reduce intraocular pressure by increasing aqueous outflow. May cause brow headache, headache, eye irritation, and blurred vision. Used for open-angle glaucoma only. May cause tachycardia and rise in blood pressure.
Alpha ₂ adrenergic agonist	Brimonidine ophthalmic (Alphagan) P	Acts on alpha receptors in the blood vessels, decreasing the production of aqueous humor. Do not use with soft contact lenses. Contraindicated in heart disease.
Anti-inflammatories	<i>Corticosteroids:</i> Pred Forte, Ocu-Pred, Ophtho-Tate <i>NSAIDs:</i> ketorolac (Acular), flurbiprofen (Ocufen) <i>Prostaglandin analog:</i> latanoprost (Xalatan)	Decrease inflammation and swelling; reduce miosis. Interact with contact lens materials.
Drugs Used to Facilitate Diagnosis and Surgery of the Eye		
Cycloplegic and mydriatic anticholinergic agents	Atropine (Atropisol), cyclopentolate (Cyclogyl), homatropine (Ispto Homatropine), scopolamine (Ispto Hyoscine), tropicamide (Mydriacyl)	Dilate the pupils and paralyze the muscles of accommodation, causing mydriasis and cycloplegia. Mydriasis facilitates observation of the eye's interior during an examination. Cycloplegia prevents movement of the lens during assessment of the eye.
Adrenergic agonist	Phenylephrine (Ocu-Phrin)	Induces mydriasis by action on the muscle of the iris. Causes blurred vision. Photophobia may be eased by using dark glasses.
Staining solution	Fluorescein	Turns corneal scratches bright green; a green ring surrounds foreign bodies. Dye will filter through the lacrimal duct into the nasal secretions.
Topical anesthetics	Proparacaine (Alcaine, AK-Taine), tetracaine (Pontocaine)	Anesthetize the eye. Caution patient not to rub the eye while it is anesthetized. Patch eye when patient leaves the office if medication is still in effect.
Anti-infective Optic Medications		
Antibiotics	Gentamicin sulfate (Garamycin ophthalmic), erythromycin (Eryc), polymyxin B sulfate, neomycin sulfate, bacitracin, sulfonamides (Sodium Sulamyd, Gantrisin), ciprofloxacin (Ciloxan), chlortetracycline (Aureomycin), ofloxacin (Ocuflox)	Used to treat infection or for prophylaxis. Caution patient to use a clean washcloth and towel on the face each time to prevent reinfection.
Antifungal	Natamycin (Natacyn ophthalmic)	To treat <i>Fusarium</i> . Caution as for antibiotics.
Antivirals	Idoxuridine (IDV, Stoxil, Herplex), trifluridine (Viroptic)	Store in refrigerator. Do not use with boric acid. If no improvement, discontinue after 1 wk.
	Vidarabine (Vira-A ophthalmic)	Effective against DNA viruses; used for keratoconjunctivitis.

Whenever glaucoma is being managed by medication, the patient must continue the eyedrops and oral medications on an uninterrupted basis. Patients admitted to the hospital for disorders other than glaucoma often are allowed to keep their glaucoma medication at the bedside if they are able to administer it themselves.

Clinical Cues

When admitting a patient with a history of glaucoma, check to see that he has his eye medication with him and that there is an order on the chart for leaving it at the bedside. Otherwise, verify that there is an order on the chart for his usual glaucoma medications. If there is no order, call the provider for one.

When drugs do not control glaucoma and increased IOP persists, surgery is an alternative. The goal is to create openings so that excess fluid can escape. A laser is used to create evenly spaced openings in the collecting meshwork (**trabeculoplasty**) to facilitate aqueous humor drainage in open-angle or chronic glaucoma. Microsurgery filtering procedures create a drainage hole in the iris between the anterior and posterior chambers. A tiny shunt may be placed to drain excess aqueous humor if other surgeries do not produce the desired result. When surgical procedures fail, the ciliary body may be treated by applying a freezing probe tip (**cryotherapy**). This permanently damages cells in the ciliary body and decreases the production of aqueous humor.

Laser surgery is performed with procedural sedation. The patient may experience a mild headache and blurring of vision during the first 24 hours. There is a possibility that IOP may increase because of an inflammatory response. **Increasing pain in the eye should be reported to the ophthalmologist immediately.** The patient should be instructed to prevent increasing the venous pressure in the head, neck, and eyes by avoiding the Valsalva maneuver (straining with a closed glottis), not bending over, keeping the head up, and not making any sudden movements. A stool softener is given to prevent constipation. Strenuous exercise should be avoided for 3 weeks. The head of the bed should be elevated 15 to 20 degrees to decrease pressure within the eyes during sleep. Elevated IOP will persist for a week or so in some patients. Glaucoma medications are continued to meet the patient's individual needs. The patient must understand the importance of

frequent checkups and the necessity of consistently following instructions; the surgical procedure does not always eliminate the need for medication.

Nursing Management

Education of the patient and his family is a major aspect of care. Failure to follow the prescribed treatment regimen to control glaucoma and neglecting to maintain regular follow-ups with the provider can result in progressive loss of vision and eventual blindness ([Figure 26-8](#)).

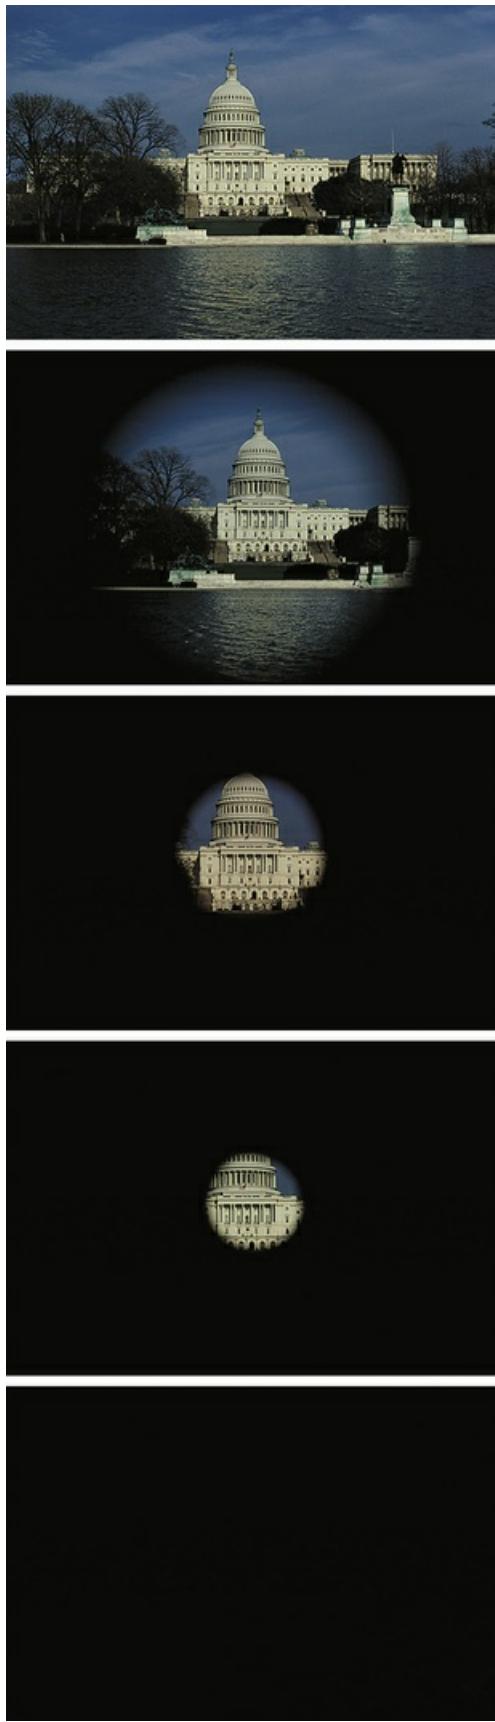

FIGURE 26-8 Glaucoma causes a progressive loss of peripheral vision. (From Monahan FD, Neighbors M, Sands JK, et al: *Phipps' medical-surgical nursing: Health and illness perspectives*, ed. 8, St. Louis, 2007, Mosby.)

Patients who have glaucoma need to be fully informed about the nature of this disorder, how it

can affect vision, the treatments available, and the expected result of those treatments. An analogy that can be used to explain the nature of the disorder is to compare the eye to a sink with an open faucet (the ciliary processes), a drain (angle), and pipes (trabecular structures). As long as water flows into and out of the sink at the same rate, there is no problem. If something blocks the drain or the pipes, the water will fill the sink beyond its holding capacity. Treatment with miotics helps keep the pipes open so that drainage is possible; beta blockers and diuretics can slow down the rate at which water flows from the tap. If the medications do not work, or if the sink suddenly is blocked by a clogged pipe, it may be necessary for the surgeon to clear the drainage system so that the water can drain from the sink.

In addition to learning about the nature of glaucoma and the expected results of prescribed treatments, the patient also must be made aware of the possibility of vision loss if the condition is not managed. **Teaching should emphasize that glaucoma medications prevent further vision loss, but medications cannot restore vision.** Teaching must be done with tact and sensitivity for the patient's feelings. The information should never be presented in such a way that the patient feels threatened or becomes so fearful that he is unable to participate in the management of his disorder.

Patient Teaching

Points to Cover in the Glaucoma Teaching Plan

- Signs of IOP include pain in the eye, redness, tearing, blurred vision, halos around lights, and frequent need for change in eyeglasses.
- Measures to prevent increase in IOP include low-sodium (Furstenberg) diet, little caffeine intake, preventing constipation and Valsalva maneuver, and decreasing stress.
- Taking prescribed medications and refraining from taking over-the-counter or other medications without the provider's knowledge are important. Glaucoma medication must be taken regularly for life.
- Use good aseptic technique when instilling eye medication.
- Wear an ID tag or bracelet stating "Glaucoma," and carry a card in the wallet that states what medications are being taken.
- Keep an extra bottle of eye medication on hand. Carry eyedrops.
- Maintain close medical follow-up with provider.
- Practice safety habits; avoid night driving if possible.

ID, Identification; *IOP*, intraocular pressure.

Narrow-Angle (Angle-Closure) Glaucoma

Signs, Symptoms, and Diagnosis

Narrow-angle, or acute, glaucoma is a medical emergency in which there is severe pain in the eye accompanied by the appearance of colored halos around lights, blurred vision, and pain in and around the eye. Nausea and vomiting may occur. The cause of narrow-angle glaucoma is the position of the iris, which lies too close to the drainage canal and bulges forward against the cornea, blocking the drainage of aqueous humor (see [Figure 26-6](#)). The IOP rises suddenly, sometimes reaching a pressure of 50 to 70 mm Hg. Relief of the situation must be prompt, or damage to the optic nerve will cause blindness in the affected eye. Diagnosis is by history, testing of IOP, and dilated eye examination.

Treatment and Nursing Management

Emergency treatment in narrow-angle glaucoma consists of measures to reduce IOP as quickly as

possible. During the attack, drugs such as pilocarpine, topical epinephrine, and IV acetazolamide are used. Surgery is performed as soon as inflammation subsides to relieve pressure against the optic nerve endings. **Laser iridotomy**, **trabeculectomy**, **laser trabeculoplasty**, or other procedures that allow filtering of the aqueous humor from the anterior chamber into the subconjunctival space are performed. If these procedures fail, sometimes **cryotherapy** (the application of a freezing tip) may be used on the ciliary body to decrease the aqueous production.

Nursing management is the same as for other eye surgeries: teaching about activity precautions during healing, schedule for eyedrops, symptoms to report to the surgeon, and aseptic handling of the eyedrops and eye shield.

Retinal Detachment

Etiology

Retinal detachments often are classified as either primary or secondary. Primary retinal detachment is the result of spontaneous or degenerative changes in the retina or the vitreous humor. Secondary retinal detachment is associated with mechanical trauma, inflammation within the eye, or some other ophthalmic disorder, such as diabetic or hypertensive retinopathy. Retinal detachments commonly occur in people with a high degree of myopia. The incidence of retinal detachment increases dramatically after 40 years of age and is most common between ages 40 and 70 years. Fifteen percent of people with retinal detachment in one eye develop detachment in the other eye.

Cultural Considerations

Incidence of Retinal Detachment in People of Jewish Descent

Retinal detachment is more common in people of Jewish ethnicity. The condition is relatively uncommon in African Americans. The reason may be that the Jewish population has more incidence of myopia, and that condition tends to be inherited. Severe myopia is a risk factor for retinal detachment.

Pathophysiology

Retinal detachment is actually not a detachment of the whole retina, but a separation of the sensory layers of the retina from the pigmented epithelial layer, the choroid. Retinal detachment can cause vitreous fluid to leak under the retina, separating a portion of it from the vascular wall and thereby depriving the retina of its blood supply ([Figure 26-9](#)).

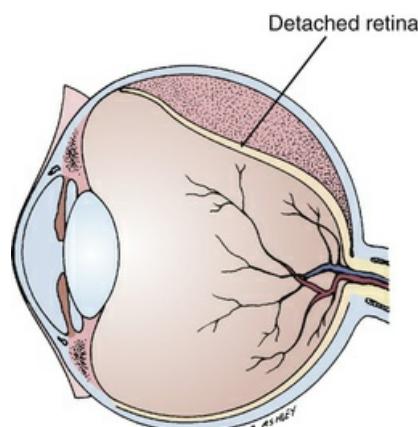

FIGURE 26-9 Retinal detachment.

Signs, Symptoms, and Diagnosis

Onset can be either gradual or sudden, depending on the cause and extent of the detachment and

the location of the area involved. The patient may see flashes of colored light accompanied by showers of floaters (black spots) or may feel as if a curtain has been drawn over a portion of the visual field. Later, cloudy vision or loss of central vision is noticed. In severe cases, there may be complete loss of vision.

Think Critically

What would you say to your friend if you were having a meal together in a restaurant and he commented that he was seeing flashes of colored light in his left eye? What would you tell him to do?

Diagnosis of detached retina can be made with a direct ophthalmoscope, but diagnosis is greatly simplified by a stereoscopic indirect ophthalmoscope. This instrument permits visualization of the entire retina and produces an image of the retina with less magnification and distortion than the direct ophthalmoscope. Ultrasound can be used to detect retinal detachment when the eye is clouded by opacity from cataract or hemorrhage.

Treatment

Retinal holes and tears sometimes can be repaired on an outpatient basis with laser therapy that creates an inflammatory reaction, causing the layers to adhere during healing. Tears located in the posterior fundus can be coagulated and sealed with a laser beam or photocoagulator. Peripheral retinal holes through which no fluid has leaked can be closed by applying a freezing probe tip (cryotherapy). The frozen area scars over in a few days, and the hole is thus sealed. A third procedure, called *scleral buckling*, requires more extensive surgery. In effect, scleral buckling places the retinal breaks in contact with the pigmented epithelial layer. Adhesions are formed that bind the sensory and epithelial layers and the choroid together. Before the procedure, gas may be injected into the eye to apply pressure on the retina from the interior of the eye. This application of pressure helps hold the layers together during healing.

If hemorrhage into the vitreous is obstructing vision, the surgeon may perform a closed vitrectomy during retinal repair. The purpose of the vitrectomy is to remove the cloudy vitreous humor and stabilize the retina against the choroid. Inert gas or oil is used to fill the space until aqueous humor eventually refills the area (Comer, 2014).

Nursing Management

Positioning of the patient and the level of activity allowed after surgery are prescribed by the surgeon. The head is positioned so that the area repaired is dependent, preventing the pull of gravity from disrupting the surgical site. The designated position for the head also is calculated to position the oil or gas bubble—if one was used—in the best place to apply pressure to the retina. Position the patient according to the provider's orders. IOP is monitored closely for at least 24 hours. Vision does not return immediately because of postoperative swelling and the effects of the dilating drops. Vision improves on a gradual basis over several weeks to months. The eyes may both be patched, or just the operative one may be patched. Eye patches are changed at least once a day (see Box 26-1). A shield is worn when napping and at night. Several types of eyedrops may be prescribed for postoperative use, as well as an antibiotic ointment. Strict asepsis must be observed when instilling eyedrops and ointment.

There usually is some degree of pain after all types of retinal surgery. Acetaminophen with oxycodone or codeine typically is prescribed for pain. If the patient is allergic to these medications, extra-strength Tylenol may be sufficient to control the pain.

Flashing lights are common for the first few weeks after retinal surgery. These decrease over 2 to 6 months; if they worsen within several weeks of surgery, the provider should be notified. Light sensitivity is common in both eyes after surgery and may cause tearing. This gradually lessens over a period of 4 to 6 weeks. Wearing dark sunglasses when outdoors helps eliminate this problem. A moderate amount of discharge from the eye is not unusual; it should be yellowish or pink-tinged. If the amount of discharge increases markedly or is accompanied by severe pain, or if discharge has a foul smell or a greenish tinge, infection may be present; notify the surgeon. Cleanse the eyelid with a gauze pad or cotton ball moistened with irrigating solution or tap water. Wipe from the inner to the outer area of the eye. A separate clean pad or cotton ball should be used for each eye.

The patient is allowed to sponge-bathe, brush the teeth, shave, and comb the hair as long as care is taken not to get water in the affected eye (see discussion later in this chapter).

At discharge, the patient is cautioned to avoid heavy lifting, straining at stool, and vigorous activity for several weeks. Eyeglasses are worn during the day for protection, and the eye shield is worn at night after an eye patch is no longer necessary.

Home Care Considerations

Home Care Instructions for Retinal Surgery or Vitrectomy

Instructions will vary if the patient has a gas bubble that was injected intraocularly. Positioning and activity are more restricted for these patients.

Activity

- Restrict activity according to the provider's instructions. Bed rest with bathroom privileges for the first few days is common. The head may need to be positioned to the left or right most of the time. A head-down or semiprone position to the right or left will be required for most of the time if a gas bubble was injected into the eye.
- The following activities are allowed immediately after discharge unless a gas bubble has been injected into the eye as part of the procedure:
 - Watching television from a distance of at least 10 feet.
 - Tub bath or shower, using extreme care not to get soap or water into the eyes. Take care to prevent a fall.
 - Walking outdoors with the guidance of a companion.
 - Reading for brief periods.
 - Gentle shampooing of hair with head tilted backward and care not to get soap or water into the eyes.
 - Riding in a car as a passenger.

Eye Care

- The operated eye is to be patched at all times and protected by an eye shield or glasses until you are told you may leave the eye uncovered. A patch or shield may still be recommended for use while sleeping. The eye patch is removed only to administer eyedrops or ointment. The eyelid may be cleansed with cotton or gauze moistened with irrigating solution. Each time the patch is changed, check the movement of the eyeballs under the lids. Gently retract the upper lid, and look down as far as possible. Next, look up while retracting the lower lid. This helps break adhesions of the eyeball to the lids.
- The following are expected and should not cause alarm: tearing, a small amount of blood on the eye patch, a scratchy sensation, blurred vision, unusual visual images, a few light flashes, and floaters. Call the provider if these symptoms **significantly** increase after discharge.
- Have someone else administer the eye medications. Assume a reclining position for eyedrop or eye ointment placement. Pull down the lower lid and, with the patient looking up, place the correct number of drops into the center of the conjunctival sac. Let the lid gently close. The

patient should try not to squeeze the eye shut or blink excessively. Wait 3 to 5 minutes between types of eyedrops so that they do not wash each other out and dilute the intended effect. Patch the eye after each set of drops or ointment is administered. If a shield is to be used, it is placed on top of the taped-down eye pad.

Comfort

- Take a prescribed analgesic or extra-strength acetaminophen to relieve pain. A cool washcloth or ice pack to the forehead may provide comfort. Report pain that grows markedly worse or is accompanied by nausea and vomiting.

Precautions

- In case of cough, take cough syrup. Do not try to hold back sneezes. Do not strain at stool; take a stool softener or milk of magnesia if needed to prevent this.

Restrictions

- Avoid driving a car until visual acuity is 20/40 or better; your provider will tell you when you may resume driving.
- Avoid lifting heavy objects (those over 20 lb) for at least 4 months.
- Refrain from work for 2 to 6 weeks (depending on type of work); your provider will tell you when you may return to work. Light housework that does not require bending over or vigorous scrubbing may be resumed within 1 to 2 weeks depending on the type of surgery performed.
- Avoid vigorous or strenuous activity for 4 months.
- Do not bend with your head down; keep the head upright, and bend at the knees.
- Avoid sports for 3 to 4 months.

Think Critically

How do the signs and symptoms of glaucoma and cataract differ?

Retinopathy

Etiology

The two major causes of retinopathy are diabetes mellitus and hypertension. Years of elevated blood pressure cause retinal vasospasm, which damages and narrows the retinal arterioles, thereby decreasing the blood supply to the retina. Contributing factors are excessive use of nicotine and caffeine and high stress levels.

Pathophysiology

Diabetic patients experience two different forms of retinopathy: proliferative and nonproliferative retinopathy. In the nonproliferative type of retinopathy, microaneurysms develop on the retinal blood vessels. These eventually swell and rupture, causing hemorrhage into the vitreous humor, which interferes with vision. The proliferative form of retinopathy occurs later in the course of diabetes. New blood vessels grow from the existing retinal vessels in a process called *neovascularization*. The new vessels are thinner and rupture more easily, causing hemorrhage. The blood from the hemorrhage causes scarring, which also interferes with vision. High blood pressure creates blockages in retinal blood vessels. Retinal hemorrhages and macular swelling may cause vision impairment.

Signs, Symptoms, and Diagnosis

It is important that patients with diabetes have regular, frequent eye examinations, because the

early stages of retinopathy present no symptoms. As the retinopathy progresses, there are alterations in vision such as blurring, missing areas in the field of vision, and seeing red or black lines or spots. These signs can be observed on ophthalmologic examination of the retina and by fluorescein angiography. When the macula is involved, there is a loss of vision that may progress to blindness. Retinal detachment may occur as a result of proliferative retinopathy.

Treatment

Tight control of blood glucose levels (100 to 115 mg/dL) is very important to prevent excessive diabetic retinopathy. There is no other known way to halt the process. The microaneurysms and the neovascularized vessels are treated with laser photocoagulation therapy to prevent hemorrhage and the consequent scarring and loss of vision. Vitrectomy also can be done if hemorrhage has caused serious impairment of vision. Hypertension must be kept under good control.

Research is under way to determine whether a deficiency of insulin-like growth factor (IGF)—a hormone that helps maintain nerve function—rather than uncontrolled glucose levels is the cause of diabetic retinopathy. If so, IGF injections may prevent the problem.

Nursing Management

Within 15 years of developing diabetes, nearly all patients with type 1 diabetes and 80% of patients with type 2 diabetes develop some retinopathy; therefore you can be instrumental in promoting glucose control and regular eye examinations. Nurses must encourage glucose testing in patients who have a family history of diabetes or who are in a high-risk category, so that the disease may be discovered early before vascular effects have occurred.

Think Critically

What would you teach a patient with diabetes about the prevention of retinopathy? What factors affect the development of retinopathy?

Macular Degeneration

Etiology

Between 2000 and 2012, the incidence of age-related macular degeneration (AMD) in people age 50 years or older has escalated by 25%, to 2,069,403 (Friedman, 2012). The macular region of the retina provides color vision, acute vision, and central vision. Macular degeneration, or AMD, occurs with aging and is the most common cause of visual loss in older adults. Inflammation may be a factor; *Chlamydia pneumoniae* has been found in the eye tissue of some people with the wet form of AMD. There is a genetic tendency for the disease, and diabetes and hypertension are associated risk factors. Wearing sunglasses regularly when outdoors may help protect against AMD. Certain vitamins, minerals, and antioxidants seem to help prevent or slow AMD.

Health Promotion

Tobacco and Alcohol and Macular Degeneration

Teaching people to quit smoking and to abstain from immoderate drinking (four or more alcoholic drinks a day) can decrease the incidence of AMD. Smoking is believed to double the risk of AMD (National Eye Institute, 2015). In Britain there is a movement to add the warning about the risk of vision loss to the other warnings on cigarette packages.

Complementary and Alternative Therapies

Preventing or Slowing Progression of Macular Degeneration

The antioxidants acetyl-L-carnitine, concentrated omega-3, and coenzyme Q-10 have been shown to improve vision in patients with AMD in a recent Italian study (UMM, 2014). The combination is available in a supplement called Ocuvite PreserVision. Fish oil, which acts as an anti-inflammatory,

may protect the retina from AMD. If patients are on blood thinners, such as warfarin or aspirin, fish oil may increase the risk of bleeding.

A new genetic test performed on saliva, Macula Risk, is available for patients at increased risk of macular degeneration.

Pathophysiology

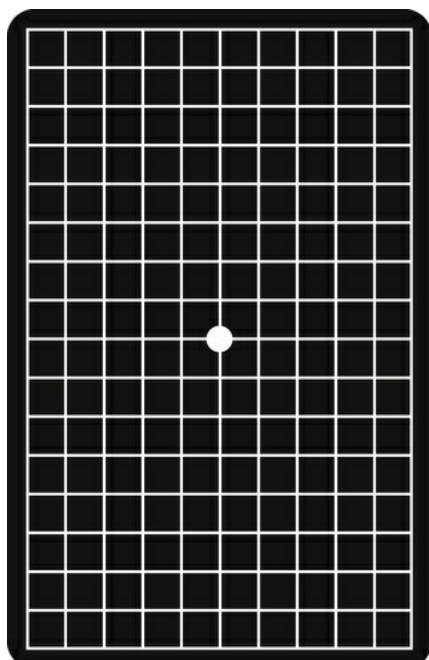

There are two types of atrophic macular degeneration: dry and wet. Exudative macular degeneration may occur at any age. In the dry form, gradual blockage in the retinal capillaries leads to death of rod and cone photoreceptors in the macula of the retina. This form accounts for 85% to 90% of cases. Dry AMD may progress to wet AMD. In the wet form, abnormal vessels develop in or near the macula. Central vision is affected. The fragile vessel network grows into the subretinal space and may bleed into the macular region, causing central visual impairment. Exudative macular degeneration is caused by a serous detachment of pigment epithelium in the macula. Sudden central vision loss occurs.

Signs and Symptoms

AMD is bilateral and progressive. Early symptoms may be an inability to see the vividness of colors or to see details. Blurred vision, presence of scotomas, or distortion of vision gradually occurs. Objects may appear to be the wrong size or shape, or straight lines may appear crooked or wavy. As central vision deteriorates, there may be a large dark spot or empty place over the center of what is viewed. The patient retains peripheral vision and can walk, dress, cook, and sometimes drive if impairment is minimal but cannot read when the disorder becomes severe. Exudative MD may occur in only one eye.

Diagnosis

Ophthalmologic examination of the retina and macula is the first step in diagnosis. In dry AMD yellow exudates called **drusen** are found beneath the retinal pigment epithelium. Drusen represent extracellular debris. In wet AMD fluid and blood are detected by the examination. Patients at risk for macular degeneration, or extension of the problem, are taught to use an Amsler grid (a small card with lines in a grid formation) at home to assess for progression of the disorder (Figure 26-10). If macular degeneration is occurring, the lines appear wavy. Fluorescein angiography or optical coherence tomography shows the specific areas of the retina involved.

USE ONLY AS INSTRUCTED BY YOUR OPHTHALMOLOGIST

REMINDERS:

- Cover one eye—Hold card directly in front of the uncovered eye
- Look at center spot
- Note any irregularities (e.g., wavy, gray, fuzzy)
- Rotate 90 degrees and repeat
- Test other eye

Contact your ophthalmologist as instructed, if necessary

Treatment

There is no specific treatment for dry AMD that restores vision, but a novel inhibitor of a protein involved in inflammation that contributes to vision loss is being developed and is in phase I trials. A combination of vitamins, minerals, and antioxidants is recommended to slow the progression of the disease. Several trials to slow or halt the progression of the dry AMD are under way ([AMD.org, 2014](#)). For wet AMD, prompt laser treatment to destroy the fragile blood vessels can sometimes prevent further bleeding and visual deterioration. **Photodynamic therapy** using IV verteporfin (Visudyne), followed by a low-light-level laser that destroys only the cells that absorbed the dye, is another therapy. This therapy destroys abnormal blood vessels, without permanent damage to the photoreceptor cells and the retinal pigment epithelium. Because direct exposure to sunlight or other intense forms of light can activate the dye in the cells, the patient must avoid those forms of light for 5 days, after which the remaining dye will have been fully excreted.

Pegaptanib sodium injection (Macugen) has received Food and Drug Administration (FDA) approval for the treatment of wet AMD. It is injected into the eye under local anesthesia once every 6 weeks. During clinical studies, this drug has limited the progression to legal blindness by 50% compared with controls. Researchers are testing the efficacy of certain drugs for use as eye drops to replace these injections.

Ranibizumab (Lucentis) has been approved by the FDA for wet AMD, but it is very expensive. Intravitreal injections are necessary monthly with Lucentis. A new drug, aflibercept (sold under brand name Eylea), which also binds and inhibits vascular endothelial growth factor (VEGF), has been approved by the FDA to treat macular degeneration. This treatment is expensive, but at \$1850 per treatment it is less expensive than Lucentis and requires fewer treatments ([Weinberg, 2013](#)).

A technique under investigation is transplantation of healthy cells of retinal pigment epithelium to replace or enhance degenerating epithelium. It is hoped that transplantation of such cells before vision has greatly deteriorated will slow or eliminate the progression of AMD.

A device called the *ForeseeHome Monitor* is available to monitor vision changes at home for those with dry macular degeneration. Treatment is most effective when changes in vision are detected early.

Nursing Management

Help patients with permanent vision loss learn to use low-vision aids. A referral to a low-vision device specialist and low-vision support group commonly is needed. Devices are available to illuminate and magnify reading material. Books with large print are easier to read. Learning to turn the head and move the eyeballs to work around the central scotoma may help. A closed-circuit television system that magnifies a printed page on screen can be used for reading or doing crossword puzzles. Telescopic lenses can help for watching movies, attending the theater, reading street signs, and seeing traffic lights. A head-mounted low-vision enhancement system provides both distance and close-up enhancement. Easy-to-read watches with large numerals, television screen magnifiers, and guides that fit over checkbooks to assist with writing on them are some of the less expensive low-vision aids that are available.

Nursing Care of Patients Having Eye Surgery

Preoperative Care

Most eye surgery procedures are done on an outpatient basis, unless the patient has other serious disorders such as cardiac dysrhythmias, severe diabetes, or a chronic disability. Therefore a large part of nursing care is directed at discharge teaching for home care. One surgery that is performed as an inpatient procedure is a scleral buckle for retinal detachment (see [Retinal Detachment](#)).

Stool softeners may be started a day or two before surgery to prevent constipation and the Valsalva maneuver postoperatively. The Valsalva maneuver can increase IOP. Some providers direct the patient to wash the face with surgical soap several times the evening and morning before surgery. The patient may be given instructions on the administration of eyedrops the night before and the morning of surgery.

After admission, the patient is fully oriented to the outpatient surgery unit and given instructions about the layout of the room and area and the ways in which help can be summoned. Side rails are usually necessary to prevent falls, and the patient should be cautioned against getting up without assistance. Preoperative eyedrops and medications are instilled in the outpatient surgery center the morning of surgery. Drugs must be given with extreme care and accuracy, especially if only one eye is affected. **Be sure that the medication is applied to the correct eye.**

Preoperative dilating (**mydriatic**) eyedrops often are administered every 5 minutes for six doses. Other eyedrops may be administered in between these doses. An IV infusion is started shortly before surgery.

Because most patients undergoing eye operations are older adults and therefore are likely to have some additional chronic disease, remember to apply the principles of geriatric nursing in administering care. Fear, anxiety over surgery, and confusion about the expected results of the surgery are all factors to be considered when preparing the patient for the operation. Instructions and information should be given both verbally and in writing. Measures to ensure patient safety are very important both preoperatively and postoperatively because the vision is impaired.

Safety Alert

Prevent Falls From Impaired Vision

An older adult who has a patched eye, has low vision, and is in a strange environment is subject to falls. The patient may need to be reoriented to place, time, and surroundings frequently to decrease confusion and agitation.

Postoperative Care

In caring for a patient undergoing any type of eye surgery, the key word is **gentleness**. The patient's head should not be jarred when transferring from the operating table or stretcher to the bed. Remember to speak before touching a patient who is blind or who is wearing bandages over the eyes.

Patients are usually kept in the recovery area of the outpatient surgery department for 2 to 3 hours postoperatively. Nausea and subsequent vomiting can wreak havoc with delicate suture lines in the eye. **If the patient becomes nauseated, antiemetic medication should be administered immediately and all food and liquids withheld.**

An eye patch is often placed over the eye that was operated on ([Figure 26-11](#)). If it is necessary to restrict movement of the eyes, both eyes are patched.

FIGURE 26-11 Patient with eye patch to protect surgical site and prevent eye movement. The head is kept elevated in the immediate postoperative period.

Instructions regarding postoperative medications and how they are to be instilled are given before discharge (Figure 26-12). Different types of eyedrop medications come with color-coded tops for easy identification. Eyedrop bottles also can be “labeled” by wrapping one, two, or three rubber bands around them so that patients with a visual impairment can differentiate one type of drop from another.

FIGURE 26-12 Instilling eyedrops.

Should the patient need to stay in the hospital because of other problems, you must be thoroughly familiar with his individual care needs. It should be known whether the patient can be turned on one or both sides or must remain flat on the back, whether pillows are allowed under the head, and how high the head of the bed may be raised. For certain types of retinal surgery, the head may need to be raised and positioned toward a particular side. If a gas bubble has been injected intraocularly, the patient is positioned prone or supine with the head toward one side or the other, according to orders. If the patient is allowed out of bed, care must be taken not to jar the head or move too suddenly.

Sexual activity can usually be resumed in 1 to 8 weeks postoperatively, depending on the procedure performed. The surgeon will explain this to the patient. Ensure that the patient understands the time of the next appointment with the ophthalmologist. The patient and family should be encouraged to follow the provider's directions faithfully during the healing period at home so that nothing will jeopardize the success of the surgery.

Discharge planning is of utmost importance. Refer to the earlier Home Care Considerations box for home care of a patient after retinal surgery or vitrectomy.

Community Care

Resources for People Who Are Vision Impaired

Loss of vision need not be devastating for a person if support and encouragement are given for coping with the impairment. There are resources to help those with visual impairments learn to care for themselves, find employment, and enjoy educational and recreational activities. Many colleges provide special funds to enable blind students to hire readers and tape recorders to help them with their studies.

Both home care nurses and those working in long-term care should be alert to signs of progressing macular degeneration. The Amsler grid can assist in identifying this problem. Patients with known eye disorders should be periodically assessed to see how much vision has deteriorated and how much the patient's ability to perform activities of daily living and partake in usual hobbies is affected. Nurses should be instrumental in helping patients obtain low-vision aids.

All nurses should encourage the donation of corneas at death. Signing a donor card for organ harvest should be a consideration for all, as well as indicating "tissue donor" on the driver's license. The nurse may be the person to approach a terminal patient or his family about the possibility of donating corneas after death and giving the gift of sight to another. The Library of Congress in Washington, D.C., lends records and recording machines without charge to people who are blind and maintains a wide selection of recordings. Recordings of required textbooks may be obtained free of charge from Recording for the Blind and Dyslexic (see Online Resources).

Common Disorders of the Ear

External Otitis

Etiology and Pathophysiology

Infection of the external ear is common and often occurs in swimmers. It is caused by either bacterial or fungal pathogens, with staphylococci being the most common cause. Other infections of the skin may affect the external ear (see [Chapter 42](#)). A moist environment or disruption of the skin from trauma provides a place for pathogens to grow.

Signs and Symptoms

Pain occurs with the infection. An early sign may be pulling at the pinna or itching in the canal. If swelling occurs in the ear canal, hearing may be impaired, because sound waves cannot reach the tympanic membrane.

Diagnosis, Treatment, and Nursing Management

Redness is evident on otoscopic examination, and there may be drainage. A culture of the drainage may be performed. Antibiotic or fungal eardrops and ointments are the usual treatment. A severe infection may require oral antibiotics as well. Teaching patients to use drops of an alcohol solution in the ears after drying them helps to prevent external otitis. A mild analgesic may help decrease the discomfort during healing.

Impacted Cerumen and Foreign Bodies

Normally the ear canal is self-cleaning, but cerumen may occasionally become impacted. Foreign objects such as insects or organic matter may obstruct the canal. A feeling of fullness in the ear combined with a hearing loss can indicate that obstruction has blocked the canal, preventing sound waves from reaching the tympanic membrane. If otoscopic examination reveals hardened cerumen blocking the canal, irrigation of the canal is performed to remove it.

Older Adult Care Points

With increased age, the auditory canal narrows and the hairs become coarser and stiffer. The cerumen glands atrophy, causing cerumen to be drier. This combination may result in impaction of cerumen that causes a conductive hearing loss and tinnitus. Older adults with this problem should be taught to use cerumen softening drops and an ear syringe to wash out the cerumen periodically. Those who are unable to cleanse the ears themselves should have regular ear checks by their health care provider.

Clinical Cues

When irrigating an ear canal, the water should be tepid. Cold water and too much irrigation pressure can cause dizziness and nausea as well as pain. Check the temperature of the water each time the syringe or irrigation container is refilled. Drape the patient so that the clothing does not become wet.

Otitis Media

Etiology

This condition is an inflammation of the middle ear caused by various types of bacteria or viruses. Although it is mostly seen in infants and young children, it does occur in adults. It results in the accumulation of fluid behind the eardrum and some temporary impairment of hearing.

Pathophysiology

The inflammation of otitis media usually follows an upper respiratory tract infection or trauma to

the ear. It is usually viral in origin but may be complicated by bacteria. Obstruction of the eustachian tube usually precedes the disorder and is caused by an upper respiratory infection or allergy. Middle ear inflammation occurs when the eustachian tube that usually drains that area becomes blocked. The obstruction changes the pressure within the middle ear. The inflammation may provide an environment for *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, *Streptococcus pyogenes*, or other pathogens to invade the tissue.

When the infection is sudden in onset and of short duration, it is termed *acute otitis media*. The eardrum is retracted inward because of negative pressure from a closed eustachian tube. The pain can be severe. When the infection is repeated, often causing perforation of the eardrum and drainage, it is called *chronic otitis media*.

Otitis media sometimes is accompanied by an allergy and may be aggravated by enlarged adenoids. Fluid may build up in the middle ear. This disorder is called *serous otitis media*.

Signs, Symptoms, and Diagnosis

Symptoms may be mild and may consist only of a feeling of fullness in the ear and evidence of impaired hearing and tinnitus. There may be pain in the infected ear, headache, fever, and pulling on the ear. If the fluid remains over an extended time, it causes tympanic membrane contraction and can permanently impair its movement.

Depending on the stage of infection, otoscopic examination may show retraction of the eardrum, redness and bulging, or pus behind the eardrum. Perforation may occur with drainage of the pus. This type is termed *suppurative otitis media*.

Treatment

There is great controversy about using antimicrobials for otitis media because so many strains of pathogens are becoming antimicrobial resistant. If there is otitis media with fluid behind the eardrum and no acute systemic or local evidence of severe infection, antimicrobials are withheld. The condition is treated conservatively with antihistamines and decongestants.

For repeated episodes of otitis with fluid, or when the fluid will not resorb, a **myringotomy** (incision into the eardrum) is done, and a ventilating tube is inserted to drain the excess fluid in the middle ear and to equalize pressure while the eustachian tube is blocked. The tympanic membrane is anesthetized locally. The procedure is painless and takes about 15 minutes. The incision heals within 24 to 72 hours unless a tube is placed in the opening. Tubes remain in place for 6 to 18 months before they are naturally expelled. The hole then heals. If allergy is believed to be responsible for the fluid buildup, antihistamines are prescribed.

Acute otitis media occurs when pus-producing bacteria infect the middle ear. Treatment consists of systemic therapy with antibiotics for at least 5 to 7 days, topical therapy with eardrops, and oral analgesics to reduce pain and fever. With repeated episodes, **tympanoplasty** to repair a ruptured eardrum and damaged ossicles, and, sometimes, mastoidectomy may be needed to eliminate all sources of infection and prevent further degeneration of bone.

Nursing Management

Keeping the patient comfortable at home, encouraging compliance with the medication regimen, and requesting return for an examination when medication is finished are usual nursing actions. Show a family member how to instill eardrops properly. Temperature should be taken each day during the course of acute otitis media to track improvement.

Infections in the middle ear always have the potential for spreading to the meninges, causing meningitis, or to the mastoid bone, causing mastoiditis. With the advent of antibiotics, surgery to scrape and clean infected mastoid bone is performed far less commonly than it was previously. Although otitis media is a fairly common occurrence, it should always be treated immediately.

Labyrinthitis

Etiology and Pathophysiology

Labyrinthitis is an inflammation involving the vestibular portion of the labyrinth in the inner ear. It most commonly occurs from a viral respiratory infection but can be a complication of bacterial meningitis or chronic otitis media.

Signs, Symptoms, and Diagnosis

The symptoms include sensorineural hearing loss in the affected ear, tinnitus, severe dizziness with nausea and vomiting, and **nystagmus** (abnormal jerking movements of the eyes). If the disorder is viral, there usually is no tinnitus and resolution occurs within 7 to 10 days. Diagnosis is made from the symptoms and by ruling out tumor or other disease.

Treatment and Nursing Management

Treatment is aimed at removing the source of infection and controlling symptoms. Meclizine (Antivert, Bonine) or another antihistamine that assists in decreasing vertigo and its associated nausea and vomiting is used. Scopolamine patches behind the ear can be used after the acute phase to control vertigo. Antibiotics may be given in massive doses to control a bacterial infection.

Clinical Cues

Remind the patient to wash his hands again after applying the scopolamine patch. If the eye is touched after touching the patch, severe eye irritation may occur.

Initially the patient is kept on bed rest to prevent falls and injury. The family is cautioned not to let the patient get out of bed without assistance. Nursing management consists of safety measures to prevent falling and instructions about the medications. Attention to hydration is important if the patient is nauseated to the point of repeated vomiting.

Ménière Disease (Ménière Syndrome)

Etiology and Pathophysiology

The exact cause is unknown, but Ménière disease occurs most commonly in people who have had chronic ear disorders and allergic symptoms involving the upper respiratory tract. There is a genetic link, and approximately 50% of those with the disorder have family members who are also afflicted.

An increase of endolymph within the spaces of the labyrinth, with swelling and congestion of the mucous membranes of the cochlea, occurs. Resultant pressure in the labyrinth of the inner ear results in permanent damage to both the cochlear and vestibular structures. The disorder is usually unilateral. Long-term stress may be a factor.

Signs, Symptoms, and Diagnosis

The symptoms include attacks of dizziness, ringing in the ear (tinnitus), and unilateral sensorineural hearing loss. Poor balance makes walking difficult or impossible. **Any sudden movement of the head or eyes during an attack usually produces severe nausea and vomiting.** Diagnosing Ménière disease usually is not difficult, but because these symptoms could indicate a tumor of the auditory mechanism, a **caloric test** (electronystagmogram [ENG]) may be performed, which involves instilling very warm or cold fluid into the auditory canal. A patient with Ménière disease will experience a severe attack; a person without the disease will complain of only slight dizziness. A person with a tumor of the auditory mechanism will have no reaction at all. Tympanometry and audiometry are ordered, and a brainstem-evoked response (BSER) test is performed to rule out an acoustic neuroma or problem in the brain.

Think Critically

How would you check for nystagmus when assessing a patient who has vertigo?

Treatment

Treatment of Ménière disease focuses on relieving symptoms; there is no cure for this condition, although the disorder does disappear spontaneously in some cases. For an acute attack with disabling vertigo, atropine may be given subcutaneously, followed by diazepam (Valium), dimenhydrinate (Dramamine), meclizine (Antivert), or other drugs for motion sickness. To control edema and reduce pressure in the inner ear, the patient may be placed on a low-sodium diet, his

fluid intake may be restricted, and diuretics may be ordered. Anticholinergic drugs, such as propantheline (Pro-Banthine) or glycopyrrolate (Robinul), may be given to help control the vertigo and nausea. To improve circulation in the ear, papaverine (Vasospan) or niacin may be prescribed. Some patients find that *Ginkgo biloba*, which acts as a vasodilator, helps. The patient is kept quiet and in bed to avoid aggravating his symptoms. He may be very irritable and withdrawn and may refuse to eat or drink because of fear of vomiting. Care should be taken to avoid increasing his irritation by jarring the bed, turning on bright overhead lights, or making loud noises.

If attacks continue and are very severe despite medical treatment, the endolymph sac from the inner ear can be removed with microsurgical techniques, but this is reserved for medical treatment failures. When hearing loss is total on the affected side, surgical destruction of the eighth cranial nerve may resolve the symptoms. Although this produces permanent deafness in the affected ear, the severe attacks are eliminated. In most persistent cases of Ménière disease, the patient will eventually suffer a serious or even total loss of hearing regardless of the treatment used.

For those with dizziness and unsteadiness who do not wish to undergo surgery, vestibular rehabilitation therapy, a home-based exercise, may decrease the dizziness and balance problems resulting from inner ear damage. The Meniett low-intensity alternating-pressure generator that is self-administered at home displaces fluid from the inner ear and relieves or prevents symptoms (Medtronic.com, 2014).

Think Critically

What would you teach a patient with Ménière disease about a low-sodium diet?

Nursing Management

Encourage patients who use nicotine products to quit, because nicotine constricts blood vessels and decreases inner ear circulation. If allergy seems to be a factor in the onset of attacks, encourage consultation with an allergist to obtain control of allergens. Decreasing stress is a helpful intervention when there has been a pattern of attacks after particularly stressful times in the patient's life.

Acoustic Neuroma

An acoustic neuroma is a rare benign tumor on the eighth cranial nerve that is usually unilateral. It occurs in 0.7 to 1.0 per 100,000 people. Symptoms are gradual hearing loss and tinnitus. This tumor is usually curable with surgery or stereotactic (gamma knife, Cyberknife) radiotherapy. If untreated it causes deafness. Treatment is surgical, and nursing care is much the same as for other intracranial surgeries, using measures to decrease intracranial pressure.

Otosclerosis and Hearing Loss

Etiology and Pathophysiology

Otosclerosis is a hereditary degeneration of bone in the inner ear. It occurs twice as often in females and begins in the late teens or early 20s. It may become worse during pregnancy. Hearing is decreased if there has been damage to the tympanic membrane (eardrum) from trauma or infection.

The sense of hearing depends in part on the vibration of very small bones of the inner ear. The **stapes**, or stirrup, is particularly important, because it conducts sound waves to the fluid in the semicircular canals in the inner ear. Otosclerosis is a disease process that causes the formation of excess bone. This causes the footplate of the stapes to be fixed so that it no longer vibrates to transmit sound waves received via the tympanic membrane.

Signs, Symptoms, and Diagnosis

The patient often complains of difficulty hearing the voices of others, yet his own voice sounds unusually loud. In response to this, he may lower his voice to the point that he can scarcely be heard by others. Diagnosis is by otoscopic examination, Rinne and Weber tests, and audiogram.

Treatment

The hearing loss of otosclerosis can sometimes be corrected by using a hearing aid. Care for a hearing aid is presented in [Box 25-5](#). Microsurgical intervention can restore air-conductive hearing by providing a new movable pathway for the sound waves. During the operation, called a *stapedectomy*, the stapes is removed and is replaced with a prosthetic device. This device may be a steel wire and fat implant, a wire and a segment of vein, or a vein graft with polyethylene tubing. In any case, the prosthesis is attached to one end of the **incus** (anvil of the middle ear) so that sound can be transmitted to the inner ear. The surgical procedure is extremely delicate and would not be possible without the dissecting binocular microscope and other modern surgical instruments that allow visualization and manipulation of the very small structures of the middle ear. Outpatient surgery with local anesthesia is typical. Hearing improvement may not occur for about 6 weeks.

Tympanoplasty reconstructs the middle ear and improves conductive hearing loss. Tympanoplasty involves the surgical reconstruction of the tympanic membrane and ossicles to restore middle-ear function. There are several types of procedures, ranging from simple closing of a tympanic membrane perforation to extensive repair of the middle-ear structures. The procedure is performed with an operating microscope via the external auditory canal or through a postauricular incision. Although performed as an outpatient procedure, tympanoplasty requires general anesthesia.

Nursing Management

Postoperative care involves keeping the patient quiet and flat in bed for at least 12 hours. The head is turned so that the affected ear is uppermost. When the patient is allowed to move around, he must be warned that dizziness is likely to occur, especially if he turns his head suddenly. Position changes should be accomplished slowly. Coughing and sneezing should be prevented; if unavoidable, they should be accomplished with the mouth open to decrease pressure in the ear ([Nursing Care Plan 26-2](#)).

Nursing Care Plan 26-2

Care of a Patient Having a Tympanoplasty

Scenario

Miss Cook, age 38 years, is a high school teacher who has had progressive hearing impairment as a result of recurrent otitis media of the right ear. She is admitted to outpatient surgery for tympanoplasty. During her initial assessment, the nurse found Miss Cook to be well informed about the nature of her disorder but somewhat anxious about the outcome of surgery. Her physical health status is good; her only previous hospitalization was for an appendectomy when she was 19 years old. Care is for the postoperative period.

Problem Statement/Nursing Diagnosis

Potential for injury/*Risk for injury related to graft displacement.*

Supporting Assessment Data

Objective: Tympanoplasty.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Graft will be successful as evidenced by restored hearing in affected ear.	Position patient side-lying on nonoperative side.	Prevents collection of fluid behind graft and reduces pressure.	Positioned on nonoperative side or back with HOB raised 30 degrees.
	Reinforce preoperative instructions to remain in bed for 4 hr and avoid sudden movements, blowing nose, or sneezing.	These measures help prevent graft disruption.	Compliant with instructions. Continue plan.
	Check vital signs for evidence of infection bid.	Elevation in temperature may indicate beginning infection.	Temperature within normal range. No sign of infection.
	Give analgesic/sedative as ordered.	Analgesic/sedative will promote rest.	Patient resting comfortably; pain at 2/10.
	Provide quiet environment.	A quiet environment will promote rest.	Instruct patient and family to limit activities.

Problem Statement/Nursing Diagnosis

Altered activity tolerance/*Risk for activity intolerance related to vertigo and instability.*

Supporting Assessment Data

Subjective: After tympanoplasty, states she is very dizzy and nauseated.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Falls and head trauma will be prevented.	Up with assistance only. Repeat explanation for safety precautions.	Helps to prevent falls.	Asking for assistance when needs to get up.
	Caution patient to change positions and turn her head very slowly.	Abrupt changes in position are likely to cause vertigo and nausea.	Compliant with instructions.
	Provide well-lit room when ambulating.	Good lighting prevents tripping over obstacles when ambulating.	Room lighting is adequate.
	Administer medication prescribed for vertigo.	Medication can help control vertigo.	Medication for vertigo is effective.

Problem Statement/Nursing Diagnosis

Insufficient knowledge/*Deficient knowledge regarding postoperative care.*

Supporting Assessment Data

Subjective: Asks about restrictions and self-care.

Objective: Cannot verbalize knowledge of medications.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will verbalize knowledge of home self-care before discharge.	Instruct to avoid loud noises and pressure changes for 6 mo, especially avoiding flying and diving.	Loud noise and pressure changes can disrupt the graft.	Instructions reviewed verbally, and printed instructions left with patient.
	Stress importance of not blowing her nose for at least 1 wk and preventing upper respiratory infection; if at all possible, protect her ear against cold; and refrain from any activity that might provoke dizziness or disturb the graft (e.g., straining at stool, bending, and heavy lifting).	Preventing pressure changes helps protect the integrity of the graft.	Provided correct feedback on postoperative precautions.
Patient will demonstrate dressing change correctly before discharge.	Teach patient how to change dressing on the external ear.	Will prepare patient for self-care.	Patient has not changed bandage as yet. Continue plan.
	Reiterate importance of taking full course of prescribed antibiotic and reporting to surgeon at scheduled times.	Taking the full course of antibiotics correctly will help prevent infection.	Acknowledges importance of taking antibiotics as directed.
	Reassure patient that because of swelling of tissues and presence of surgical pack, it may be several weeks before she can fully evaluate effectiveness of the surgery.	Inflammation at the surgical site will cause swelling that interferes with hearing initially.	Reassurance given. States she understands that it may be a while before hearing is as good as it will get.

Critical Thinking Questions

1. Why can dizziness and vertigo occur after a tympanoplasty?

2. What level of noise would be considered “too loud”?

bid, Twice daily; *HOB*, head of bed.

Nursing Care of Patients Having Ear Surgery

Most ear surgeries are performed as outpatient procedures. Nursing care is focused on the immediate preoperative and recovery periods and on instructions for home care.

Preoperative Care

Nursing care of patients during the preoperative period is rather routine, except for the administration of eardrops or other special medications. Physical preparation for ear surgery may or may not involve removing some of the hair from the scalp. Male patients should be clean shaven the morning of surgery. The external ear and surrounding skin should be thoroughly cleansed, preferably with a surgical soap. Female patients with long hair should have it braided or pinned back securely so that it will not become soiled by drainage from the ear or serve as a source of infection at the operative site.

Postoperative Care

The patient will often return from major ear surgery with an ear dressing (Figure 26-13). Positioning of the patient after ear surgery depends on specific instructions from the provider. Often the patient is placed flat in bed, and his head is supported so that he does not turn it from side to side. In addition to noting the vital signs, watch for signs of injury to the facial nerve, including inability of the patient to close his eyes, wrinkle his forehead, or pucker his lips. The patient and family are advised to report such symptoms to the surgeon. If they appear later than 12 hours after surgery, they may indicate edema, and the provider may order a loosening of the dressings.

FIGURE 26-13 An ear surgery dressing. The patient is positioned with the head elevated or side-lying on the unaffected side.

Safety precautions, such as raising side rails, should be taken to prevent injuries from dizziness and loss of balance during the recovery period. Balance is temporarily affected as a result of disturbance to the mechanism that maintains equilibrium. When the patient is allowed to get up and move around, assistance should be provided to prevent falls. The patient should arise slowly to a sitting position and sit for a few minutes. Then the patient stands while holding on to something or being supported by another person. Dizziness must pass before the patient attempts walking.

Because the ear is so near the brain, special effort must be made to prevent contamination of the surgical site. Dressings may be reinforced to keep them dry, but excessive drainage must be reported to the surgeon.

The patient should be instructed beforehand about what is to be expected from the surgery. Hearing is usually slightly impaired immediately after surgery because of edema or bandages but is expected to improve in time.

Home Care Considerations

Instructions After Ear Surgery

The following instructions are given to the patient after ear surgery at the time of discharge:

- Sneezing, coughing, and nose blowing are all ways in which the operative site may be disturbed. If necessary, blow the nose gently one side at a time. Cough or sneeze with the mouth open. Continue this for 1 week after surgery.
- Do not drink through a straw for 2 to 3 weeks. Avoid drinking directly from the mouth of a plastic bottle, because negative pressure occurs if the bottle opening is sealed.
- Limit physical activity for 1 week after surgery. Refrain from exercising and sports for 3 weeks or until the surgeon discharges you.
- Avoid heavy lifting for 3 weeks. Avoid bending over from the waist or moving the head rapidly for 3 weeks.
- Keep the ear dry for 4 to 6 weeks after surgery by placing a cotton ball covered with petroleum jelly (such as Vaseline) in the ear canal; refrain from shampooing hair with water for 1 week after surgery.
- After the initial dressing is removed, place a cotton ball loosely in the ear to keep it dry and protected; change the cotton ball daily.
- Avoid people with colds.
- Do not fly until the surgeon allows it.
- Wear ear protectors when exposed to a loud environment.
- A return to work is usually allowed after 3 to 7 days; strenuous work may not be resumed for 3 weeks.

The surgeon will explain the specific time limitations for each activity based on the type of surgery.

Myringotomy (incision of the eardrum) with placement of tubes is a lesser outpatient procedure, and the only dressing may be a cotton ball in the ear. There is less occurrence of dizziness or nausea with this surgery.

Community Care

Cautioning people about the dangers of listening to loud music through earpieces can help curb hearing loss. Teaching adults to seek prompt medical attention for symptoms of otitis media prevents damage to the tympanic membrane and preserves hearing ability.

A hearing assessment should be part of any thorough health assessment. Encouraging those who have any difficulty with hearing to have a thorough evaluation and to try a hearing aid, if the need is indicated, could help improve the quality of their lives. Nurses in home and long-term care settings should frequently assess the function of the patient's hearing aid.

Various accommodations are available for individuals who are hearing impaired. Assistance dogs can help keep a person with a hearing impairment safe both in the home and on the streets.

Get Ready for the NCLEX® Examination!

Key Points

- A problem with refraction is the most common eye disorder.
- Cataracts cause a blurring or loss of vision and usually develop slowly.
- Cataract surgery with lens implant usually restores vision.
- The increase in IOP that occurs with glaucoma will eventually cause blindness if untreated.
- Glaucoma medication typically must be used for the rest of the patient's life.
- Acute narrow-angle glaucoma is a medical emergency.
- Symptoms of retinal detachment include flashing colored lights followed by the appearance of "floaters."
- Unless treated quickly and successfully, retinal detachment causes vision loss.
- Positioning and restriction of amount of movement are crucial after eye surgery.
- Retinopathy is a disorder that occurs most commonly in people with diabetes or hypertension.
- Tight glucose control helps prevent diabetic retinopathy.
- Retinopathy is commonly treated by laser.
- Keratoplasty may be performed to repair damaged corneas.
- Macular degeneration is a common problem in older adults but can occur at an earlier age.
- There is presently no cure for macular degeneration, but new drugs and treatments may be able to slow it or reverse some of the vision loss.
- Eye trauma should be treated by a health care provider promptly.
- Keep patients who have had eye surgery still, and treat nausea immediately.
- Otitis media is a common malady that may be induced by allergy or upper respiratory infection.
- Impacted cerumen or foreign bodies in the ear interfere with hearing.
- Otosclerosis is generally hereditary.
- Tympanoplasty may be performed for otosclerosis or for tympanic membrane dysfunction.
- Labyrinthitis and Ménière disease cause vertigo and tinnitus.

Review Questions for the NCLEX® Examination

1. A male patient was informed that he would need to wear a pair of corrective lenses for

astigmatism. When asked about the condition, the patient demonstrates understanding when he states that:

1. "Astigmatism is hardening of the ciliary muscles."
2. "Astigmatism is an irregular curvature of the cornea."
3. "Astigmatism enables focusing of light in front of the retina."
4. "Astigmatism is an increased opacity of the lens."

NCLEX Client Need: Health Promotion and Maintenance, Self-Care

2. Which instruction must be included in the discharge teaching of a patient who has undergone corneal transplant?

1. Increase physical activity.
2. Wear an eye shield when in close contact with children or pets.
3. Remove pressure dressing as needed.
4. Lie only on the operative side.

NCLEX Client Need: Health Promotion and Maintenance, Self-Care

3. An older adult is admitted for cataract extraction. Which sign or symptom is associated with this condition?

1. Increased tearing
2. Increasing farsightedness
3. Increasing complaints about glare
4. Bluish discolorations

NCLEX Client Need: Physiological Integrity, Basic Pathophysiology

4. People with diabetes may face several eye problems and diseases as a complication of their illness. Which of the following can cause severe vision loss or blindness in a person with diabetes? (Select all that apply.)

1. Glaucoma
2. Retinopathy

3. Presbyopia

4. Glaucoma

NCLEX Client Need: Physiological Integrity, Basic Pathophysiology

5. After eye surgery, a patient is instructed to avoid movements that increase the venous pressure in the head, neck, and eyes. Which movement(s) increase(s) venous pressure? (*Select all that apply.*)

1. Straining

2. Bending over

3. Keeping the head up

4. Sudden head movements

5. Strenuous exercises

NCLEX Client Need: Safe and Effective Care Environment, Safety and Infection Control

6. A woman complains of eye itching, tearing, halos around lights, and decreased central vision. Which symptom most clearly relates to macular degeneration?

1. Eye itching

2. Tearing

3. Halos around lights

4. Decreased central vision

NCLEX Client Need: Physiological Integrity, Basic Pathophysiology

7. Before eye surgery, a patient is instructed to take stool softeners. When asked about the rationale for taking the stool softener, an appropriate response would be:

1. “The medication reduces the possibility of straining at stool postoperatively.”

2. “The medication prevents constipation caused by anesthetic agents.”

3. “The medication cleanses the gastrointestinal tract.”

4. "The medication enhances surgical recovery."

NCLEX Client Need: Physiological Integrity, Pharmacological Therapies

8. Older adults are more prone to conductive hearing loss and tinnitus because of:

1. hypertrophy of the cerumen glands.
2. hardened cerumen.
3. widening of the auditory canal.
4. hair loss in the auditory canal.

NCLEX Client Need: Physiological Integrity, Basic Pathophysiology

9. The nurse emphasizes safety precautions to a 60-year-old female Hispanic patient with Ménière disease. An appropriate nursing approach would be to:

1. use the patient's first name when addressing her.
2. include family members in instructions.
3. address decision making to the patient.
4. set a specific schedule for providing instructions.

NCLEX Client Need: Safe and Effective Environment, Safety and Infection Control

10. What advice may you give an aging adult to help prevent macular degeneration? (*Select all that apply.*)

1. Do not smoke, or quit if you do.
2. Maintain a healthy weight; especially do not carry weight around the waist.
3. Avoid bending or heavy lifting.
4. Drink with a straw.

NCLEX Client Need: Health Promotion and Maintenance, Disease Prevention

Critical Thinking Questions

Scenario A

Mr. Lavant, age 52 years, and his wife, who has diabetes, have heard about a glaucoma screening clinic being held in their community. They are interested in attending the clinic but are very apprehensive about the kind of tests that will be done. They ask you about the tests and whether you think they should go to the screening clinic when they have no symptoms of glaucoma or any other eye disease.

1. How would you explain a test with a tonometer?
2. How would you explain glaucoma in terms Mr. and Mrs. Lavant could understand?
3. Who are among the people at high risk for glaucoma?
4. What is the usual treatment for chronic, open-angle glaucoma?

Scenario B

Mr. Wilson, age 78 years, is scheduled for a right cataract extraction and intraocular lens implant. He has bilateral cataracts that have made him legally blind for years. He did not consult a provider until recently, because he had always heard that cataracts had to be "ripe" before they could be treated, and he felt he could not afford frequent trips to a provider when nothing could be done for his condition. Mr. Wilson enters the outpatient surgery area, and you are assigned as his nurse.

1. How would you approach and orient Mr. Wilson to his surroundings?
2. What would you tell Mr. Wilson about the preoperative routine and medications at this time?
3. What problem statements would be appropriate for Mr. Wilson at this time?
4. What are the advantages of intraocular lens implants over cataract glasses and/or contact lenses?

Scenario C

Mr. Thompson is suffering from a severe attack of Ménière disease and vertigo. He is severely nauseated, and his vertigo prevents him from getting out of bed. The provider wants to rule out the possibility of tumor as a cause of Mr. Thompson's vertigo, so he is scheduled for an ENG with a caloric test and a MRI scan.

1. What nursing actions would be appropriate for him?
2. How would you explain this disorder to Mr. Thompson?
3. How would you explain these tests to Mr. Thompson?

UNIT IX

Gastrointestinal System

OUTLINE

Chapter 27 The Gastrointestinal System

Chapter 28 Care of Patients With Disorders of the Upper Gastrointestinal System

Chapter 29 Care of Patients With Disorders of the Lower Gastrointestinal System

Chapter 30 Care of Patients With Disorders of the Gallbladder, Liver, and Pancreas

CHAPTER 27

The Gastrointestinal System

Objectives

Theory

1. Explain the various functions of the gastrointestinal system.
2. Distinguish major causative factors in the development of disorders of the gastrointestinal system.
3. Summarize measures to prevent disorders of the gastrointestinal system.
4. Determine nursing responsibilities in the pretest and post-test care of patients undergoing diagnostic tests for disorders of the gastrointestinal system.
5. Develop a nursing care plan for a patient with diarrhea.
6. Correlate changes that occur with aging with alterations in gastrointestinal function.

Clinical Practice

7. Perform an assessment of gastrointestinal status.
8. Provide pretest and post-test care of patients undergoing tests of the liver, gallbladder, and pancreas.
9. Provide care for a patient who is experiencing vomiting.
10. Teach a patient strategies to alleviate constipation.

Anatomy and Physiology of the Gastrointestinal System

• Organs and Structures of the Gastrointestinal System

- The organs of the gastrointestinal (GI) system are the mouth, pharynx, esophagus, stomach, small intestine, large intestine, rectum, and anus ([Figure 27-1](#)).

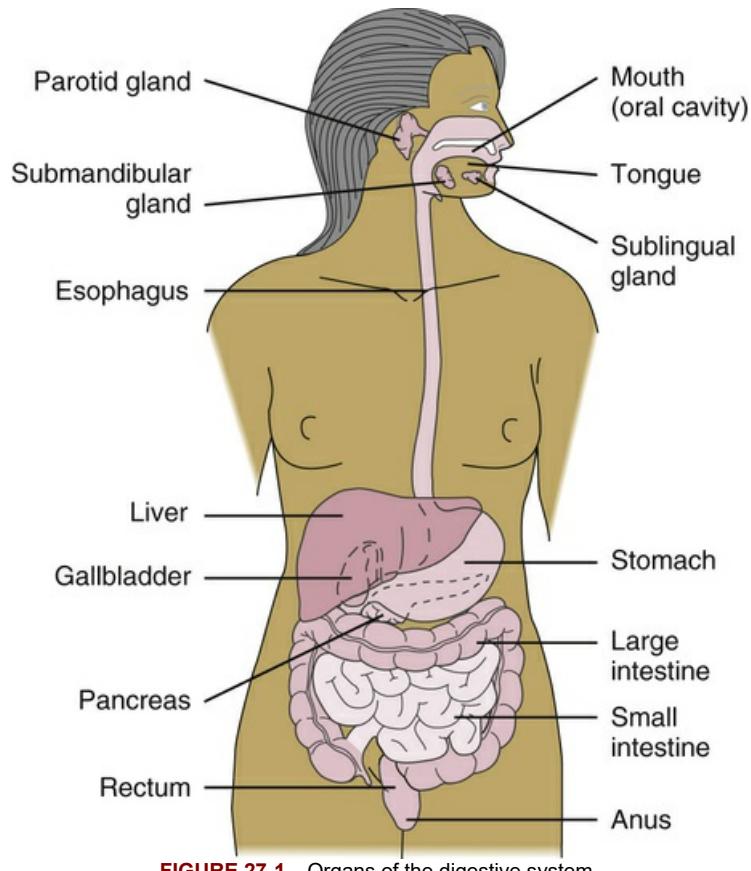

FIGURE 27-1 Organs of the digestive system.

- The accessory organs are the liver, gallbladder, and pancreas ([Figure 27-2](#)).

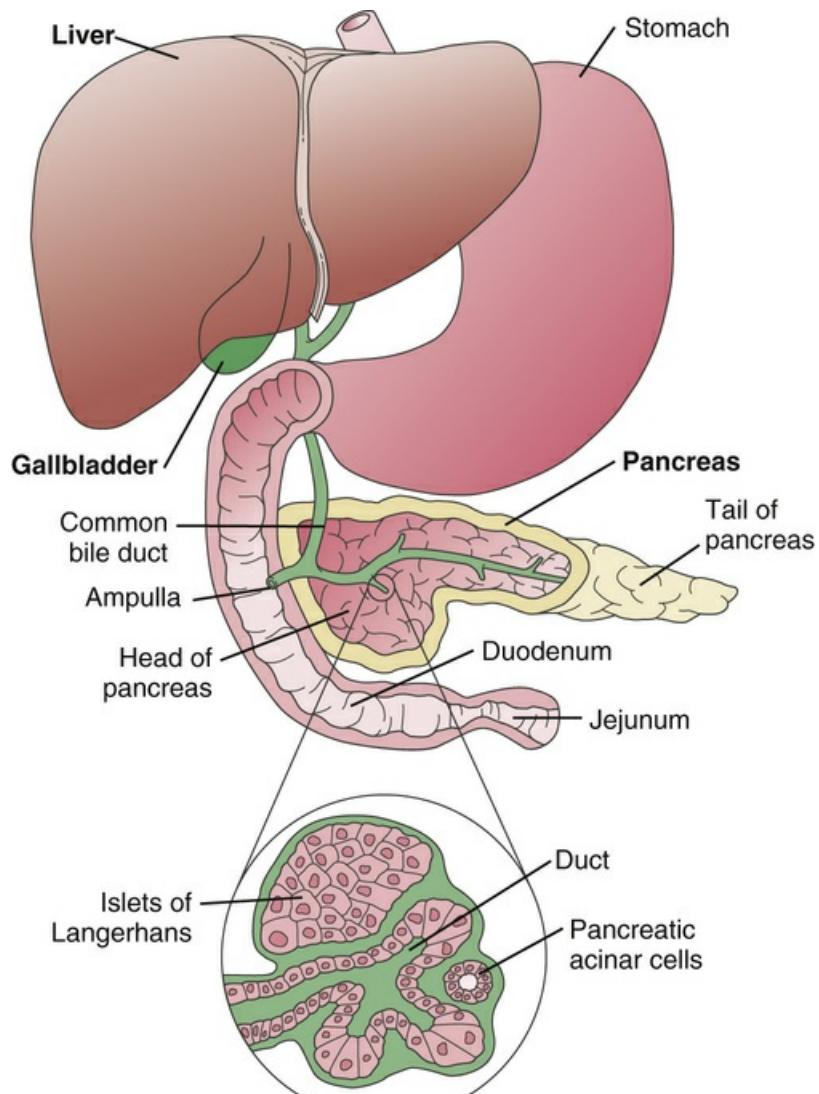

FIGURE 27-2 Accessory organs of the digestive system.

- The gastroesophageal sphincter (cardiac sphincter) controls the opening from the esophagus into the stomach; it prevents reflux from the stomach into the esophagus.
- The stomach lies in the upper left portion of the abdominal cavity (see [Figure 27-1](#)).
- The pyloric sphincter controls release of food substances into the small intestine ([Figure 27-3, B](#)).

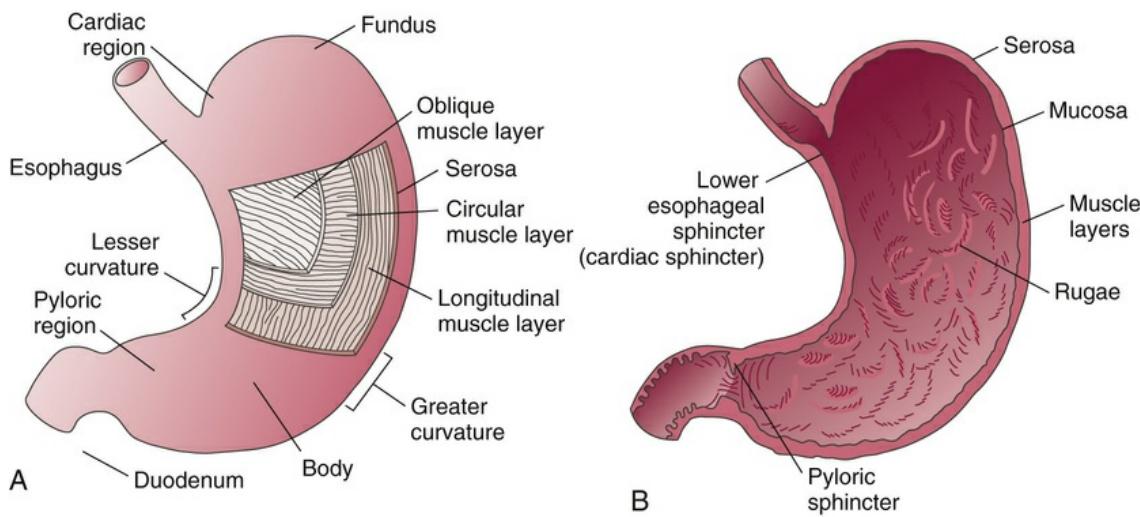

FIGURE 27-3 The stomach. **A**, External view. **B**, Internal view.

- The small intestine is divided into the duodenum, jejunum, and ileum and is about 6 m long.
- The ileocecal valve controls the progress of substances into the large intestine.
- The large intestine is divided into the cecum, colon, rectum, and anal canal; the colon is about 1.5 m long.
- The colon has four portions: the ascending, transverse, descending, and sigmoid colon.
- The appendix is attached to the cecum and has no known function in the digestive process.
- The walls of the digestive tract have four layers: mucosa, submucosa, muscular layer, and a serous layer called serosa.
- The peritoneum is a serous sac that lines the abdominal cavity and encloses the intestines, stomach, liver, and spleen and partially encloses the uterus and uterine tubes.

Functions of the Gastrointestinal System

- The teeth and tongue are instrumental in the chewing (**mastication**) process, and they help break down food into smaller pieces that can be acted on by various enzymes.
- Food moves from the mouth through the pharynx down the esophagus to the stomach, where mixing movements occur.
- Mucus, hydrochloric acid (HCl), intrinsic factor, pepsinogen, and gastrin are secreted into the stomach from cells within its walls and are mixed into the food to break down further the particles for absorption. This mixture of partially digested semi-liquid food is called **chyme**.
- The small intestine receives the chyme from the stomach, adds more digestive enzymes and fluids, receives bile and pancreatic enzymes from the common duct, and further digests the chyme into a more liquid state.
- Substances are moved along the intestinal tract by the peristaltic action of the intestinal smooth muscle.
- Digested food particles are absorbed into the bloodstream from the villi on the walls of the small intestine.
- The large intestine reabsorbs water and electrolytes, formulates some vitamin K, and eliminates waste products (Figure 27-4).

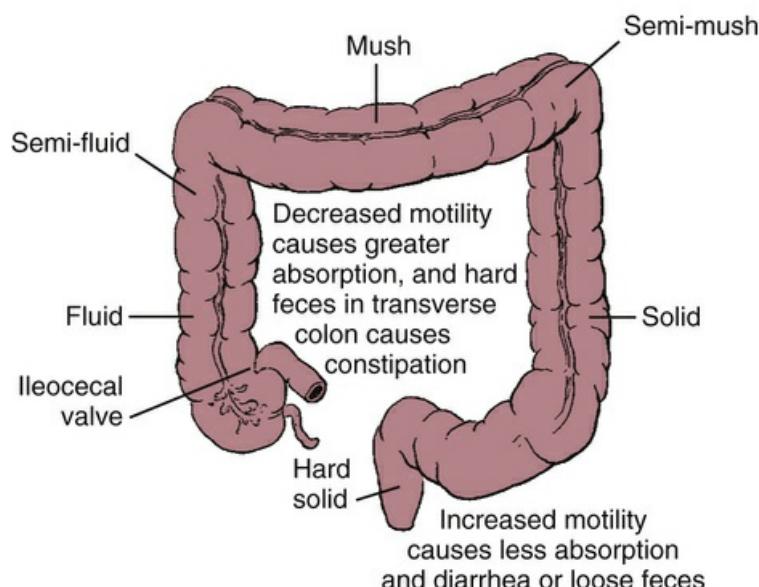

FIGURE 27-4 Absorptive and storage functions of the large intestine.

- The large intestine is populated with bacteria that aid in the breakdown of waste products.
- The rectum stores fecal material until it is eliminated through the anus.
- The internal anal sphincter at the top of the anal canal is under involuntary control; the external anal sphincter at the end of the anal canal is under voluntary control.
- The gastrocolic reflex initiates elimination; it is stimulated by the ingestion of food. By tightening the voluntary anal sphincter, the reflex emptying of the rectum can be stopped.

Effects of Aging on the Gastrointestinal System

- Dentures or partial plates and bridges are common in those older than 65 years. Ill-fitting dentures cause eating problems and can lead to nutritional deficits.
- With advanced age, muscles used for swallowing may become weaker and less coordinated, and food particles are retained in the cheek pouches or pharynx.
- The esophageal sphincter becomes less efficient at opening and closing, and risk for aspiration increases.
- Taste buds atrophy, causing inability to distinguish between flavors, particularly between salty and sweet.
- After age 70 years, the parietal cells in the stomach decrease their secretion of HCl; enzyme and intrinsic factor secretion also decrease. The lack of intrinsic factor may cause pernicious anemia.
- The mucosa of the small intestine becomes less absorptive, and the large intestine may develop diminished motility.

Structures and Locations of the Accessory Organs

- The **gallbladder** is a small sac attached to the lower portion of the liver.
- The **liver** is a large reddish brown organ located in the upper right quadrant of the abdominal cavity under the diaphragm; it is protected by the rib cage.
- The portal vein transports venous blood and nutrients absorbed from the small intestine to the liver.
- The **pancreas** is an elongated, flat organ that sits behind the stomach and consists of a "head" and a "tail" (see [Figure 27-2](#)).
- The gallbladder connects to the common bile duct that leads from the liver to the duodenum.
- The pancreatic duct extends the length of the pancreas and connects with the common bile duct, conducting its secretions into the duodenum.

Functions of the Gallbladder, Liver, and Pancreas

- The gallbladder stores bile produced in the liver and delivers it as needed to the small intestine; the gallbladder can store up to 50 mL of bile.
- The liver manufactures and secretes bile and bile salts necessary to digest fat.
- The liver synthesizes albumin, fibrinogen, globulins, and clotting factors.
- The liver is a storage area for glucose (in the form of glycogen); vitamins A, D, E, K, and B₁₂; and iron.
- The liver receives blood directly from the digestive tract via the hepatic portal vein. All nutrients and oral medications pass through the liver before being distributed to other parts of the body.
- The liver is responsible for how drugs are metabolized.
- The liver detoxifies and breaks down many compounds and drugs, preparing them for excretion; it alters ammonia, a byproduct of protein metabolism, so that it does not harm the body.
- The liver helps break down and excrete hormones, drugs, cholesterol, and hemoglobin from worn-out red blood cells.
- The liver plays a major role in glucose metabolism, removing excess glucose from the blood, converting it to glycogen, and then, as glucose is needed, converting glycogen back to glucose.
- The liver plays key roles in lipid metabolism, breaking down fatty acids and synthesizing cholesterol and phospholipids, and in converting excess carbohydrates and proteins into fats.
- The liver is instrumental in protein metabolism, converting certain amino acids into different ones as needed for protein synthesis.
- The liver is a large filter containing phagocytic Kupffer cells that remove bacteria, damaged red blood cells, and other toxic materials from the blood.
- The liver may store between 200 and 400 mL of blood.
- The liver synthesizes the prothrombin needed for normal blood clotting.
- The islets of Langerhans, which are regions of endocrine tissue in the pancreas, secrete the hormones insulin and glucagon into the blood; insulin is essential to the metabolism of carbohydrates.
- The pancreatic acinar cells secrete digestive enzymes into ducts that connect with the pancreatic duct.
- The major pancreatic enzymes are amylase, protease, trypsin, and lipase; these enzymes are essential to the digestion and absorption of nutrients from the small intestine.
- Secretion of pancreatic enzymes is controlled by secretin and cholecystokinin, two substances secreted by the intestinal mucosa.

Effects of Aging on the Accessory Organs of Digestion

- Gallstone incidence is higher in older adults, possibly because of an increase in biliary cholesterol related to diet and a tendency toward dehydration.
- Secretion of lipase from the pancreas decreases, altering fat digestion, and may contribute to a depressed nutritional state in older adults.

The Gastrointestinal System

The intestinal tract and accessory organs of digestion perform the intake, absorption, and assimilation of food to provide nourishment for the body. The transfer of nutrients from the intestine into the blood is referred to as **absorption**. Food substances are moved along the intestinal tract by **peristalsis** (wavelike motions of involuntary muscles within the walls of the organs).

Metabolism is the sum of many physical and chemical processes of the absorbed nutrients. Metabolic activities involve the synthesis of substances needed to build, maintain, and repair body tissues (**anabolism**). Metabolism is also responsible for the breakdown of larger molecules into smaller molecules so that energy is available (**catabolism**).

Gastrointestinal System Disorders

Causes

The GI tract is subject to infection, inflammation, physical and chemical trauma, and structural defects. An intestinal tract problem may be caused by blockage of movement of food through the intestine (intestinal obstruction). Postoperative **adhesions** sometimes cause intestinal obstruction. Adhesions are bands of scar tissue that bind two anatomic surfaces together that are normally separate. Tumor may also cause intestinal obstruction. Obstruction of the bile or pancreatic ducts can cause interference with the flow of digestive juices and of the enzymes needed for digestion. Continued irritation and inflammation of the GI mucosa can lead to intestinal bleeding and to increased peristalsis, causing inadequate absorption of nutrients.

Psychological and emotional stresses greatly influence appetite and motility of the stomach and intestines. The secretion of digestive juices in amounts sufficient for the breakdown of food is regulated in part by the emotions. The stress response may cause excessive GI secretions and decreased perfusion to the organs.

Think Critically

Why do you think providers frequently place hospitalized patients on GI prophylaxis medication?

Excessive stimulation of digestive acid and enzymes can cause a breakdown in the integrity of the mucous membrane lining the digestive tract. The damage to the mucous membrane can result in gastric or duodenal ulcers or chronic colitis.

Some disorders, such as Crohn disease and ulcerative colitis, are correlated with a genetic predisposition. Both disorders are more common among the Jewish population. Certain forms of colon cancer have been identified as having a genetic link, and there is a familial tendency for the occurrence of colon cancer. Esophageal and stomach cancer are linked to consumption of charred foods and those containing nitrates. Cigarette smoking is linked to stomach cancer.

Patient Teaching

Foods That May Contribute to Colon Cancer

The patient should be taught that the following foods may contribute to the development of colon cancer.

Nitrates and Nitrites

- Hot dogs
- Bologna and other luncheon meats
- Bacon
- Ham

- Smoked fish
- Some imported cheeses (check labels)

Nitrates and nitrites are used extensively as food preservatives. Check labels on “deli” products. Charred grilled foods and meat cooked at high temperatures also contain substances that are potentially cancer-causing.

Autoimmune diseases often affect the GI system, causing inflammation or fibrosis of organs. Treatments such as drug and radiation therapy may cause GI problems as a side effect. Some people who have undergone chemotherapy for cancer develop a mechanical form of sprue, a malabsorption problem that remains even after chemotherapy is complete. Lactose intolerance, which is common among older adults, may cause continuous diarrhea and malabsorption.

Think Critically

Can you identify any GI problems that seem to run in your family? What measures can family members take to prevent such problems?

Prevention of Gastrointestinal System Disorders

Eating a normal, well-balanced diet aids digestion. Maintaining good oral health is important to the health of the rest of the body. Consuming sufficient bulk in the diet helps maintain a healthy colon by enhancing passage of waste. A diet lacking in fiber is one factor in the development of diverticulosis, in which pockets form along the colon where waste material can lodge. Drinking at least eight glasses of fluid a day prevents constipation by helping to keep the stool moist.

Heeding the need to defecate promptly aids in keeping the gastrocolic reflex functioning well and prevents constipation and hemorrhoids. Straining at stool increases intra-abdominal pressure, which causes the hemorrhoidal vessels to engorge and contributes to hemorrhoid formation. Decreased mobility in older adults often leads to digestive problems; therefore ambulation is encouraged.

Health Promotion

Maintaining Abdominal Tone

Obtaining sufficient daily exercise maintains abdominal muscle tone and contributes to peristalsis and the ability to defecate normally. Defecating at more or less the same time each day aids the defecation process and helps promote continued ability to control defecation.

Maintaining body weight within normal limits helps prevent hiatal hernia and esophageal reflux. Developing healthy coping mechanisms and keeping stress within acceptable limits may prevent ulcers and chronic irritability of the bowel.

Mechanical and chemical irritants that produce inflammation often can be identified by elimination diets to determine the foods that cause GI upsets. Once the offending foods are identified, the patient can learn to avoid those foods while maintaining adequate nutrition.

Following general rules of good hygiene and sanitation can prevent many infectious GI events: wash the hands before cooking and eating and clean cooking and eating utensils properly. Food poisoning can be prevented by adequate refrigeration and by proper canning, freezing, and food-handling methods. Meats and foods containing mayonnaise or dairy products should be kept chilled. When not in the refrigerator, food should be kept covered.

Think Critically

How would you teach your family and friends about ways to decrease the risk of colon cancer? What would you recommend to your adult relatives regarding screening for colorectal cancer?

Causes of gallbladder disorders.

The formation of stones within the gallbladder can cause irritation and create areas susceptible to inflammation and infection. Stones can lodge in the common duct, causing obstruction to the flow of bile. Liquid weight loss diets or very rapid weight loss appears to be associated with developing gallstones. Women develop gallstones more frequently than men. The incidence increases with age, obesity, and having several children because pregnancy causes stasis of bile. People who have diabetes mellitus or Crohn disease are at higher risk for the disorder. Gallbladder disease tends to run in families, and it appears that there may be a genetic link.

Cultural Considerations

Genetic Gallstone Risk

Native Americans secrete high levels of cholesterol in their bile. Most Native American men have gallstones by age 60 years, and 70% of the women of the Pima Indians in Arizona have gallstones by age 30 years. Mexican Americans of both sexes and all ages also have high rates of gallstones ([National Digestive Diseases Information Clearinghouse, 2013](#)).

Prevention of gallbladder disorders.

Maintaining a normal body weight; eating a low-fat, low-cholesterol, high-fiber, and high-calcium diet; avoiding rapid weight loss diets; consuming alcohol moderately; and maintaining an active lifestyle all help prevent gallstones ([Watson, 2014](#)).  If gallstones are irritating the gallbladder, prompt surgery might help to prevent cancer.

Causes of liver disorders.

The liver filters out many toxic substances and is constantly exposed to any infectious organisms circulating in the bloodstream. The hepatitis virus in particular attacks the liver, causing inflammation and damage to the tissue. Hepatitis B and C are implicated in liver cancer ([Hepatitis B Foundation, 2014](#)). *Healthy People 2020* objectives include reducing the number of hepatitis infections and increasing awareness of having a hepatitis infection.

Many drugs and chemicals are toxic to the liver, and nurses should always be aware of the drugs their patients are taking that may cause liver damage. Alcohol and other toxic substances are major factors in  the development of cirrhosis of the liver ([Box 27-1](#)).

Box 27-1

Drugs and Substances Toxic or Harmful to the Liver

Toxic Drugs and Substances

- Acetaminophen (Tylenol)
- Carbon tetrachloride
- Ethyl alcohol
- Mushroom: *Amanita phalloides*
- Polychlorinated biphenyls (PCBs)
- Toluene
- Many pesticides

Many more drugs can cause liver problems. Consult the nursing implications for each drug administered. Consider the adequacy of the patient's liver function when administering medications because the liver detoxifies all medications.

Chemical Substances

- Acetaldehyde
- Aerosolized paint
- Cadmium
- Ethylene oxide
- Mercury
- Nitrosamines
- Paint thinner
- Many cleaning solvents

Liver trauma or laceration may cause massive internal hemorrhage. However, the liver is resilient and will regenerate if part of the liver remains functional and repair is performed quickly.

Parasites may cause cirrhosis, cysts, or abscesses. Most parasites that damage the liver enter the body when people wade or swim in contaminated water in tropical countries or eat contaminated food.

Cancer in the liver may be primary or may be secondary to metastasis from a site elsewhere in the body.

Prevention of liver disorders.

Obtaining immunization against hepatitis A and hepatitis B helps to prevent these viral diseases. A vaccine against hepatitis C is currently undergoing clinical trials (Vaccine News, 2015). Adults should be tested for the presence of hepatitis C. Using Standard Precautions (see [Appendix B](#)) when handling any body fluids, particularly blood, greatly reduces the risk of infection with hepatitis B and C, which may decrease the chance of developing liver cancer. Refraining from consuming excessive amounts of alcohol decreases the risk of developing cirrhosis of the liver. Avoiding exposure to known toxic or carcinogenic chemicals and drugs helps prevent liver damage and liver cancer.

Health Promotion

Preventing Contraction of Hepatitis

Practicing good hygiene and avoiding contact with substances that harbor the hepatitis virus, such as raw oysters and shellfish from contaminated waters, may prevent infection with hepatitis A. Avoiding unprotected sex with people who are drug users, or those known to be carriers of hepatitis B or C, helps prevent the contraction of both types of hepatitis.

Causes of pancreatic disorders.

Pancreatitis (inflammation of the pancreas) is associated with alcoholism, obstructive cholelithiasis, peptic ulcer, hyperlipidemia, and trauma. Pancreatic cancer incidence rises steadily with age. Although the cause of pancreatic cancer is not known, the incidence is higher in cigarette smokers. Obesity, chronic pancreatitis, and diabetes mellitus are also risk factors for this cancer. (See [Chapter 37](#) for information on diabetes mellitus.)

Prevention of pancreatic disorders.

Avoiding consumption of large quantities of alcohol may prevent pancreatitis. Removing a gallbladder that has gallstones can help prevent obstruction of the pancreatic duct with stones. Removal prevents backup of pancreatic enzymes that are believed to be a cause of pancreatitis. Compliance with therapy for a peptic ulcer helps prevent irritation of the pancreas and resultant

pancreatitis. Smoking cessation decreases the risk of pancreatic cancer.

Diagnostic Tests, Procedures, and Nursing Implications

Diagnostic tests for disorders of the intestinal tract and accessory organs consist of x-rays, computed tomography (CT) scans, nuclear medicine scans, magnetic resonance imaging, ultrasound studies, endoscopy, biopsy, laboratory tests, tests of gastric secretions, and stool and urine studies ([Table 27-1](#)).

Table 27-1
Diagnostic Tests for Gastrointestinal (GI) Disorders

TEST	PURPOSE	DESCRIPTION	NURSING IMPLICATIONS
Radiologic Examinations			
Upper GI series (UGI)	Radiographic examination with fluoroscopy to locate obstruction, ulceration, or growths in the esophagus, stomach, and duodenum	Patient drinks a contrast medium and is placed in various positions on the x-ray table.	Keep patient NPO for 8-12 hr before the test. Explain what happens during test. After radiographs, increase fluids and give ordered laxatives to clear GI tract of contrast medium and prevent impaction. Stool may be white up to 3 days after test.
Barium enema (BE)	Radiographic examination of the colon using fluoroscopy to locate tumors, obstruction, and ulceration	A radiopaque substance is instilled into the colon by enema. After evacuation of this substance, air may be instilled for contrast studies.	Keep patient NPO for 8 hr before test. Give ordered laxatives and enemas. Bowel must be clear of stool. Explain what will happen during the test. Post-test care is same as for upper GI series.
Computed tomography (CT)	To visualize soft tissue and density changes when sonography is inconclusive To detect tumors, abscesses, trauma, cysts, inflammation, and bleeding	Radiography is combined with computer techniques to provide a series of sectional pictures of the gallbladder, intestines, and other abdominal structures.	Patient is kept NPO for 4 hr when oral contrast is to be used. Verify presence of signed informed consent form for this procedure. Assess for allergy to iodine or shellfish. Explain to patient that she will be positioned supine on a special, narrow table, and her body will be in the circular opening of the scanner. She will have a strap over her waist to secure her to the table. Clicking noises will be heard from the machine. The test takes about 30 min. An IV contrast agent that causes a transitory warm feeling may be given to enhance images. Patient will be asked to hold her breath at certain points in the test. The machine uses narrow x-ray beams.
Virtual colonoscopy	Noninvasive method of determining whether there are polyps or abnormalities in the colon Does not allow for biopsy of suspicious areas	Helical CT scan of the colon is performed. An oral contrast agent may be given 1 day before the scan.	Patient must lie still during the procedure. Remove all metal from the body surface. Usually takes about 30 min. Encourage large quantities of fluid after the procedure if barium contrast material was swallowed.
Magnetic resonance imaging (MRI) with or without contrast	To evaluate abnormalities in the liver or other abdominal structures.	Places the patient in a magnetic field. Uses radiofrequency signals to determine how hydrogen atoms behave in the magnetic field. Provides better contrast than CT between normal tissue and pathologic tissue. Administration of IV contrast may be used to provide better imaging.	Explain that there is no exposure to radiation. Antianxiety medication may be administered to those patients who are claustrophobic. There are no food or fluid restrictions before the test. The test takes 30-90 min. Remove all metal objects from the body, including dental bridges. Inform patient that she will be required to remain motionless during this study. A thumping sound will be heard during the test. There may be a tingling sensation in metal fillings.
Ultrasound Imaging			
Ultrasonography	To obtain images of soft tissue that indicate density changes To diagnose gallstones, tumor, cysts, abscess, etc.	Sonograms are produced with high-frequency sound waves that pass through the body. Echoes vary with tissue density.	Patient is kept NPO after midnight. Explain procedure: will be supine on table, lubricant will be applied to the skin surface, and a handheld metal probe is passed back and forth with light pressure. Test takes about 30 min. Patient needs to remain still.
Nuclear Imaging Scans (Scintigraphy)			
Hepatobiliary scintigraphy (hepatobiliary iminodiacetic acid [HIDA] scan)	To determine blood flow distribution in the liver, biliary tree, gallbladder, and proximal small bowel To confirm cirrhosis, neoplasm, and acute cholecystitis	^{99m} Tc is injected. Patient is positioned under imaging camera, and images are taken as radioactive material is distributed.	Only traces of radioactivity are administered, and there is little radioactivity danger. Patient will lie flat during scanning.
GI scintigraphy	To determine site of active GI bleeding	Radioactive tracer is administered IV and attaches to red blood cells. Images of the abdomen are obtained at intermittent intervals.	Same as for hepatobiliary scan.
Endoscopic Studies			
Esophagogastroduodenoscopy	To visualize the esophagus, stomach, and duodenum with a lighted tube (endoscope) to detect tumor, ulceration, site of bleeding or obstruction Separate study of esophagus, stomach, or stomach and duodenum may be done	Patient is given IV sedation for the test. A local spray or gargle may be used to anesthetize the throat. The patient lies on a table with head extended, and the endoscope is introduced through the mouth.	Keep patient NPO for 8 hr. Verify presence of signed informed consent form for procedure. Explain what she will experience during the test. Make sure an IV is in place. After procedure, keep patient NPO until gag reflex has returned. Take vital signs q15-30min as ordered. Watch for signs of perforation: rising temperature, pain, changes in vital signs.
Endoscopic retrograde cholangiopancreatography (ERCP)	Performed when common radiologic studies do not reveal the cause of the problem To identify obstruction and other pathologic conditions in the	An endoscope is passed through the mouth into the duodenum with the use of fluoroscopy. A cannula is positioned in the common bile duct, and a contrast medium is injected. Radiographs are then taken.	Verify presence of signed informed consent form for procedure. Patient is kept NPO after midnight. Explain the procedure to the patient (same as for esophagogastroduodenoscopy). Postprocedure care is same as for esophagogastroduodenoscopy.

	biliary and common ducts		
Flexible sigmoidoscopy	To examine the lining of the rectum and sigmoid colon to detect polyps, tumor, obstruction, or ulceration	The patient is placed in the knee-chest position, often on a special table. A sigmoidoscope is introduced through the anus. Biopsies can be taken from areas of suspect tissue; polyps can be removed. The patient will experience some cramping during the procedure.	Give bowel preparation medications the evening before or as prescribed. Give clear liquids for dinner the night before, then keep patient NPO until after examination. Explain what she will experience. Encourage use of deep breathing and relaxation techniques to decrease cramping. Observe for rectal bleeding after biopsy or polyp removal.
Colonoscopy	To directly view the lining of the colon with a flexible endoscope	Patient is moderately sedated for this procedure, which takes about 30 min to 1 hr. Polyps can be removed or biopsies taken.	Give clear liquid diet 1-3 days before test. Patient is kept NPO for 8 hr before test. Give bowel prep as ordered. Explain procedure and what she will experience. Verify presence of signed informed consent form for procedure. After procedure, observe for rectal bleeding and signs of perforation: abdominal distension, pain, elevated temperature.
Gastric analysis	To determine the rate of secretion of gastric juices and degree of acidity	A nasogastric tube is inserted, and the stomach contents are aspirated. A substance may be given to stimulate the flow of gastric secretions, and another sample is aspirated in 30 min. Increased secretion can indicate peptic ulcer or pancreatic tumor. A low degree of acidity may indicate gastric ulcer. An absence of acid can accompany cancer of the stomach or pernicious anemia.	Withhold drugs affecting gastric secretion for 24-48 hr before test. No smoking the morning of test (nicotine stimulates secretions). Keep patient NPO for 8 hr before test. Explain use of NG tube and procedure.
Liver biopsy	To remove a tissue sample for microscopic examination and diagnosis of various liver disorders	Under local or general anesthesia, a special biopsy needle is inserted through the abdominal wall into the desired area of the liver, and a tissue sample is aspirated.	Verify presence of signed informed consent form for procedure. Patient must be kept NPO 4-8 hr before procedure. Place patient in supine or left lateral position. Patient will need to hold very still if performed under local anesthesia. The needle is introduced during sustained exhalation. She will feel pain similar to a punch in the shoulder lasting only a minute or so. Procedure takes about 15 min. Take baseline vital signs. Assess for allergy to local anesthetic. Have patient empty her bladder before the procedure. Check coagulation studies for abnormalities. After biopsy, place a small dressing over puncture site; position patient on right side with support to provide pressure over biopsy site for 1-2 hr. Observe for bleeding. Monitor vital signs q15min for 1 hr; then q30min for 4 hr; then q4hr for 24 hr. Assess for tenderness at biopsy site. Observe for respiratory problems, such as dyspnea, cyanosis, or restlessness, which might indicate pneumothorax. Instruct patient to avoid coughing or straining that might increase intra-abdominal pressure. She should refrain from heavy lifting or strenuous activities for 1-2 wk.
Laboratory Tests			
Tubeless gastric analysis	To determine of presence or absence of hydrochloric acid in the stomach secretions	The patient is given special granules in 240 mL of water. Urine specimens are collected at specific intervals. If HCl is present in the stomach, the urine will be blue; if none is present, the urine will be normal color.	Explain test and procedure to patient.
Fecal analysis (stool examination): fecal occult blood test (FOBT) stool culture or fecal immunochemical test (FIT)	To analyze for presence of mucus, elevated fat content, blood (guaiac), bacteria, or parasites	Stool specimen is obtained in bedpan or container in commode. For fecal occult blood test, a small smear is made on special paper and tested with special solution for guaiac or with Hemoccult test. To culture stool a specimen is placed in container and sent to laboratory for testing. For FIT, swab is taken from middle of stool specimen and then placed in tube with special solution.	Explain test to patient. Provide means for collection of stool. Promptly retrieve stool, obtain sample for guaiac test, place specimen in laboratory container, and dispatch to laboratory immediately (bacteria will multiply if specimen is left at room temperature for extended period; parasites may disintegrate). Patient must have red meat-free diet for at least 3 days before a stool guaiac test can be considered accurate.
Serum bilirubin <i>Normal values:</i> Total: 0.3-1.9 mg/dL Direct: 0.0-0.3 mg/dL	To detect abnormal bilirubin metabolism Jaundice is present when bilirubin is >2.5 mg/dL	Collect venous blood. Protect sample from bright light.	Explain that a blood sample will be taken. Some laboratories require an 8-hr fast.
Alanine aminotransferase (ALT) <i>Normal value:</i> 1-45 International Units/L	An enzyme used to detect liver disease With viral hepatitis, ALT/AST ratio is >1.0 With other liver disease, ALT/AST ratio is <1.0	Collect venous blood. Injury of liver cells causes release of this enzyme.	Explain that a blood sample will be collected. No fasting is required.
Aspartate aminotransferase (AST) <i>Normal range:</i> 1-36 units/L	An enzyme found in heart, liver, and muscle tissue To detect acute hepatitis or biliary obstruction	Collect venous blood. Diseases affecting hepatocytes cause this enzyme to rise in the blood.	Explain that a blood sample will be drawn. Prevent hemolysis of sample. IM injection will affect level.
Alkaline phosphatase (ALP) <i>Normal range:</i> 35-150 units/L	Enzyme found in bone, liver, and placenta To detect liver tumor in conjunction with other clinical findings Rises when there is obstruction of biliary tree	Collect venous blood.	No fasting is required.
Ammonia <i>Normal range:</i> 10-80 mcg/dL	Is a product of protein metabolism To support diagnosis of severe liver disease with encephalopathy	Collect venous blood. May need to ice the specimen.	No fasting is required.
Gamma-glutamyl transpeptidase (GGT) <i>Normal range:</i> 510 g/dL	To detect liver cell dysfunction, biliary obstruction, cholangitis, or cholecystitis	Collect venous blood.	Explain that a blood sample will be taken. Drugs that affect this test are alcohol, phenytoin, phenobarbital, clofibrate, and oral contraceptives.
Protein <i>Normal range:</i> 6.0-8.0 g/dL	To detect altered protein metabolism Decreased in liver failure	Collect venous blood.	Explain that a blood sample will be drawn. No fasting is required.
Albumin <i>Normal range:</i> 3.5-5.5 g/dL	To detect altered protein metabolism	Collect venous blood.	No fasting is required.
Prothrombin time (PT) <i>Normal range:</i> 12.0-14.0 sec	Protein produced by the liver and used in blood clotting Depends on adequate intake and absorption of vitamin K Reduced in patients with liver disease, causing a prolonged clotting time	Collect venous blood.	No fasting is required. Apply pressure to venipuncture site. INR used to determine therapeutic level of anticoagulant medication.
Partial thromboplastin time	To detect deficiencies	Collect venous blood.	No fasting is required.

(PTT) Normal range: 60-70 sec	of stage II clotting mechanisms Prolonged in liver disease		Apply pressure to venipuncture site.
Activated PTT (APTT) Normal range: 20-35 sec	Activators have been added to PTT tests reagents: APTT decreased in liver failure	Collect venous blood.	If patient is receiving heparin injections, draw specimen 30-60 min before next dose.
<i>Helicobacter pylori</i> antibody test Normal: none present	To detect antibodies to <i>H. pylori</i> bacterium in the stomach <i>H. pylori</i> is a risk factor for gastric and duodenal ulcers, chronic gastritis, or ulcerative esophagitis	Collect a sample of venous blood according to the laboratory's instructions.	Explain to patient that a blood sample will be drawn. No fasting is required.

GI, Gastrointestinal; IM, intramuscular; INR, international normalized ratio; IV, intravenous; NG, nasogastric; NPO, nothing by mouth; ^{99m}Tc , technetium-99m.

The patient often is scheduled for a series of tests, some of which use a contrast medium. Check the patient's allergies to verify that a particular contrast medium or injectable marker is not contraindicated. For women of childbearing age, a pregnancy test might be ordered. It is important that GI tests be performed in the correct order, so that the contrast media do not interfere with other tests. For example, if a patient is scheduled for an upper GI series, a gallbladder sonogram, and a barium enema, she should have them done in this order: sonogram, barium enema, upper GI series.

A relatively new test, virtual colonoscopy, is available for colon cancer screening. The procedure combines images from a high-tech spiral CT scan to create a computer-generated three-dimensional picture of the colon. The procedure is less costly than standard colonoscopy and requires no sedation. However, if a polyp or suspicious area is seen, the patient must undergo a regular colonoscopy for tissue specimens to be obtained. For screening, a yearly fecal occult blood test, or fecal immunochemical test (FIT), is recommended. Stool DNA is a new primary screening test for colorectal cancer. Take-home fecal occult blood test smears should be performed in sets of three; positive results indicate the need for colonoscopy (American Cancer Society, 2014).

The patient needs specific instructions about preparing for a diagnostic test. Many of the studies require cleansing of the GI tract; inadequate bowel preparation may cause a delay or necessitate a repeat of the test. When laxatives are administered in liquid form, the patient can drink them more easily if they are chilled or poured over ice.

Older Adult Care Points

Older adults are especially at risk for problems of electrolyte imbalance, fluid overload, or dehydration when preparing for diagnostic tests that require a fasting state and/or bowel cleansing.

Assignment Considerations

Assisting with a Bowel Preparation

When a UAP is assigned to care for a patient who is undergoing a bowel preparation for a diagnostic test, ask the assistant to be prompt in answering a call bell for assistance to the bathroom. The need to defecate may be urgent. When a patient is consuming large quantities of fluid, such as with GoLYTELY, ask the UAP to promptly report any degree of confusion, shortness of breath, extra weakness, or muscle cramping. Remember that delegation is never a substitute for good nursing assessment.

Clinical Cues

If a patient has trouble with nausea, sucking on an ice cube first and then using a straw to drink the solution for colon preparation helps to decrease the taste sensation.

For many GI tests, the patient is kept on nothing-by-mouth (NPO) status the night before. In the hospital, mouth care should be offered in the morning, and the door of the room should be kept closed so that food odors do not enter and increase hunger. A food tray should be obtained immediately on return to the floor, as long as NPO status is no longer in effect. Provide juices and coffee or tea while waiting for the meal tray to be delivered. Frequent assessment for signs of

dehydration is necessary. Lack of oral intake can quickly dehydrate a patient who has already been ill with nausea, vomiting, or diarrhea.

❖Nursing Management

■ Assessment (Data Collection)

Assessment for problems of the digestive system and accessory organs begins during history taking. Ask questions regarding family history, diet, dietary intolerances, pain, bowel patterns, exposure to toxins or chemicals, and problems with blood clotting. Verify immunization status. Because of the many functions of the liver, assessment of a patient with liver disease must include all systems of the body.

▣ Focused Assessment

Data Collection for the Gastrointestinal System and Accessory Organs

When obtaining a GI history, ask the following questions:

- Have you gained or lost weight recently?
- Do you have any difficulty chewing or swallowing?
- When did you have your last dental examination?
- Do you ever experience indigestion? Do certain foods disagree with you? Do you have known food intolerances?
- Do you drink alcohol? About how often do you drink? How many drinks do you average?
- Has your appetite changed in any way?
- Have you been experiencing any abdominal pain or nausea and vomiting? Do you experience any regurgitation or reflux? Is pain related to your eating patterns?
- Can you describe your usual diet? How much of each item do you eat? (Ask about what is eaten at each meal typically, and then ask about between-meal snacks and drinks.)
- What drugs do you take on a regular basis? (Aspirin, nonsteroidal anti-inflammatory drugs [NSAIDs], and corticosteroids are particularly important.)
- Are you able to shop and prepare meals? Is there any problem with obtaining sufficient food (if patient is known to have economic constraints)?
- Do you have any cultural preferences for food?
- What is the typical frequency of your bowel movements? Have you noticed any changes in color, frequency, or form of stools?
- How do you handle stress? How do you relax?

Additional questions pertinent to the accessory organs:

- Does eating fatty or fried food give you pain or diarrhea?
- Does your blood take a long time to clot when you cut yourself?
- Have you had any rapid weight loss? Are you dieting?
- Have you been immobile for a long period of time?

- Have you been exposed to chemical toxins such as cleaning agents, pesticides, or industrial chemicals?
- Have you had hepatitis B and/or hepatitis A immunizations?
- Have you ever had a blood transfusion?
- Have you had any surgeries? If so, what were they and what year?
- Do you use recreational drugs?
- Do you have any tattoos or body piercings?
- Do you smoke? If so, how much do you smoke? How many years have you smoked?
- Have you experienced any abdominal trauma?
- Do you have a sexual partner? Are you monogamous? Has any sexual partner been a carrier of hepatitis B or hepatitis C?

Physical Assessment

Inspect the patient's teeth, gums, and oral mucosa for obvious problems. Examine the skin for color and lesions, and note any discolorations on the abdomen. Assess for the presence of edema and **ascites** (fluid in the abdominal cavity) by observing for marked abdominal distention and by taut, glistening skin. Check the contour of the abdomen, and note any outpouchings indicating a hernia.

Auscultate bowel sounds for each quadrant of the abdomen using the diaphragm of the stethoscope ([Figure 27-5](#)). **Perform auscultation before palpation or percussion, because palpation may cause peristaltic movement** that otherwise would not have occurred. Bowel sounds are caused by air and fluid moving through the intestinal tract and are heard as soft gurgles and clicks every 5 to 15 seconds. The normal frequency for these sounds is about 5 to 30 in 1 minute. Note both the character and frequency of sounds. Loud, frequent sounds occur when there is excessive motility in the bowel. Although routinely performed, there is controversy about the usefulness or accuracy of bowel sound auscultation ([Felder et al, 2014](#)).

Clinical Cues

For bowel sounds to be considered absent, it is necessary to verify that no sounds are heard after listening in each of the four quadrants for 5 minutes. Hypoactive bowel sounds can be noted in the medical record when no sounds are heard after listening in each of the four quadrants for 30 seconds. If hyperactive, high-pitched sounds are heard in one quadrant, and decreased sounds are heard in another quadrant, assess for nausea and vomiting, because the patient may have an intestinal obstruction.

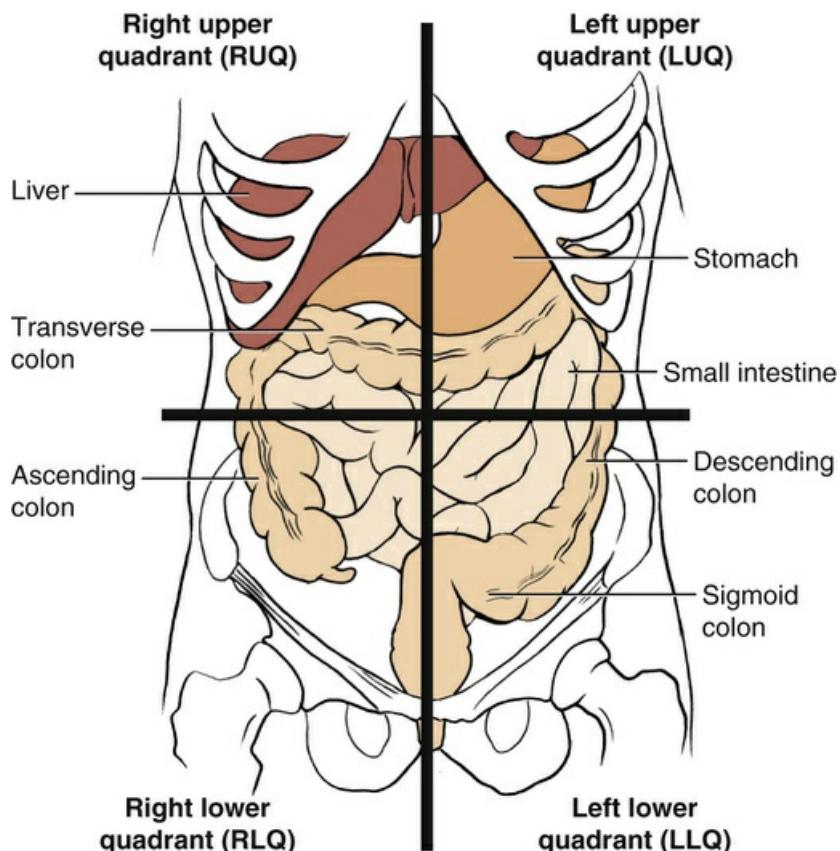

FIGURE 27-5 Auscultate bowel sounds in all four quadrants. (From deWit SC, O'Neill P: *Fundamental concepts and skills for nursing*, ed. 4, St. Louis, 2013, Saunders.)

Lightly palpate over each quadrant of the abdomen to detect areas of tenderness and any masses that might be present. Watch the patient's face during palpation to detect signs of discomfort. If a pulsating abdominal mass is present, do not perform palpation; this pulsation could signal an abdominal aneurysm with a potential danger of sudden rupture.

Percussion is performed by placing the middle finger of one hand on the abdomen and striking the finger lightly below the knuckle and listening for the pitch of sound produced. A resonant sound is heard over areas filled with air, and a dull, thudding sound is heard over solid organs. **Percussion detects excessive air in the intestinal tract, which occurs with irritation and inflammation.**

Assess ascites by placing the patient supine and exposing the abdomen. With the patient's arms at the sides and knees flexed, observe for **bulging flanks**, indicating fluid accumulation. If ascites is present, measure abdominal girth. Place a tape measure around the fullest part of the abdomen, usually at the umbilicus. Place small ink marks at the sides of the tape on the axillary lines, so that future measurements may be taken at the same place for comparison. If ascites is continuous, the abdominal girth will increase with subsequent measurements. Percuss from the umbilicus to the flanks to detect shifting dullness caused by air rising and fluid shifting to the dependent areas.

Check the laboratory values and diagnostic test results (see Table 27-1). Evaluate the urine for presence of bilirubin, which makes the urine dark or tea-colored. Inspect stool for the presence of fat and urobilinogen. If undigested fat is present, the stool will float in the toilet bowl. If bile is not reaching the intestine, the stool appears clay-colored or whitish.

Focused Assessment

Physical Assessment of the Gastrointestinal System and Accessory Organs

- Inspect the mouth for condition of teeth, gums, and mucous membranes.
- Assess swallowing ability.

- Inspect the skin for color, areas of discoloration, and presence of surface vessels and easy bruising.
- Inspect the sclera and mucous membranes for signs of icterus.
- Inspect the contour of the abdomen.
- Auscultate for bowel sounds in all four quadrants.
- Lightly palpate each quadrant of the abdomen.
- Percuss each quadrant of the abdomen if there seems to be a problem with intestinal irritation or inflammation.
- If there is evidence of ascites, measure abdominal girth.
- Inspect stool, if available, for characteristics; test for occult blood if indicated.
- Inspect color of urine.
- Inspect anus for presence of external hemorrhoids.
- If vomiting has occurred, inspect vomitus for characteristics; test vomitus for blood if indicated.

Older Adult Care Points

Recording all the medications an older adult is taking, both prescription and over-the-counter, is very important when assessing the digestive system. Many drugs affect digestion, bowel motility, and appetite in these patients and can cause nausea, constipation, or diarrhea.

Nursing Diagnosis and Planning

Problem statements and examples of expected outcomes for problems of the GI tract are listed in **Table 27-2**. Specific NANDA-I nursing diagnoses are chosen from the NANDA-I list (see inside back cover). More time is typically needed to care for a patient who has diarrhea or is incontinent of feces. It is important to consider the time it takes for toileting and cleaning up after loose bowel movements. A bowel retraining program takes patience and time. These time-consuming tasks are also assignment considerations for UAPs. Patients may need to be treated using isolation precautions which will increase time for care.

Table 27-2
Common Problem Statements, Expected Outcomes, and Interventions for Patients With Gastrointestinal Disorders

PROBLEM STATEMENTS	GOALS/EXPECTED OUTCOMES	NURSING INTERVENTIONS
Fluid volume deficit due to nausea and vomiting or diarrhea	Vomiting will be controlled within 24 hr; diarrhea will be controlled within 24 hr. Fluid volume will be within normal limits within 48 hr as evidenced by adequate skin turgor and urine output >50 mL/hr.	Assess urine output for signs of fluid deficit. Provide mouth care after vomiting to decrease nausea. Medicate for nausea and vomiting as ordered. Provide quiet environment and rest. Medicate for diarrhea as ordered; keep patient clean and dry. Give only small sips of clear liquids by mouth until vomiting subsides. Continue clear-liquid diet until diarrhea is controlled.
Altered nutrition status due to anorexia, nausea, and vomiting	Patient will ingest at least 1200 calories per day after vomiting subsides.	Offer mouth care before meals. Provide six small meals a day plus small, high-calorie snacks between meals. Weigh every 3 days and record. Keep room odor free. Provide company and quiet atmosphere for mealtime.
Diarrhea due to intestinal infection or inflammation	Infection or inflammation episode will resolve within 72 hr. Diarrhea will be controlled to prevent fluid imbalance within 24 hr.	Medicate with antibiotics, anti-inflammatories, and antidiarrheals as ordered. Rest bowel with clear-liquid diet or bland diet as ordered. Protect anal mucosa with barrier ointment. Keep anal area clean and dry. Provide warm sitz bath to soothe anal tissues as needed. Medicate for discomfort from abdominal cramping as ordered. Provide restful environment.
Constipation due to side effects of medication, loss of ability to initiate defecation, or improper diet	Patient will have normal bowel movements regularly within 2 wk.	Increase fluid intake to 2500 mL/day unless contraindicated. Add fruit juices to diet. Increase fiber in diet; add slowly to prevent excessive gas formation. Increase exercise on a daily basis. Encourage patient to heed gastrocolic reflex and not delay defecation. Administer stool softener or bulk laxative as ordered. Monitor for fecal impaction.
Incontinence due to lack of rectal sphincter	Patient will use bowel training program.	Institute bowel training program.

control	Continence will be achieved within 1 mo.	Provide toileting opportunity after each meal. Provide privacy and comfort for attempts at defecation. Adjust diet to provide optimal fiber in diet. Keep patient clean, dry, and odor free.
Limited coping ability due to inability to handle excessive stress	Patient will identify desired ways of coping within 3 wk. Patient will learn new coping techniques within 2 mo.	Assist to identify present coping mechanisms. Assist to identify stressors. Instruct in ways to develop more effective coping mechanisms, such as relaxation techniques, alterations in perspective, exercise, or imagery. Refer for counseling as needed.

■ Implementation

Institute nursing interventions to control and eliminate pain; maintain fluid and electrolyte balance; promote adequate nutrition, rest, and healing; and prevent complications (see [Table 27-2](#)). All nurses must ask each patient each day about bowel movements to prevent constipation and possible impaction in hospitalized patients.

■ Evaluation

Analyze laboratory values to see whether problems are resolving with treatment. Ideally, the patient should demonstrate normalization of eating habits and bowel patterns; however, **continually evaluate whether the patient is experiencing adverse side effects of therapy or complications of the disease process**. For legal reasons and for continuity of care, your evaluation findings and your follow-up actions must always be documented.

Common Problems Related to the Gastrointestinal System

Anorexia

Anorexia is the absence of appetite. Physical causes for a diminished interest in eating include poorly fitting dentures, stomatitis, decaying teeth, halitosis, and a bad taste in the mouth. Pain or nausea or the presence of a mouth or GI infection or irritation decreases appetite. Diseases of the GI tract also can diminish appetite.

Appetite depends on complex mental processes having to do with memory and mental associations that can be pleasant or extremely unpleasant. Appetite is stimulated by the sight, smell, and thought of food. The physical and social environment in which a person is eating stimulates appetite. The enjoyment of eating can be inhibited by unattractive or unfamiliar food, by unpleasant surroundings, and by emotional states such as anxiety, anger, and fear. Mental depression also may cause anorexia.

Nursing management.

Loss of appetite is to be expected when a person becomes ill. However, persistent anorexia must be addressed to prevent the consequences of inadequate nutrition. Because of the complex nature of anorexia, it may be necessary for you to talk with the patient, family, and significant others and to consult the medical record to learn why appetite has diminished.

▣ Older Adult Care Points

Both taste and smell sensation diminish with age. Sometimes this is because of a zinc deficiency. Older adults may lose teeth because of gingival or dental disease, making eating more difficult. Dental plates may not fit correctly, making eating painful. Many older adults take a variety of medications for various conditions. The combination of these medications may greatly affect appetite and digestion. **Polypharmacy** (taking many medications) is often a cause of anorexia in older adults.

Nursing interventions include mouth care before each meal to eliminate or minimize oral causes of poor appetite. Laboratory results regarding albumin and electrolyte levels should be monitored. The percentage of each meal eaten should be noted and documented.

If psychosocial or cultural factors are involved, you might try offering preferred foods if possible and not detrimental to health. Meals that are planned to include a variety of colors, textures, and tastes are more appealing and enjoyable than those that are monotonous and bland.

▣ Assignment Considerations

Assisting with Meals

Instruct the UAP who is assisting with meals to encourage patients to eat slowly and enjoy the meal. If it is necessary to feed the patient, this should be done cheerfully and in a manner that encourages the social aspect of eating.

Older Adult Care Points

If weight loss and loss of appetite occur in an older adult without evidence of any specific cause, the possibility of depression should be investigated. A depressed older adult may give up hope and just stop eating much.

The nurse, a family member, or a friend can provide companionship while the patient eats. If there is a patient cafeteria or gathering place for patients to eat together, and the patient is able to go there for meals, this can sometimes alleviate or minimize anorexia.

Any time a patient has continual problems with eating, a dental care history and an oral cavity examination should be performed. Some people may be embarrassed by physical limitations that cause them to be awkward with eating, and so will eat very little in the company of others. Others who have difficulty swallowing and are afraid of choking are afraid to eat alone, but are embarrassed when eating with others. It is essential to explore each patient's causes of anorexia and feelings about eating.

Food from home often is a welcome addition to institutional meals. The person bringing it will need to be advised of any restrictions on the patient's dietary intake and the importance of adherence.

Assignment Considerations

Oral Rehydration for Older Adults

Institutionalized older adults are at high risk for dehydration. Instruct the UAP to directly offer small amounts of fluid, especially water, to patients throughout the day (unless contraindicated) and to assist by opening containers and positioning fluids within reach. A variety of fluids, such as juice, milk, or low-sodium liquids, should be available. Caffeine-containing beverages should be limited because of the diuretic effects (Mentes, 2012).

Nausea and Vomiting

Persistent nausea and vomiting interferes with eating and hinders nutrition. Nausea and vomiting may be related to illness, anesthesia, pain, effects of cancer treatment, or stress. Transient nausea is not treated, but when the disorder persists, medication with antiemetics, GI tube feedings, and administration of intravenous (IV) fluids are necessary.

Assignment Considerations

Smells Exacerbate Nausea

When caring for patients who are prone to nausea, all health care personnel should be instructed to avoid using self-care products with strong scents. Some very sensitive patients may be affected by the fragrance from common products such as laundry detergent, lotions, hair products, soaps, deodorant, or makeup.

Complementary and Alternative Therapies

Ginger for Nausea

Ginger has been used for centuries in Asia to combat nausea and vomiting, motion sickness, and

dyspepsia. It is available candied; in capsules, fluid extract, and tablets; and as a tincture or as fresh gingerroot that can be grated and used to make tea. Ginger may decrease the action of histamine (H_2)-receptor antagonists and proton pump inhibitors and may increase absorption of medications taken orally. Ginger may decrease the effect of antidiabetic medications. It should not be used during pregnancy or lactation.

Clinical Cues

A quick and temporary measure that relieves nausea is to have your patient sniff a fresh alcohol prep pad.

Accumulation of Flatus (Gas)

Surgical intervention, mechanical obstruction, and accidental injury to the intestinal tract can cause disturbances in the passage of gas and fecal material. Whenever ingested material cannot pass through the intestinal tract as it should, the material accumulates in the stomach and the intestines. Pressure and distention occur when peristalsis is decreased or the flow of chyme (semiliquid, partially digested stomach contents) is inhibited by an obstruction. **Flatus** (gas) is formed by the action of digestive juices and bacteria on the ingested material, resulting in bloating.

Nursing management.

Assisting the patient to ambulate has traditionally been the nursing intervention for sluggish peristalsis or bloating. This works for some patients, but others continue to have discomfort. If the provider will permit it, a slight Trendelenburg position can be useful in speeding the expulsion of gas. Placing the buttocks and legs higher than the trunk and head causes gas to rise toward the rectum, making it easier to expel flatus. For patients who do not have abdominal incisions, massaging the abdomen gently is helpful. Work up the right side, across, and down over the left colon to move gas toward the rectum. Use both hands, placing the left hand behind the right after moving the gas along the bowel before lifting the right hand. This helps prevent gas from moving backward. Advise the patient to avoid chilled or hot drinks, which may create more gas. Antiflatulent medications that contain simethicone, such as Phazyme, are helpful if the patient is not NPO.

Patient Teaching

Exercise to Reduce Gas and Bloating

Teach patients experiencing bloating and excessive gas the following exercise unless contraindicated:

- Lie on your back with your legs extended and a pillow under your knees.
- Slowly raise your right leg, bend the knee, and bring the leg down toward the abdomen.
- Hold this position for a count of 10, then slowly lower your leg back down to the bed.
- Take three slow deep breaths and repeat the exercise with the left leg.
- When you feel the need to expel gas, do so; do not hold back.
- Repeat the exercise three or four times with each leg. Perform the exercise several times a day with rest periods between the exercise periods.

Think Critically

Can you teach a patient three ways to prevent the occurrence of excessive gas postoperatively?

Constipation

When constipation occurs, the stool is hard, dry, and difficult to pass. There may be a bloated feeling, and defecation may be painful. Consistency of stool is greatly influenced by the type of food eaten and the quantity of liquid consumed. A diet low in fiber or inadequate fluid intake predispose to constipation. Physical inactivity, ignoring the gastrocolic reflex, stress, and some neurologic disorders affecting the nerves in the intestinal tract also may contribute to constipation. Opioid medications can also contribute to constipation by slowing peristalsis. Methylnaltrexone bromide (Relistor) was originally approved by the Food and Drug Administration for patients with advanced illness who are receiving opiates for palliative care. It has recently been approved for general use in all patients with opioid-induced constipation (Jeffery, 2014).

In addition to not passing stool regularly, signs and symptoms of constipation include hypoactive bowel sounds, abdominal distention, a firm abdomen, and abdominal discomfort or pain.

Older Adult Care Points

Constipation is a problem among many people older than 60 years. Decreased GI motility, lack of exercise, limited fluid intake, and constipating medications taken for various conditions all contribute. In much older adults, difficulty getting to the bathroom and suppression of the defecation urge may also contribute to the problem. Reliance on laxatives is common among older adults and is to be discouraged. Counsel individual patients about ways to increase dietary fiber and encourage fluid intake of at least 2500 mL/day, if not contraindicated by the presence of cardiac or renal disease.

Nursing management.

The first step is to identify the cause of constipation. Initial treatment may include a rectal suppository to induce evacuation or the administration of a laxative. A stool softener may be prescribed. Fiber and liquids are increased in the diet. If this does not resolve the problem, the patient is placed on one of the bulk-forming laxatives, to be used daily, such as Metamucil. If the colon has become impacted with stool, digital extraction may be needed. The patient may be medicated with a mild analgesic 30 to 60 minutes before impaction removal to decrease the discomfort of the procedure, and an oil retention enema may be given. Then apply a lubricant, such as K-Y jelly or the anesthetic lubricant lidocaine (Xylocaine) jelly, into the rectum and around the anus and, using a gloved finger, break up and remove the feces.

Counsel the patient to add lots of raw fruits and vegetables to the diet, to eat more whole-grain cereals and breads, add bran to the diet, and drink lots of fluids. Fruit juices are particularly helpful, because they contain fructose, which is a natural laxative. Help the patient to design an acceptable exercise program, such as walking, bicycling, running, swimming, or active sports participation. Advise her to heed the urge to defecate without delay.

Think Critically

Can you list six foods high in fiber that a patient might add to the diet to combat constipation?

Diarrhea

The frequent passage of liquid or semiliquid stool is called *diarrhea*. It occurs with a variety of illnesses, food poisoning, excessive stress, and inflammation of the bowel. Mild diarrhea is not treated. If diarrhea persists for more than 24 to 48 hours or the number of stools is so excessive that great quantities of fluid are lost, treatment should begin. Signs and symptoms include multiple liquid or semiliquid bowel movements, hyperactive bowel sounds, and abdominal cramping.

Antidiarrheal agents such as diphenoxylate hydrochloride (Lomotil), loperamide hydrochloride (Imodium), tincture of opium (paregoric), or a combination product, such as Kaopectate, are administered (see Table 29-1). If the diarrhea is severe, nothing is given by mouth until it subsides. If diarrhea is moderate, only clear liquids are permitted by mouth. Severe, long-term diarrhea may require the use of total parenteral nutrition. When diarrhea is caused by infection, stool cultures and antibiotics may be necessary. As the condition improves, the diet is advanced.

Complementary and Alternative Therapies

Probiotics for Infectious Diarrhea

When probiotics (“friendly” bacteria that are normally present in the intestinal tract) are used in conjunction with rehydration therapy, risk for diarrhea and duration of diarrhea are reduced ([WebMD, 2014](#)).

Nutrition Considerations

Foods That Thicken Stool

When a patient has severe diarrhea and is allowed to resume solids foods, slowly introduce foods that help to thicken the stool, including applesauce, bananas, rice, bread, beets, potatoes without skin, oatmeal, creamy peanut butter, pasta, tapioca, or yogurt.

Nursing management.

For patients with diarrhea, monitor intake and output and assess the amount of fluid lost in the stool, measuring it if needed. Administer ordered medications and replace lost fluids. Monitor the patient for electrolyte imbalances and watch for signs of dehydration, such as decreased skin turgor, thick oral secretions, and decreased urine output. Taking small amounts of an electrolyte replacement solution, or Gatorade, helps prevent imbalances. Avoiding coffee or tea helps, because caffeine is a gastric stimulant and increases peristalsis. Thorough hand hygiene is essential when caring for the patient, and Standard Precautions are followed (see [Appendix B](#)). When infection is the cause of the diarrhea, follow contact precautions to prevent spread of the infection. Antibiotics kill harmful bacteria but they also eliminate normal intestinal flora. Patients taking antibiotics can develop a bacterial infection with *Clostridium difficile* (*C. diff.*) that causes severe diarrhea. Isolation precautions for *C. diff.* are not the same as Contact Precautions (see [Chapter 6](#)).

Warm sitz baths may relieve soreness and discomfort in the tissues; help the patient cleanse the area and avoid excessive wiping. Keeping the patient clean and dry is a high priority. Odor in the room may be reduced with a deodorizing spray and by emptying and cleaning bedpans and commodes quickly.

Clinical Cues

Frequent, loose bowel movements cause rectal irritation. Instruct or assist the patient to apply a lubricant such as A&D ointment, Aquafor, Desitin ointment, or petroleum jelly to protect the skin and promote comfort.

Bowel Training

Severe illness, trauma, neurologic damage, or prolonged bed rest may bring about bowel incontinence. This is very embarrassing for alert patients. Make every effort to keep the patient clean and dry. Tracking the time of incontinent movements and offering toileting after each meal may help eliminate the problem. Should incontinence be persistent, the cause should be identified and then a bowel training program instituted. For bowel training, the patient should be in a private environment 20 to 40 minutes after a meal and assume a normal sitting position for defecation if possible, or a side-lying position if bedridden. The nurse or patient performs digital stimulation by gently inserting and rotating a gloved, well-lubricated finger into the rectal sphincter. This action should be done on a regular basis to mimic the patient's normal bowel pattern. A warm drink with lemon or prune juice may also help to stimulate the bowels. Consistency and patience are vital to the success of retraining the bowel. In accordance with National Patient Safety Goals, encourage safety and instruct the patient to call for help in getting to and from the toilet. Reassure the patient that calling for help ensures safety and provides an opportunity to observe the progress of the training program.

Get Ready for the NCLEX® Examination!

Key Points

- Peristalsis moves food through the GI tract.
- The process by which the nutrients are used in the body after digestion and absorption is called *metabolism*.
- **Anabolism** is the building of body tissues from the nutrients. **Catabolism** is the breakdown of larger molecules into smaller molecules so that energy is available.
- The gallbladder stores bile and can be removed without harm to the body.
- The pancreas provides enzymes for digestion and insulin, and daily replacement of these substances must occur if the pancreas is removed. The secretion of lipase from the pancreas decreases with age, altering fat digestion.
- Problems of the GI system include infection, inflammation, trauma, and structural defects. Continued irritation and inflammation of the GI mucosa can lead to intestinal bleeding and increased peristalsis with inadequate absorption of nutrients.
- Immunization for hepatitis A and B prevents liver disease. Hepatitis B and C are risk factors for liver cancer.
- Controlling alcohol consumption helps prevent cirrhosis of the liver and pancreatitis.
- If damage to the liver is halted before all tissue is affected, the liver can regenerate.
- Check urine color for darkness (color of tea), and check stool for whitish or clay color; these findings suggest that the bile ducts may be blocked.
- Taste and smell diminish with age, and the gradual loss of these senses may decrease appetite. Poor dentition may make eating difficult for the older adult.
- Medications can affect appetite and digestion.
- Ambulation and oral simethicone are helpful in reducing gas.
- Severe diarrhea can cause fluid and electrolyte imbalances and dehydration.
- Increasing fiber, fluids, and exercise helps prevent or relieve constipation.
- Bowel training is designed to mimic and restore the patient's normal bowel pattern.

Review Questions for the NCLEX® Examination

1. A common cause of liver toxicity is:

1. daily hydrochlorothiazide administration for hypertension.
2. regular consumption of a high-fat diet throughout life.
3. long-term smoking of a pack of cigarettes per day.

4. taking extra-strength acetaminophen at doses of 4500 mg per day.

NCLEX Client Need: Physiological Integrity: Basic Pathophysiology

2. Measures used to teach patients to prevent gastrointestinal ulcers include:

1. limiting the amount of routine alcohol consumption
2. refraining from the use of aspirin for a headache
3. taking an H₂ inhibitor to decrease stomach acid daily
4. eating hot, spicy food at least once each day.

NCLEX Client Need: Health Promotion and Maintenance: Health Promotion/Disease Prevention

3. The nurse is planning care for several patients who had diagnostic testing. Which patient will require the most time for postprocedural care?

1. Patient who had an ultrasound
2. Patient who had hepatobiliary scintigraphy
3. Patient who had a liver biopsy
4. Patient who had a *Helicobacter pylori* antibody test

NCLEX Client Need: Physiological Integrity: Reduction of Risk Potential

4. The nurse is preparing a patient for a liver biopsy. Which nursing interventions should be included? (Select all that apply.)

1. Attending to patient's fears and anxiety
2. Checking for a signed consent form for the procedure
3. Assessing for dehydration and electrolyte imbalance
4. Positioning on right side
5. Checking coagulation studies for bleeding problems
6. Noting any allergy to local anesthetics

NCLEX Client Need: Physiological Integrity: Reduction of Risk Potential

5. A patient is consuming large quantities of laxative fluid as part of the bowel preparation for a diagnostic procedure. Which side effect is most likely to occur?

1. Constipation
2. Rashes
3. Dehydration
4. Chest pains

NCLEX Client Need: Physiological Integrity: Basic Pathophysiology

6. A decreased secretion of intrinsic factor is a physiologic change associated with the aging process; therefore the nurse suspecting decreased intrinsic factor should assess for which behavior?

1. A refusal to eat salty or sweet foods
2. A change in stools after eating fatty foods
3. Fatigue and activity intolerance
4. Difficulties with mastication

NCLEX Client Need: Physiological Integrity: Basic Pathophysiology

7. During assessment of the liver, the nurse assesses:

1. the right abdomen by palpation.
2. for areas of gas within the intestines.
3. history of episodes of vomiting.
4. for signs of gastrointestinal ulcer.

NCLEX Client Need: Integrated Processes: Clinical Problem-Solving Process (Nursing Process)

8. The nurse emphasizes the importance of eating natural sources of fiber to a patient who has frequent constipation. Which patient statement indicates effective health teaching?

1. "I will consider eating more white bread."
2. "I will drink fluids only while consuming meals."

3. "I will add more milk to my morning cereal."
4. "I will eat more fruits and vegetables."

NCLEX Client Need: Health Promotion and Maintenance: Health Promotion/Disease Prevention

9. A 30-year-old woman is admitted with complaints of severe nausea and vomiting over the past 2 days. On admission she is hypotensive and extremely weak. What is the priority problem?

1. Altered breathing pattern.
2. Altered activity tolerance.
3. Deficient fluid volume.
4. Altered cardiac output.

NCLEX Client Need: Integrated Processes: Clinical Problem-Solving Process (Nursing Process)

10. A nurse is discussing healthy lifestyle measures with a group of older adults during a senior seminar. What instruction(s) should the nurse include as accurate information? (*Select all that apply.*)

1. Consume sufficient fiber.
2. Eat a normal, well-balanced diet.
3. Exercise regularly.
4. Drink at least three glasses of fluids.
5. Take laxatives regularly.

NCLEX Client Need: Health Promotion and Maintenance: Health Promotion/Disease Prevention

11. An older adult woman of Puerto Rican descent is admitted for persistent anorexia and dehydration. There are no apparent underlying organic causes for loss of appetite. Which intervention(s) would be culturally appropriate? (*Select all that apply.*)

1. Determine food preferences.
2. Encourage family visits.
3. Provide small amounts of food and fluid frequently.
4. Consider parenteral nutrition.

5. Consult dietitian and speech therapy.

NCLEX Client Need: Psychosocial Integrity: Cultural Awareness

12. A patient who is dehydrated because of vomiting and diarrhea needs IV fluid therapy. The provider orders 1000 mL normal saline to infuse over 6 hours. The drip factor is 10 gtt/mL. Calculate the rate to infuse per gravity at _____ drops per minute.

NCLEX Client Need: Physiological Integrity: Pharmacological Therapies

Critical Thinking Questions

Scenario A

Mr. Achaba, 68 years old, was admitted with jaundice, abdominal distention, abdominal pain, and malaise. He is to undergo an ERCP. He is apprehensive and frightened about what may be wrong with him.

1. What is involved in an ERCP procedure?
2. Explain pretest care to help alleviate Mr. Achaba's apprehensions.
3. What is included in the post-test care?
4. What could be possible causes of his jaundice?

Scenario B

Ms. Hopgood is a resident in your extended care facility. She has been losing weight, has no appetite, and is becoming more withdrawn. Her daughter has a new job and is not able to visit as many times a week as she had been.

1. What assessments would you think appropriate for Ms. Hopgood at this time?
2. What nursing interventions could you institute that might improve her nutritional status?
3. What could you do to help her loneliness now that her daughter cannot visit as often?

Scenario C

You are making home visits to an older adult to check his blood pressure. During the visit he tells you that he is having trouble with constipation.

1. What questions should you ask to further assess the problem?
2. Why is constipation a common problem for people older than 60 years?
3. Would you recommend the use of an over-the-counter laxative? Why or why not?
4. What dietary and lifestyle recommendations would you make?

CHAPTER 28

Care of Patients With Disorders of the Upper Gastrointestinal System

Objectives

Theory

1. Discuss eating disorders and their management, including bariatric surgery.
2. Compare the signs and symptoms of oral, esophageal, and stomach cancer.
3. Illustrate the cause of gastroesophageal reflux disease (GERD).
4. Explain the etiology and prognosis for Barrett esophagus.
5. Describe the pathophysiology, means of medical diagnosis, and treatment for gastritis.
6. Compare and contrast the treatment and nursing care of a patient with GERD and a patient with a peptic ulcer.
7. Contrast the difference between the care of a patient with a nasogastric tube for decompression and the care of a patient with a feeding tube.
8. Determine reasons why total parenteral nutrition might be prescribed for a patient and describe necessary precautions to take during administration.

Clinical Practice

9. Implement a teaching plan for a patient who has GERD.
10. Provide appropriate care for a patient with dysphagia.
11. Plan postoperative care for a patient having gastric surgery.
12. Demonstrate proper care of a patient with a Salem sump tube for gastric decompression.
13. Manage a tube feeding for a patient receiving formula via a feeding pump.
14. Write a nursing care plan for a patient with an upper gastrointestinal disorder.

KEY TERMS

vagotomy (vă-GŎT-ō-mē, p. 657)

Eating Disorders

Anorexia Nervosa

Anorexia nervosa is classified as a psychological disorder (see [Chapter 45](#)), but it has serious nutritional consequences. In many contemporary cultures, the emphasis on a slim body has influenced young women's body image. A patient with anorexia nervosa refuses to eat adequate quantities of food and is in danger of literally starving to death. Although it is a psychiatric disorder, the patient may be admitted to the medical floor for treatment of malnutrition by enteral or parenteral therapy. Diagnosis requires extensive interviewing and treatment—including behavior modification and nutrition support—which may take months to years.

Bulimia Nervosa

Bulimia nervosa is another psychological disorder covered in [Chapter 45](#). A person who has bulimia nervosa consumes large quantities of food and then induces vomiting to get rid of it so that weight is not gained. Laxatives may be taken to purge the system after an eating binge. Some patients with anorexia nervosa also have bulimia nervosa. Some individuals practice bulimia occasionally, without harm. When it is practiced frequently, it can lead to severe fluid and electrolyte imbalances, starvation, dental problems, and death. Treatment of bulimia includes psychotherapy, antidepressant medication, and behavior modification.

Obesity

Obesity is a worldwide problem and is particularly prevalent in industrialized nations. More than one third of adults in the United States are obese, and more than one third are overweight ([Centers for Disease Control, 2014](#)). Obesity is a known risk factor for cardiovascular disease and associated death. Type 2 diabetes and certain cancers are also linked to obesity. Children are showing a continued trend for increasing obesity. There is an ongoing search to determine a possible genetic predisposition to this disorder. Prevention of obesity and encouraging healthy and nutrition-dense foods are goals of *Healthy People 2020*.

Etiology and Pathophysiology

Several factors must interact for obesity to occur: a diet of foods high in calories and fat, lack of exercise, and overconsumption of food. There may be a genetic predisposition as well. Some medications increase appetite. Known contributors to obesity include readily available high-calorie prepackaged foods, the prevalence of high fructose corn syrup in foods, consumption of sodas, and high-fat fast food and “supersized” portions available in restaurants.

For some people overeating is a reaction to stress; for others overeating is a substitute for absent pleasures. Some obese people seem to metabolize nutrients differently from others. The way a person develops fat cells and deposits fat is another factor in obesity. Family lifestyle is most likely a factor because obesity seems to occur among family members.

Signs and Symptoms

A person is considered obese if he weighs more than 20% above the ideal weight for his height, age, and body type. Approximately 3 million Americans are **morbidly obese**, meaning being 100% above their ideal body weight, or having a body mass index greater than 40.

Obese patients should be counseled to lose weight to help prevent the many diseases in which obesity is a contributing factor. Complications of obesity include:

- Diabetes mellitus
- Hypertension
- Hyperlipidemia
- Coronary artery disease
- Obstructive sleep apnea
- Cholelithiasis

- Cancer
- Arthritis with back and/or knee problems
- Increased susceptibility to infectious disease and decreased wound healing.

Think Critically

You have a friend who is overweight, and she asks your opinion about the effectiveness and safety of over-the-counter “diet” pills. How would you respond?

Diagnosis

To determine whether a patient is obese, the following measurements are used:

- Height and weight chart: if more than 20% above ideal body weight for age and body build, the patient is considered obese.
- Measure the waist and then the hip circumference. Calculate the waist-to-hip ratio (waist measurement divided by the hip measurement). If the ratio is more than 1.0 in men or 0.8 in women, it indicates that the person is overweight. This is a more accurate indicator for obesity in the older adult.
- A body mass index (BMI) of more than 30 indicates obesity .

$$\text{BMI} = \frac{\text{Weight (kg)}}{\text{Height (m}^2\text{)}}$$

Thyroid function should be determined to ascertain that hypothyroidism is not a cause of the weight gain.

Treatment

Dietary control and exercise are the main treatments for obesity. A general health assessment should be conducted before a patient is placed on a weight reduction diet. A provider will usually prescribe a lower-calorie diet and exercise. The patient is taught ways to change thinking about food and weight. Those with a BMI greater than 40 may have surgery to achieve weight reduction if they meet established criteria. Participation in a support group and behavior modification with some sort of reward for weight loss are part of the total treatment plan. Teaching stress reduction and alternate ways of coping are essential to success. Medications that suppress appetite or block fat absorption may be used on a short-term basis. Orlistat (Xenical, Alli) inhibits lipase, causing fats to remain partially undigested and unabsorbed. Gastrointestinal (GI) side effects of orlistat include diarrhea (sometimes uncontrolled), abdominal cramping, and nausea. Lorcaserin (Belviq) can cause a 5% weight loss within 1 year for those for whom it works. It has a potential serious side effect of serotonin syndrome if taken along with selective serotonin reuptake inhibitor (SSRI) antidepressants or monoamine oxidase inhibitor (MAOI) medications. Phentermine-topiramate (Qsymia) was approved in 2012 for obesity. It has been found to be safe for 2 years of usage. A 12-week trial is used to determine whether it will work for the patient. These drugs are not to be used during pregnancy. Some of the newer medications being marketed are a combination of older Food and Drug Administration (FDA) approved medications paired with newer drugs.

Older Adult Care Points

Older adults may become obese because of decreased mobility from arthritis or other joint disorders. Cooking and eating are less appealing if the person is living alone, and snacking on junk food may replace meals. Metabolic rate slows with age, and a decreased calorie intake is needed to maintain a normal weight.

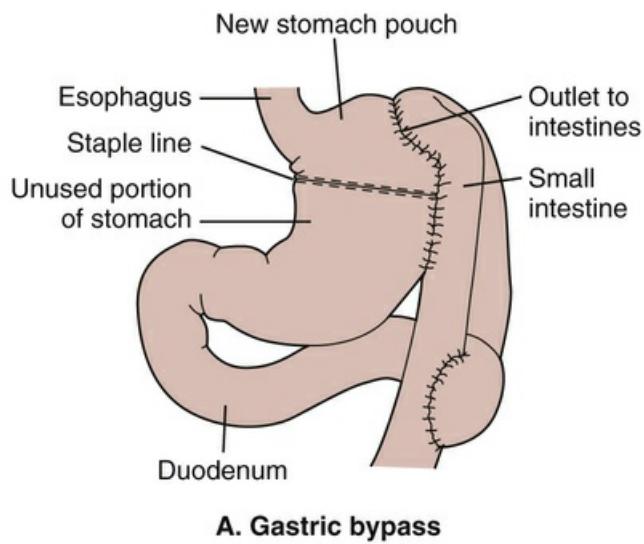

Bariatric surgery.

Bariatric surgery reduces gastric capacity. The patient undergoes extensive counseling and assessment. The patient must agree to modify his lifestyle and follow the stringent regimen

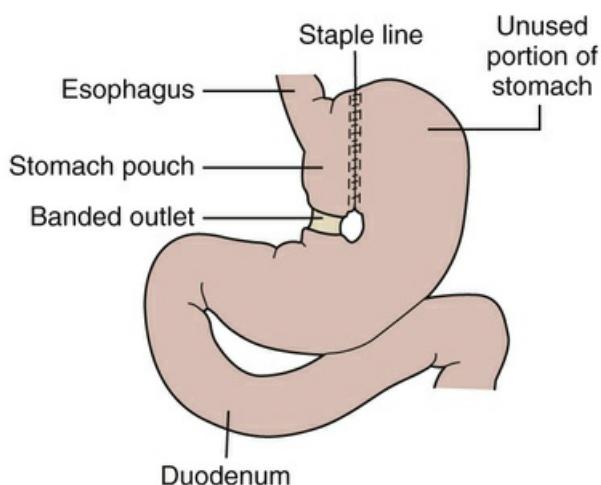

required to lose weight and keep weight off. Three common types of bariatric surgery are gastric restrictive, malabsorptive, and gastric restrictive combined with malabsorptive surgery.

Restrictive procedures.

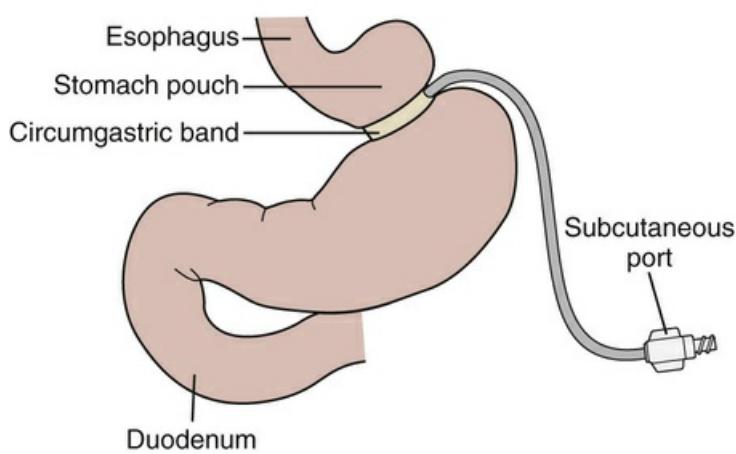

Adjustable gastric banding is a laparoscopic procedure performed by placing an inflatable band around the fundus of the stomach. The band is inflated and deflated via a subcutaneous port to change the size of the stomach as the patient loses weight. For **vertical banded gastroplasty**, the surgeon creates a small stomach pouch by placing a vertical line of staples. A band is placed to provide an outlet to the small intestine ([Figure 28-1](#)).

A. Gastric bypass

B. Vertical banded gastroplasty

C. Circumgastric banding

FIGURE 28-1 Bariatric surgical procedures. **A**, Gastric bypass. **B**, Vertical banded gastroplasty. **C**, Circumgastric banding.

Malabsorptive and combination procedures.

The total gastric bypass procedure causes severe nutritional deficiencies and is no longer recommended. The **roux-en-Y** gastric bypass (RYGB) limits the stomach size, and the duodenum

and part of the jejunum are bypassed. This limits the absorption of calories.

Biliopancreatic diversion with a duodenal switch creates a more tubular gastric “sleeve” with connection to a small part of the duodenum. Long-term problems can result from the decrease in the amount of food, vitamins, and minerals that can be absorbed. **Vertical sleeve** gastrectomy removes at least half of the stomach, restricting ghrelin, the hormone that prompts appetite. This reduces hunger more than other restrictive surgeries.

Complications.

With the RYGB procedure, there is danger of leakage of stomach contents into the abdomen in the early postoperative period. Later, gastric stretching may cause the staple line to break and a leak to occur. Signs and symptoms are abdominal pain, nausea and vomiting, tachycardia, fever, and hypotension. An upper gastrointestinal (UGI) series or computed tomography scan can diagnose the problem. The band in the vertical banding procedure may erode into the stomach over time and cause leakage. RYGB patients are also at risk for **dumping syndrome**, which results in nausea, weakness, sweating, and diarrhea that occurs after meals. Other complications of major surgery may occur in the respiratory and cardiovascular systems (see [Chapter 5](#) for complications of surgery). Patients who are obese have a greater risk of pulmonary dysfunction, thrombus formation, and death. Approximately one third of patients who undergo bariatric surgery develop gallstones because of the rapid weight loss.

All bariatric surgery patients are at risk of nutritional deficiencies. Those who have RYGB procedure are most likely to develop deficiencies of iron, vitamin B₁₂, calcium, and folate. Supplements must be taken for life. Support by a dietitian is very important both preoperatively and postoperatively.

7 Think Critically

What effect might a RYGB have on an individual's nutritional status? Why? What might be the physical long-term consequences?

❖Nursing Management of Obesity

■ Assessment (Data Collection)

Data collection includes establishing whether there is a family history of obesity, determining contributing factors, and obtaining an accurate record of eating patterns for a 7-day period. Physical assessment includes measuring weight and height, calculating BMI, and taking a skin fold thickness measurement. A general health assessment is performed.

■ Nursing Diagnosis and Planning

Examples of problem statements relevant to the care of obese patients include:

- Altered body image due to excess weight
- Altered nutritional status due to high-fat diet and excessive weight gain
- Decreased self-esteem due to excess weight

Specific NANDA-I diagnoses may be chosen from the NANDA-I list (see inside back cover).

Goals should be long term, and expected outcomes might include:

- Patient will make positive statements about decreasing body size.
- Patient will consume less fatty food and more fruits and vegetables.
- Patient will verbalize feelings of self-worth.

■ Implementation

The diet and exercise plan should be designed according to the patient's lifestyle and preferences.

Encourage the patient to keep an eating and exercise diary. Weekly meetings for counseling and evaluation are important to provide guidance. Offer support by being available to talk about the positive aspects and frustrations of staying on the diet. Discourage fad diets and emphasize the importance of a well-balanced, nutritious, low-calorie diet. Commercial programs are available to assist patients with weight reduction. Weight Watchers and TOPS (Take Off Pounds Sensibly) are two commercial programs that have shown good long-term results with maintenance of normal weight.

Preoperative and postoperative care for a patient having bariatric surgery depends on the type of surgical procedure performed, but general principles are similar to other types of abdominal or abdominal laparoscopic surgery. Because of the weight and size of the client, lifting apparatus and an extra-wide bed and chair must be available. Hospitalization may be for 1 to 5 days depending on the procedure and the patient. If a nasogastric (NG) tube is in place, do not reposition it because you might disrupt the suture line. Feedings are designed in consultation with a dietitian; you would anticipate feeding progression in the early postoperative period, then onto multiple small meals, a balanced meal plan, and possibly parenteral nutrition (PN) in high-risk patients ([Mechanick et al, 2013](#)). For example, feedings begin with 1 ounce of clear liquid at a time, advancing to pureed foods, thinned soups, and milk. Doses of multivitamins and other supplements are administered as needed per individual. The diet is increased in 1-ounce increments taken over 5 minutes until the patient's appetite is satisfied. The diet is maintained for 6 weeks and then progressed to regular foods. Nausea, vomiting, and discomfort may occur, especially if too many liquids are ingested. After hospitalization, the support of a registered dietitian is recommended and increases the amount of weight loss for most patients. Sugar in any form is to be avoided, as well as concentrated sweets such as fruit juice; juice (if approved by provider) should be diluted. In addition to the calories, concentrated sugar can cause dumping syndrome. For the first 2 months, calorie intake is between 300 and 600 calories a day; thereafter no more than 1000 calories a day should be consumed. The patient remains under medical supervision to monitor for vitamin deficiency or malnutrition and for the need for further micronutrient supplementation.

Evaluation

The patient's diet and exercise diary should be evaluated each week if possible. Weight is tracked on a graph to show progress in weight loss. If the outcomes are not being met, the plan's interventions must be reconsidered. Bariatric surgery patients do best with group support.

Upper Gastrointestinal Disorders

Stomatitis

Stomatitis is a generalized inflammation of the mucous membranes of the mouth. Causes include trauma from ill-fitting dentures or malocclusions of the teeth, poor oral hygiene, and nutritional deficiencies. Excessive smoking, excessive drinking of alcohol, pathogenic microorganisms, radiation therapy, and drugs (especially anticonvulsants and those used in chemotherapy for malignancies) are other contributors to the problem.

Common symptoms of stomatitis include pain and swelling of the oral mucosa, increased salivation or excessive dryness, severe halitosis, and sometimes fever. Small crater-like aphthous ulcers may appear in the mouth, commonly called *canker sores*.

Treatment of stomatitis is chiefly symptomatic, unless a specific infectious causative agent is identified. Nursing measures to control the symptoms of stomatitis—including special mouth care, artificial saliva, and diet—are discussed in [Chapter 8](#).

■ Complementary and Alternative Therapies

Lysine for Canker Sores

Canker sores from food sensitivities or stomach upset often can be healed more quickly by taking the dietary supplement lysine three or four times a day. This often helps reduce the length of time of a “fever blister” on the lips as well.

Dysphagia

Dysphagia means difficulty in swallowing. It is the most common symptom of disorders of the esophagus and varies from a mild sensation that something is sticking in the throat to a complete inability to swallow solids or liquids. Tumors, esophageal diverticula, inflammation, or motility disorders from a neurologic disorder may cause swallowing problems. If the patient is experiencing choking or difficulty with swallowing, he is kept on nothing-by-mouth (NPO) status and swallowing ability is evaluated at the bedside by a speech therapist. If additional information is needed a modified barium swallow test may be ordered to determine the specific cause. Videofluoroscopy is used during the test to visualize the swallowing process.

Treatment and Nursing Management

Have the patient take some “practice swallows” before beginning a meal or giving oral medications for the first time. Watch to see that the larynx rises with each swallow. Observe the kinds of food the patient can tolerate and the conditions under which difficulties are experienced. Knowing the consistency and temperature of the foods most easily ingested by the patient is helpful. Some patients may choke on liquids, but will tolerate soft and semisolid foods. Others may have the feeling that high-fiber foods are not moving past a certain point in the esophagus. Measures that may be helpful in relieving dysphagia include instructing the patient to chew food more thoroughly or to eat semisoft or pureed foods. Drinking liquids throughout the meal may help; however, **liquids will cause many patients to choke. If thin liquids are a problem, adding thickener to liquids makes them easier to swallow.** Sitting upright with the head forward and the neck flexed with the chin slightly tucked aids in swallowing. Head position may be altered, depending on the particular type of problem present. A speech pathologist should be consulted to design the most effective therapy for the patient.

■ Older Adult Care Points

Older patients who have experienced a stroke may have impaired swallowing ability. Swallowing pills is often difficult for this age group. Instruct older adults to take a drink of water, swallow, place the pill on the back of the tongue, take another drink of water, tuck the chin down slightly, and swallow, then drink at least 6 to 8 ounces of water.

The patient may be a candidate for neuromuscular electrical stimulation (NMES). One type of NMES device stimulates muscle at rest, to compensate for muscle wasting. Another NMES device is used for patients who have swallowing issues related to neurologic disorders such as stroke. Some helpful strategies to improve swallowing include licking lollipops to strengthen tongue movements, practicing vowel sounds to stimulate movement, and sucking or blowing through a straw to strengthen the soft palate. Meals should be served in a relaxing atmosphere with pleasant surroundings and relief from emotional stress.

Problem statements for patient with swallowing problems are:

- Altered swallowing ability
- Altered nutrition: less than body requirements
- Potential for aspiration

Both acute and chronic dysphagia are likely to produce nutritional deficiencies and electrolyte imbalances. If the dysphagia is such that the patient cannot swallow sufficient amounts of food for adequate nutrition, tube feeding may be indicated. This sometimes is necessary when the dysphagia is the result of cerebral damage, as in cerebrovascular accident.

Clinical Cues

When your patient has a swallowing problem, the oral suction equipment should always be readily available. Aspiration of food or mucus can occur quickly. The patient or family should be taught how to quickly use the oral suction apparatus (Yankauer). Aspiration can cause pneumonia; the patient's respiratory status should be monitored after a choking episode.

If the patient cannot swallow anything because of a neurologic condition (see [Chapters 21](#) and [23](#)), or if the esophagus is obstructed and cannot be corrected surgically, the patient must have a gastrostomy. An opening in the wall of the stomach is created, and a permanent feeding tube is sutured in place. Nursing interventions for feeding tubes are discussed later in this chapter.

Cancer of the Oral Cavity

Etiology, Pathophysiology, and Signs and Symptoms

Approximately 37,000 people will develop oral cancer in the United States annually ([American Cancer Society, 2014b](#)). Although the specific cause is unknown, oral or throat cancer is curable if discovered early. Cell mutation occurs until an area of cells becomes neoplastic. A genetic factor is most likely present. Oral and pharyngeal cancer risks are cigarette smoking, use of smokeless tobacco, pipe smoking, and heavy alcohol use. The effect of using electronic cigarettes is not yet known. Infection with the human papillomavirus is another risk factor. Leukoplakia, a precancerous lesion, may occur on the tongue or mucosa. Dental examinations should include inspection for this lesion. Sores or discolorations on the lips or in the mouth that do not heal within 2 weeks should be checked by a health care provider.

Diagnosis and Treatment

Diagnosis is made by physical examination and biopsy. Oral cancer treatment varies depending on the structures involved. Radiation, chemotherapy, and surgery are treatment options.

Mandibulectomy (removal of the mandible), **hemiglossectomy** (removal of half of the tongue), or **glossectomy** (removal of the tongue) with resection of other parts of the mouth may be necessary. If the cancer has spread to the cervical lymph nodes, radical or modified neck dissection is performed. This surgery involves wide excision of the primary tumor with removal of the regional lymph nodes, the deep cervical lymph nodes, and lymph channels. A tracheostomy accompanies these procedures to protect the airway (see [Chapter 13](#)). A drain is placed to prevent fluid accumulation. Tube feedings are used as long as swallowing is difficult.

Targeted modulated radiation and chemotherapy may be indicated depending on the degree of involvement of the lymph nodes and whether or not margins of the surgical specimen are clear of cancer cells. Chemotherapeutic agents used may include 5-fluorouracil, methotrexate, cisplatin, carboplatin, paclitaxel, docetaxel, cetuximab, and bleomycin singularly or in combination.

Nursing Management

Postoperative care includes close monitoring of respiratory status, airway, and oxygenation. Cold packs and elevation of the head prevent excessive swelling in the neck that might compress the airway, circulation, and nerves. Aseptic wound care and tracheostomy care are provided.

Nutritional support is an ongoing concern and is very important in the healing process. Many of these patients are malnourished before surgery. See [Chapter 8](#) for the specific care of a patient undergoing radiation and/or chemotherapy.

Think Critically

You are caring for a young woman who was recently informed that she would need surgery and radiation treatment for oral cancer. What are the implications for her sense of body image and psychological well-being?

Cancer of the Esophagus

Etiology and Pathophysiology

Cigarette smoking is a major cause of esophageal cancer in the United States. When combined with heavy alcohol consumption, the risk for esophageal cancer greatly increases. Both substances are irritants to the mucosa of the esophagus. About 18,170 new cases were diagnosed in 2013 ([American Cancer Society, 2014a](#)). The cancer is usually well advanced when discovered. The tumor is either adenocarcinoma or squamous cell cancer.

Gastroesophageal reflux disease (GERD) is a cause of Barrett esophagus, which is a precancerous condition. The cellular changes caused by irritation of the stomach fluids may eventually become malignant. About 0.5% of patients with Barrett esophagus develop esophageal cancer per year. Care is focused on measures encouraging the prevention of GERD and on regular checkups. Periodic endoscopy and biopsy are performed for those who show dysplasia in the esophagus.

Signs, Symptoms, and Diagnosis

Signs and symptoms of esophageal cancer may include progressive dysphagia, hoarseness, regurgitation of foods, foul breath, and persistent cough. At first the dysphagia only occurs with solids such as meat, but then it happens with soft foods and eventually even with liquids. Pain occurs late in the disease and is substernal, epigastric, or in the back and occurs with swallowing. Weight loss is typical. Barium swallow with fluoroscopy may show a narrowed esophagus. Definitive diagnosis is by esophagogastroduodenoscopy (EGD) and biopsy.

Think Critically

A 76-year-old Chinese man complains of progressive difficulty swallowing and fullness of the throat. When interacting with this patient, what would be the most effective approach?

Think Critically

A patient who smokes is awaiting surgery for esophageal cancer and desires to smoke. How would you approach the situation?

Treatment

Options for treatment are endoscopic ablative therapy such as photodynamic therapy, radiotherapy ablation, or endoscopic mucosal resection. An esophagectomy, or removal of sections of the esophagus with reconstruction with part of the stomach, is only occasionally performed because of multiple potential complications. Radiofrequency ablation uses bursts of radiofrequency energy to burn away abnormal cells. Photodynamic therapy uses a medication that causes damaged cells to be sensitive to light; a laser is used to destroy the damaged cells while preserving normal tissue. Endoscopic mucosal resection is a procedure in which a saline solution is injected under the lining of abnormal tissue, which makes it easier to suction away ([National Digestive Diseases Information Clearing House, 2013](#)). For patients who have advanced-stage cancer, palliative care may include a combination of external beam radiation, chemotherapy, esophageal dilation, electrocoagulation,

photodynamic therapy, and the insertion of expanding metal stents to relieve severe dysphagia (American Cancer Society, 2014c).

Nursing Management

Postoperative care is the same as for any patient having gastroendoscopic, thoracic, or abdominal surgery depending on the surgical procedure. Maintaining a patent airway is the top priority.

Nursing interventions focus on promoting adequate respiration, providing a way to adequately communicate, ensuring adequate nutritional intake to promote wound healing, and attention to pain and discomfort. Nutrition is initially supplied by parenteral fluids. Oral intake begins with small amounts of water every hour while the patient is awake with gradual progression to small, frequent, bland meals. The patient should be upright when eating to prevent regurgitation. After esophageal resection, pain, increased temperature, and dyspnea may indicate leakage of the feeding into the mediastinum. Intolerance of food is evidenced by vomiting and abdominal distention. The patient may need a feeding tube for several weeks or a gastrostomy tube to sustain nutrition.

Hiatal Hernia (Diaphragmatic Hernia)

Etiology and Pathophysiology

Loss of muscle strength and tone, factors that cause increased intra-abdominal pressure (such as obesity or multiple pregnancies), and congenital defects contribute to the formation of a hiatal hernia. Hiatal hernia is the result of a defect in the wall of the diaphragm where the esophagus passes through; this creates protrusion of part of the stomach or the lower part of the esophagus up into the thoracic cavity. The herniated portion often slides back beneath the diaphragm. Women are more frequently affected with hiatal hernia than are men.

Signs and Symptoms

Often there are no signs and symptoms of hiatal hernia unless there is reflux of stomach acid. Signs of reflux include indigestion, belching, and substernal or epigastric pain or feelings of pressure after eating caused by the reflux of gastric fluid into the esophagus. Regurgitation of a hot, sour liquid coming into the throat or mouth may occur. Nighttime coughing may awaken the patient. The symptoms are more severe when the patient lies down.

Diagnosis and Treatment

Hiatal hernia is diagnosed by a UGI series. Treatment includes weight reduction; avoidance of tight-fitting clothes around the abdomen; administration of antacids, histamine (H_2)-receptor antagonists, or proton pump inhibitors; and elevating the head of the bed 6 to 8 inches. The patient is instructed not to eat within 3 hours of going to bed. Intake of alcohol, chocolate, caffeine, and fatty food is limited, and smoking should be avoided. Ingestion of fats relaxes the sphincter, allowing reflux. Occasionally a patient with reflux esophagitis, which is caused by the hernia, may bleed extensively. If bleeding or discomfort cannot be controlled, surgical correction of the hernia is required.

Nursing Management

Patients with hiatal hernia are taught ways to prevent pain and reflux. If weight is above normal, encourage weight reduction. Remind the patient to stay upright for 2 hours after eating and not to eat 3 hours before bedtime. Lifting or moving heavy items is to be avoided. If the head of the bed cannot be raised, a wedge pillow should be used to elevate the upper body; this position helps prevent reflux and assists gravity in maintaining the stomach in the abdominal cavity. Prescribed H_2 -receptor antagonists or proton pump inhibitors should be taken at bedtime to prevent reflux and damage from acid entering the esophagus. The patient should avoid foods that cause bloating, which increases abdominal pressure. Increased abdominal pressure may push the stomach upward through the diaphragmatic defect.

Gastroesophageal Reflux Disease

Etiology and Pathophysiology

GERD is a syndrome, not a disease. Ninety percent of patients with GERD have a hiatal hernia. GERD occurs equally in men and women. It is caused by transient relaxation of the lower esophageal sphincter and may accompany a hiatal hernia. The relaxation allows fluids or food to reflux into the esophagus from the stomach. Delayed stomach emptying is another factor. Certain foods and medications contribute to this mechanical problem. Being overweight is common among patients with GERD. GERD may contribute to bronchoconstriction and asthma symptoms because of irritation of the upper airway by gastric secretions. About 75% of patients with asthma have GERD ([Kerr, 2012](#)).

Signs and Symptoms

Heartburn ([dyspepsia](#)) and reflux are the most common symptoms of GERD. Other symptoms may include chest pain, coughing, dysphagia, belching, flatulence, and bloating after eating. Symptoms are aggravated by lying down.

Diagnosis

GERD is diagnosed by EGD and sometimes barium esophagram. Occasionally, other tests such as an esophageal manometry, ambulatory 24-hour pH monitoring, or radionuclide measurement of gastric emptying are performed. Esophageal manometry measures pressures in the esophagus; pressures will be increased during episodes of reflux. For 24-hour pH monitoring, a tiny tube with a transducer is introduced into the esophagus to take measurements of the esophageal pH.

Treatment and Nursing Management

Diet therapy, lifestyle changes (particularly weight loss for those who are overweight), drug therapy, and education are the mainstays of GERD treatment. Drug therapy may include antacids, H₂-receptor antagonists, proton pump inhibitors, and prokinetic drugs ([Table 28-1](#)). Check for interactions with other drugs the patient is taking. Verify that the patient can afford the drugs prescribed because some are very expensive.

Clinical Cues

Patients prescribed long-term use of proton pump inhibitors are at risk for nutrient malabsorption, particularly of magnesium, calcium, and B₁₂. There is also risk of bacterial overgrowth because of the decreased stomach acid secretion. There have been links to pneumonia and possibly to more cases of *Clostridium difficile* in patients who are receiving these drugs. More clinical research is under way. Unless there is a good indication of need, these drugs should not be taken for more than 6 weeks ([Johnson and Oldfield, 2013](#)).

Patient Teaching

Measures to Decrease the Symptoms of Gastroesophageal Reflux Disease

Dietary Alterations

- Avoid high-fat oils and spicy foods.
- Eat four to six small meals a day.
- Eat slowly and chew food thoroughly, and avoid using a straw for liquids to decrease belching and reflux.
- Avoid carbonated beverages because they increase bloating.
- Eliminate or limit alcohol, tomato-based products, caffeine, citrus juice, raw onions, chocolate, coffee, peppermint, and spearmint from the diet. These foods either relax the esophageal sphincter or increase acid production.

Lifestyle Alterations

- Wait 2 to 3 hours after eating before lying down.
- Do not wear clothes that constrict around the middle of the body.
- If overweight, lose the extra pounds; a 10% weight loss can decrease symptoms considerably.
- Sleep with the head of the bed elevated 6 to 8 inches with blocks or a foam bolster pillow.
- Take medications as directed in relationship to meals and bedtime.
- Stop smoking because it may stimulate gastric acid secretion.
- Participate in regular stress-reducing activities such as exercise, meditation, deep breathing, and laughter.

Safety Alert

Proton Pump Inhibitors and Cardiac Problems

The Food and Drug Administration (FDA) has issued a warning that long-term use of the proton pump inhibitors esomeprazole (Nexium) or omeprazole (Prilosec) may increase the risk of heart problems, particularly in those with pre-existing cardiovascular disease. Patients taking these drugs should consult their health care provider.

 **Table 28-1**
Drugs Commonly Used to Treat Upper Gastrointestinal Disorders

CLASSIFICATION	ACTION	NURSING IMPLICATIONS	PATIENT TEACHING
Antacids			
There are four antacid families consisting of compounds of aluminum, magnesium, calcium, and sodium. Gelusil, Maalox, Mylanta-II, Riopan, Di-Gel, Amphojel, Basalgel, Gaviscon	Neutralize stomach acid	Aluminum hydroxide compounds promote constipation, whereas magnesium hydroxide compounds promote diarrhea. Sodium compounds may adversely affect hypertension and heart failure. All antacids may adversely affect the dissolution and absorption of other drugs. One hour should be allowed between antacid administration and administration of another drug. Magnesium compounds are used cautiously in patients with renal insufficiency.	Antacids for treatment of peptic ulcer should be taken seven times a day: 1 hr and 3 hr after meals and at bedtime. Separate from other drug administration by 2 hr. Shake liquid preparations well before pouring from container. Chew antacid tablets thoroughly, and follow with a glass of water or milk. Report problems of constipation or diarrhea to the provider. Take even after pain has disappeared; consult provider.
Histamine (H₂)-Receptor Antagonist			
Cimetidine (Tagamet) Famotidine (Pepcid) Nizatidine (Axid) Ranitidine (Zantac)	Suppress acid secretion by blocking H ₂ receptors on parietal cells	Cimetidine may interact with many other drugs; check drug interactions for other drugs patient is receiving. Cimetidine may cause confusion and other CNS effects. Separate administration of these drugs and antacids by 1 hr. Monitor for decreased abdominal pain and ulcer symptoms.	These drugs should be taken with meals and at bedtime. Once-a-day dose should be taken at bedtime. Advise patient to avoid cigarettes, aspirin, and other NSAIDs. Advise to avoid alcohol or only consume it in moderation and only in conjunction with food. Advise to use stress-reduction techniques.
Proton Pump Inhibitors			
Omeprazole (Prilosec) Omeprazole and sodium bicarbonate (Zegerid) Lansoprazole (Prevacid) Dexlansoprazole (Kapidex)	Suppress secretion of gastric acid	May cause headache, nausea, vomiting, or diarrhea. Use is preferably limited to 4-8 wk.	Follow regimen of diet and stress reduction for ulcer healing.
Rabeprazole (AcipHex)	Same as above	Do not crush delayed-release tablets.	This is a slow-release preparation that acts throughout the day. Teach patient to wear sunscreen; drug may cause sun sensitivity.
Pantoprazole (Protonix)	Same as above	Do not crush tablets.	A slow-release preparation.
Esomeprazole (Nexium)	Same as above	Do not administer with digoxin, rabeprazole, or iron salts.	May affect absorption of digoxin, rabeprazole, and iron salts.
Misoprostol (Cytotec)	Prevents gastric ulcers caused by long-term therapy with NSAIDs	May cause diarrhea or abdominal pain. Not safe during pregnancy.	Is a synthetic prostaglandin. Report abdominal pain, diarrhea, or GI bleeding.
Miscellaneous			
Sucralfate (Carafate)	Provides protective coating barrier over ulcer crater	Monitor for constipation.	Take only as directed. Wait 30 min before taking any other drug.
Antimicrobials			
Clarithromycin (Biaxin)	Suppresses protein synthesis in bacteria Used to kill <i>Helicobacter pylori</i>	Assess for drug allergy. Report hematuria or oliguria. Administer every 12 hr to maintain serum levels. Do not crush tablets. Monitor for diarrhea, abdominal pain, or signs of jaundice.	May cause diarrhea, anorexia, or nausea. Must be taken at regular intervals to be effective. Take the entire prescription. Taking acidophilus between doses may alleviate diarrhea. Increase fluid intake if diarrhea occurs.
Amoxicillin (Amoxil)	Causes cell wall of bacteria to swell and burst, preventing replication	Assess for drug sensitivity. Assess for side effects. Monitor renal function. Monitor for blood in stool and abdominal pain.	Take on an empty stomach with a full glass of water. Take at regular intervals around the clock to sustain blood levels. Take entire prescription.
Tetracycline	Bacteriostatic Inhibits protein synthesis in microorganism	Assess for drug sensitivity. Monitor CBC, liver, and kidney functions. Increases effect of warfarin and digoxin. Decreases effect of penicillin and oral contraceptives.	Do not take with dairy products or antacids; separate by 2 hr. Avoid sun exposure. Supplies may be limited.
Metronidazole (Flagyl)	Kills amoebas and <i>Trichomonas</i> ; degrades DNA in organism	Do not give during second and third trimesters of pregnancy. Increases action of anticoagulants.	Do not drink alcohol during or for 48 hr after therapy has ended. May cause severe vomiting.

		Decreases action of phenobarbital and phenytoin. May cause toxicity if administered with cimetidine or lithium. Patient should have vision examination before and after therapy. Monitor for neurotoxicity. Discontinue if fever, chills, rash, or itching occur.	and prostration. Urine may turn dark brown. Notify provider of numbness or tingling. Dizziness may occur; avoid hazardous activities. May cause dry mouth; chew sugarless gum or sip water frequently.
Antispasmodics			
Dicyclomine hydrochloride (Bentyl, Antispas) Propantheline bromide (Pro-Banthine), hyoscyamine (Levsin)	Block acetylcholine, thereby decreasing smooth-muscle spasm and GI motility and inhibiting gastric acid secretion	These drugs interact with many other drugs; check each drug patient is taking for interactions. Most of these drugs are contraindicated in glaucoma, prostatic hypertrophy, myasthenia gravis, and other conditions; consult information on each drug individually. May predispose to drug-induced heat stroke. Monitor vital signs and urine output carefully.	Take 30-60 min before meal. Patient can suck on hard candy to relieve mouth dryness unless contraindicated. Drink 2500-3000 mL of fluid to prevent constipation. Avoid driving and hazardous activities if drug causes dizziness, sleepiness, or blurred vision. Report rash or skin eruption to provider.
Metoclopramide (Reglan)	Hastens gastric emptying and relaxes pyloric and duodenal segments of GI tract	Assess for neurologic or psychotropic side effects such as restlessness, anxiety, ataxia, or hallucinations. Not for long-term use.	Take before meals.

CBC, Complete blood count; CNS, central nervous system; GI, gastrointestinal; NSAIDs, nonsteroidal anti-inflammatory drugs.

If these therapies do not control the problem, endoscopic noninvasive therapies often are effective. Laparoscopic surgical fundoplication—in which the fundus of the stomach is wrapped around the esophagus to create a new valve junction (Figure 28-2)—may be effective. It is not recommended for morbidly obese patients because it tends not to relieve symptoms in this group. This is the same procedure used to correct a hiatal hernia.

Think Critically

Many patients with GERD and hiatal hernia do not really modify their diet and lifestyle over the long term; instead they rely on medications, which can be expensive, to decrease their symptoms. What measures could you use to show patients that lifestyle changes may control symptoms without medication?

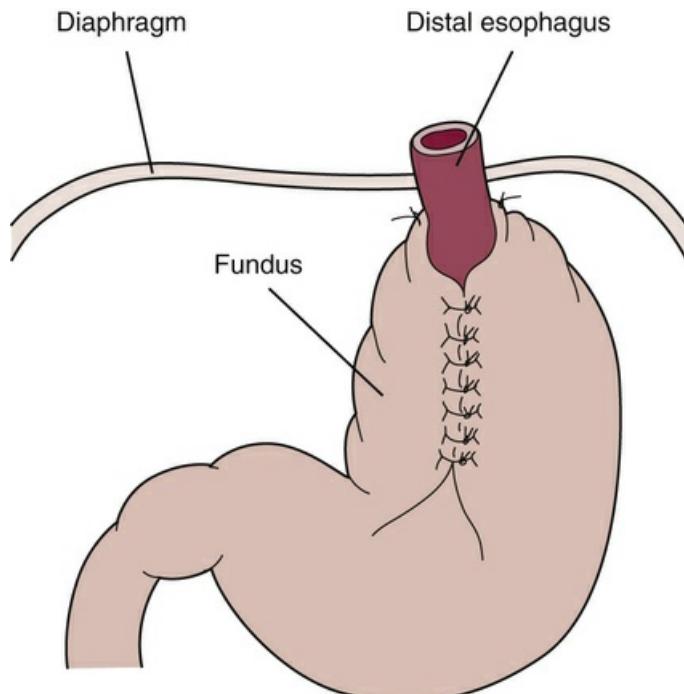

FIGURE 28-2 Nissen fundoplication surgery for hiatal hernia or to treat gastroesophageal reflux disease.

Complications

Irritation results when stomach contents containing hydrochloric acid, pepsin, and other enzymes are refluxed into the esophagus. Constant irritation may cause cellular changes, such as the precancerous lesions in Barrett esophagus. Reflux is also a risk factor for aspiration of stomach contents and pneumonitis. Acid reflux into the mouth, over time, may cause dental caries.

Gastroenteritis

Gastroenteritis is inflammation of the stomach and small intestine. It is caused by intake of food or water contaminated with a virus, a pathogenic bacteria, or parasites. The Norwalk virus (Norovirus) is a common cause, as are *Giardia*, *Shigella*, and *Clostridium difficile*. Signs and symptoms of gastroenteritis include vomiting, diarrhea, abdominal cramping, and distention. Fever, elevated white blood cell count, and blood or mucus in the stool may occur. In healthy adults the disorder is self-limiting and does not require hospitalization. Young children, older adults, and chronically ill patients may need intravenous (IV) therapy to take in enough fluid to compensate for the fluid lost from vomiting and diarrhea.

A patient with gastroenteritis should be kept NPO until vomiting has stopped. When tolerated, fluids containing glucose and electrolytes should be started (e.g., Pedialyte, Gatorade). If diarrhea continues beyond 3 or 4 days, stool studies for the causative organism should be performed. Therapy to eradicate the causative agent can then be started. Rest is important during the course of the vomiting and diarrhea. After 24 to 48 hours, medication may be prescribed for the vomiting, abdominal cramping, and diarrhea.

Nutrition Considerations

Dietary Guidelines for a Patient With Vomiting

- Liquid diet for 12 to 24 hours. Frequent, small amounts of clear liquids are best.
- Avoid milk, ice cream, pudding, cheese, yogurt, citrus juice, and cream soups.
- Foods allowed on the liquid diet are electrolyte solutions, carbonated beverages, bouillon, unflavored gelatin, apple juice, peach or pear juice, plain hard candy, sugar, honey, sugar substitutes, and frozen Popsicles.

When nausea and vomiting stop:

- Add some of the following foods for the next 12 to 24 hours: soda crackers, toast and jelly without butter, tea, rice, pretzels, bananas, applesauce, cooked cream of wheat or cream of rice, and fruit or vegetable juice (BRATT diet: banana, rice, applesauce, tea, and toast).
- If this diet is tolerated without further symptoms, add the following foods for the next 12 to 24 hours: potatoes (not fried), soups, soft eggs, custards, puddings, white turkey meat or white chicken meat, and cottage cheese.
- If no further symptoms occur, resume a regular diet but avoid highly seasoned foods, greasy or fried foods, heavy fatty foods, excessively hot or cold foods, raw vegetables, coffee, colas, and milk products for 1 week after symptoms have stopped.

Gastritis

Etiology

The main cause of chronic gastritis is *Helicobacter pylori* bacteria, but other bacteria, viruses, or parasites can also be a cause. Contributors to acute gastritis are drinking excessive amounts of alcohol; infection from eating contaminated food; cocaine use; and ingestion of medications. Corticosteroids are very harsh on the stomach, as well as nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin and ibuprofen.

Pathophysiology

Gastritis is not a disease; it is an acute or chronic inflammation of the mucous membrane lining the stomach. **Atrophic** gastritis involves all layers of the stomach. It is seen in association with gastric ulcer and malignancies of the stomach. Gastritis associated with uremia is common in patients with kidney failure. The excessive urea that builds up from the kidney failure causes gastric irritation. Untreated chronic gastritis may progress to ulcer formation and upper GI hemorrhage.

Signs, Symptoms, and Diagnosis

The main symptoms are anorexia, nausea, vomiting, pain and tenderness in the stomach region, hiccoughs, and sometimes diarrhea. A patient with chronic gastritis may have no symptoms, but may suddenly experience massive hemorrhage from the stomach. Diagnosis is by history, physical examination, and endoscopic examination.

Treatment and Nursing Management

Acute gastritis usually is of very short duration. Treatment consists of withholding all foods by mouth and administering drugs that slow down the peristaltic action of the GI tract. If severe dehydration or nausea and vomiting occur, IV fluids may be given. Patients with gastritis must be watched closely for signs of fluid and electrolyte imbalance. Treatment for chronic gastritis consists of antispasmodics to decrease the pain of stomach spasms, antacids, an H₂-receptor antagonist such as ranitidine to decrease acid secretions and change pH, or a proton pump inhibitor to decrease the secretion of hydrochloric acid. All NSAIDs and substances known to cause gastritis are discontinued. When *H. pylori* is present, treatment is proton pump inhibitors, amoxicillin, and clarithromycin for 7 to 14 days, with metronidazole substituted for amoxicillin if the patient is allergic to penicillin.

Older Adult Care Points

If an older adult experiences vomiting and is unable to retain fluids for 12 hours, IV fluids may need to be infused to prevent severe dehydration.

Chronic gastritis is not as easily treated as acute gastritis. Diet therapy is of primary importance; patients frequently admit to indiscretion in dietary and drinking habits and find it difficult to change. Patients with chronic gastritis should not eat any spicy or acidic foods. Tact and patience may convince the patient to follow the prescribed diet.

Peptic Ulcer

Etiology

About 4.5 million people in the United States have experienced a peptic ulcer. *H. pylori* infection is the major cause. Smoking and the continued use of NSAIDs are other causes. *H. pylori* is rich in an enzyme that may cause corrosion of the coating of the upper GI mucosa, making it more susceptible to damage from gastric acid and pepsinogen. Duodenal ulcers and some prepyloric ulcers are associated with an increased amount or hyperacidity of the gastric juices, and 70% are associated with *H. pylori*. Gastric ulcers, by contrast, are characterized by normal or abnormally low levels of hydrochloric acid, but 90% have been associated with *H. pylori*. Colonization of the stomach with *H. pylori* is an important cause of gastric cancer and of gastric mucosa-associated lymphoid tissue (MALT) lymphoma ([National Cancer Institute, 2013](#)).

Older Adult Care Points

By age 60 years, approximately 65% of the population in the United States is infected with the *H. pylori* bacterium. However, most people never have symptoms of gastritis, and few develop ulcers.

There is a weak genetic link for peptic ulcer that is not fully understood. Neither hot, spicy foods nor caffeine has been proven to be a risk factor for ulcers, but these substances make symptoms worse in many people. Gastric ulcers do occur in those who are poorly nourished because of poverty or because of poor eating habits. Despite the stereotype of the hard-driving executive suffering from an ulcer and ingesting antacid tablets, there is a greater incidence of ulcers in lower-income workers.

Stress does have a bearing on the progression of peptic ulcer. Tension, anxiety, and prolonged stress alter gastric function. Prolonged physiologic stress produces what is known as a *physiologic stress ulcer*, which is believed to be the result of unrelieved stimulation of the vagus nerves and decreased perfusion to the stomach. A stress ulcer is pathologically and clinically different from a

chronic peptic ulcer. It is more acute and more likely to produce hemorrhage. Perforation occurs occasionally, and pain is rare. Stress ulcers are a hazard for patients who are severely ill and in intensive care units for prolonged periods. Patients with multiple trauma, burns, or multisystem disorders are subject to physiologic stress ulcers. Such patients often receive medication to prevent ulcer formation.

Drug-induced ulcers are most commonly caused by aspirin, NSAIDs, biphosphonates, alcohol, and glucocorticoids (Mayo Clinic Staff, 2013).

Pathophysiology

Normally, the upper GI mucosa can resist corrosion; all areas exposed to hydrochloric acid and pepsin in gastric juices have an ample supply of mucous glands that secrete a protective alkaline mucus. Ulcers develop when the mucosa cannot protect itself from corrosive substances, such as gastric acid, pepsinogen, alcohol, bile salts, and irritating food substances. A **peptic ulcer** is an ulceration with loss of tissue of the upper GI tract. The term includes both duodenal and gastric ulcers (Figure 28-3). The most common site for development of a peptic ulcer is in the first few centimeters of the duodenum, just beyond the pyloric muscle.

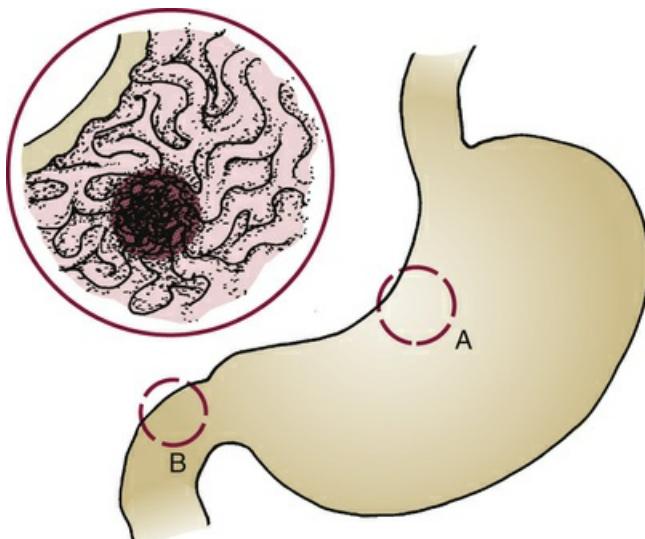

FIGURE 28-3 Peptic ulcers. A, Gastric. B, Duodenal.

Signs and Symptoms

Symptoms of uncomplicated ulcer include epigastric pain that might be described as burning, gnawing, cramping, or aching that usually comes in waves and lasts several minutes. The daily pattern of pain is associated with the secretion of gastric juices in relation to the presence of food, which can act as a buffer. **For example, with a gastric ulcer the pain is diminished in the morning when secretion is low and after meals when food is in the stomach, and pain is most severe before meals and at bedtime.** Discomfort often appears for several days or weeks and then subsides, only to reappear weeks or months later. Other subjective symptoms include nausea, loss of appetite, anemia, and weight loss. Spontaneous vomiting is more common with duodenal ulcers than with gastric ulcers.

Older Adult Care Points

Older adults may not display the typical ulcer symptoms. Pain is less typical and may be poorly localized, or it may be described as lower chest discomfort or left-sided pain. Anorexia, weight loss, general weakness, anemia, nausea, and painless vomiting may occur; peptic ulcer is difficult to diagnose in this population.

Gastrointestinal bleeding.

Signs of acute GI bleeding include complaints of weakness and feeling faint, nausea and vomiting, restlessness, thirst, and mental confusion. **Hematemesis** (the vomiting of bright red blood) indicates an active bleed; blood that has been sitting with gastric juices looks like coffee grounds. Diarrhea, decreased blood pressure, rapid pulse, and other signs of hypovolemic shock may occur. Blood in the GI tract acts as a cathartic and causes diarrhea. If bleeding from the upper GI system is profuse, maroon or bright red blood may appear in stool because of the rapid transit of the blood through the intestinal tract. Black stools almost always indicate the presence of digested blood, which means that the source of bleeding is in the upper GI tract.

Clinical Cues

Remember that iron salts can cause the stool to be black and that the ingestion of beets can cause the stool to be bright red.

Estimates of blood loss from the GI tract are based in part on blood pressure readings and pulse rates. Blood pressure and pulse rate should be monitored every 15 to 30 minutes when there is evidence of extensive GI hemorrhage.

Clinical Cues

Changes in the vital signs that signal hypovolemic shock do not appear until after the patient has lost 20% or more of the blood volume.

Hemoglobin and hematocrit levels are useful in determining the status of patients with GI bleeding. These levels can be normal or even slightly elevated at the beginning of a bleeding episode. It takes 4 to 6 hours for the body to shift fluids from other compartments to the intravascular compartment. The shift of fluid changes the ratio of formed elements to fluids in the blood. The white cell count may be elevated in massive GI bleeding, probably because of the body's response to injury or hypovolemia. An elevated level of blood urea nitrogen (BUN) can indicate digestion of large amounts of blood.

Diagnosis

Peptic ulcer is diagnosed by endoscopy, which can locate the site of ulceration and bleeding. It also allows for differentiation between benign and malignant ulcerations and between the esophageal ulcer and a *diverticulum* (pouching of the intestinal wall). UGI series may be done if endoscopy is not available.

Testing for the presence of *H. pylori* is essential. The urea breath test measures the gas released in the breath after ingestion of a radio-labeled urea isotope; when *H. pylori* is present, the test result is positive. Serum tests for *H. pylori* detect antibodies, indicating active or recent infection. A fecal antigen test for *H. pylori* is another option.

Think Critically

How do the symptoms of a gastric ulcer differ from those of a hiatal hernia?

When a patient is experiencing extensive GI bleeding, the patient's condition is stabilized and diagnostic procedures are performed to locate the source of bleeding. These procedures include endoscopic examination of the esophagus, stomach, and small intestine.

Treatment

Peptic ulcer is initially treated with medication. Surgical treatment is used when conservative treatment is not effective. Medications to relieve pain from local irritation of the intestinal mucosa include antacids and proton pump inhibitors, which decrease gastric secretions (see [Table 28-1](#)).

An NG tube may be used for normal saline lavage. Studies have shown no benefit from lavage and no difference in patient outcomes ([Saltzman, 2015](#)). NG tubes can help evacuate the stomach

contents to decrease vomiting.

Clinical Cues

The practice of inserting an NG tube in a patient with frank gastric bleeding may become obsolete because these patients undergo endoscopy quickly to determine the site of the bleeding and its treatment (Rockey, 2014).

Endoscopy is routinely performed to identify the source of bleeding and, if indicated, to treat it. A tissue biopsy may be done. Proton pump inhibitors are given IV or orally to decrease or stop acid secretion (see Table 28-1). These treatments are effective to stop the bleeding 80% of the time; the other 20% will require surgery.

If there is major blood loss, transfusions of packed cells, platelets, or fresh frozen plasma may be necessary. Normal saline, Plasmanate (plasma protein fraction), or Ringer solution may be administered until blood is available. Maintenance of fluid balance is extremely important. Intake and output must be measured and recorded accurately. Oxygen therapy is started to maximize tissue oxygenation.

Sucralfate (Carafate) tablets may be used for short-term (up to 8 weeks) treatment of a duodenal ulcer. Sucralfate has negligible acid-neutralizing capacity because the action of this drug is local. Its benefits probably derive from its adherence to the ulcer site, providing protection from further damage by gastric juices. Misoprostol (Cytotec) is used to replace gastric prostaglandins depleted by NSAID therapy and helps to prevent ulcer formation caused by NSAIDs. Sedatives are sometimes prescribed for a patient with a peptic ulcer to help reduce anxiety and relieve tension.

Safety Alert

Proton Pump Inhibitor Drug Interactions

Because proton pump inhibitors slow the liver's ability to metabolize and clear some drugs from the bloodstream, they should be used with caution in patients taking diazepam (Valium), phenytoin (Dilantin), and warfarin (Coumadin). Patients taking a proton pump inhibitor along with any of these three drugs should be watched closely for signs of toxicity.

Complications

The three major complications of peptic ulcer are hemorrhage, perforation, and obstruction. Hemorrhage occurs when the ulcer erodes vessels, causing bleeding into the stomach. Signs of hemorrhage include the vomiting of blood. If the hemorrhage is unchecked, hypovolemic shock may occur.

Perforation is erosion of the ulcer through all walls of the stomach or intestine. A spilling of the contents of the GI tract into the peritoneal cavity ensues; it constitutes a surgical emergency because of the danger of hemorrhage and peritonitis. **Perforation is characterized by a sudden and severe pain in the upper abdomen that persists and increases in intensity and sometimes is referred to the shoulders.** The abdomen is rigid and boardlike and extremely tender. In a short time the patient shows signs of shock.

Obstruction occurs as a result of scarring and loss of musculature at the pylorus, narrowing the stomach outlet, and is manifested chiefly by persistent vomiting.

Surgical Treatment

Surgical treatment becomes necessary when a chronic ulcer fails to respond to medical or endoscopic treatment; when complications such as perforation, obstruction, or hemorrhage occur; or when malignancy is present.

In **pyloroplasty with truncal or proximal gastric vagotomy**, the pylorus, which has been narrowed by scarring, is widened. The branches of the vagus (tenth cranial) nerve that stimulate acid secretion in the stomach are selectively severed (**vagotomy**) so that the stomach does not receive impulses from the brain and therefore does not secrete hydrochloric acid. A vagotomy is often done at the same time that a gastric resection is performed.

Subtotal gastrectomy (gastric resection) consists of removing a part of the stomach and then joining the remaining portion to the small intestine by anastomosis. **Anastomosis** is the joining of two hollow organs by suturing the open ends together so that they become one continuous tube. An **antrectomy**, in which the gastrin-producing portion of the stomach (the antrum) is removed, may be done in conjunction with a truncal vagotomy. When the fundus of the stomach is anastomosed to the duodenum, the procedure is known as a *Billroth I*. In the *Billroth II* procedure, the duodenum is closed, and the fundus of the stomach is anastomosed to the jejunum. **Total gastrectomy** is the surgical removal of all of the stomach. The esophagus is anastomosed to the small intestine ([Figure 28-4](#)).

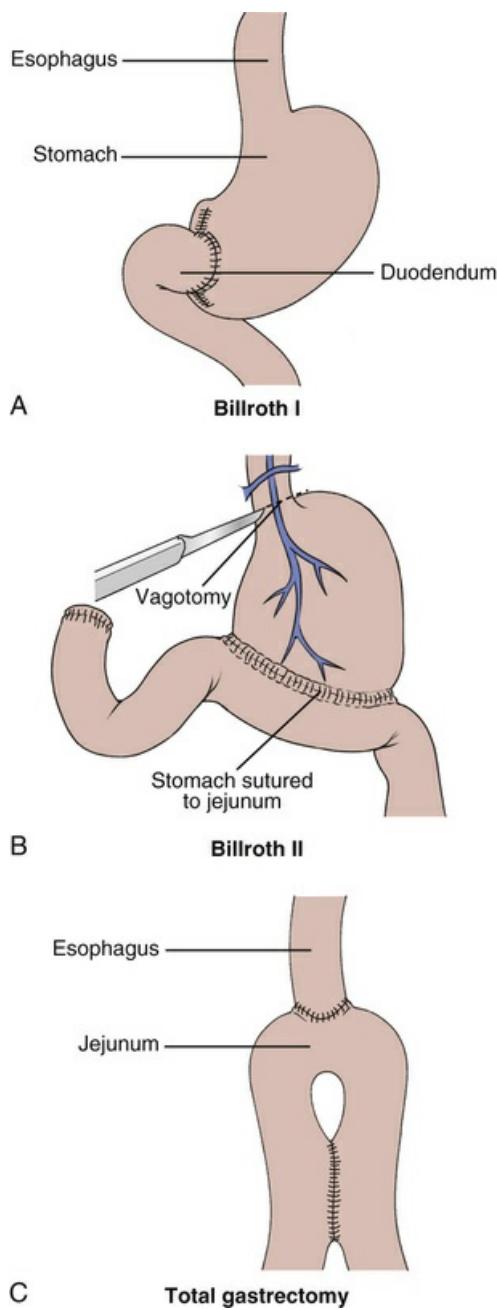

FIGURE 28-4 Stomach surgical procedures. **A**, Billroth I. **B**, Billroth II. **C**, Total gastrectomy.

Nursing care of patients undergoing gastric surgery.

Preoperative care.

Patients having gastric surgery are restricted to a liquid diet during the day before surgery. On the day of surgery, the patient is kept NPO. An NG tube is inserted once the patient is in the operating room, and all stomach contents are suctioned out before surgery.

The patient undergoes the routine preparations necessary for all major abdominal surgery, including bowel preparation with oral laxatives and antibiotics so that the colon is emptied of fecal material and bacteria. If the patient has had a barium enema, look for and report stools that contain whitish material. The whitish material is barium, and it will become hardened if left in the colon, thus presenting the possibility of fecal impaction later on.

Postoperative care.

Care of patients who have had gastric surgery is routine, with some exceptions. After surgery in which part of the stomach has been removed, care must be taken in handling the NG tube to prevent injury to the sutures and to prevent introduction of infectious agents. The surgeon will write specific orders about irrigating fluids and movement of the gastric tube.

After the tube is removed, the patient is given small amounts of liquid to determine tolerance. These liquids are gradually increased. The patient's ability to take them without nausea, vomiting, or abdominal distress is assessed. If the liquids are well tolerated, the patient progresses to small, frequent feedings. Within 6 months, most patients are able to take three regular meals a day. The remaining portion of the stomach stretches to accommodate more and more food. Patients who have had a **total** gastrectomy have restricted diets. They are usually restricted to small, frequent feedings of easily digested semisolids for the rest of their lives. Before discharge, the hospital dietitian usually is called to help the patient and his family learn about the special diet needed after undergoing gastric surgery. Medications may not be as effective due to altered absorption. The provider should be consulted for all medications.

Dumping syndrome.

Some patients who have had a gastrectomy experience a complication known as *dumping syndrome*. The patient has nausea, weakness, abdominal pain, and diarrhea and may feel faint and perspire profusely or experience palpitations after eating. These sensations are caused by the rapid passage of large amounts of food and liquid into the jejunum. This occurs because part or all of the stomach and duodenum has been surgically removed. The progress of the ingested foods and fluids is not slowed by passing through the upper portion of the GI tract. The patient with dumping syndrome should be taught to avoid eating large meals and to minimize fluids during the meal. Fluids may be taken in small amounts later, between meals. Refined sugar can cause or aggravate the condition, and the patient should try to avoid sugary foods or snacks. It also may be helpful for the patient to lie down flat for 30 minutes after a meal.

❖ Nursing Management

■ Assessment (Data Collection)

Begin by asking the patient to describe the chief complaint (patient's perception of the main problem).

☒ Focused Assessment

Data Collection for Peptic Ulcer

Assess the following areas:

History

- Pain: where located, characteristics, what affects pain, what relieves it, when pain began
- Nausea or vomiting; presence of bright red or "coffee-ground" emesis
- Dark "tarry" stool or maroon-colored stool
- Anorexia, weight loss

Physical Assessment

- Vital signs and changes from baseline
- Presence of restlessness, confusion, or thirst
- Skin tone
- Appearance and amount of emesis
- Stool color, characteristics, frequency
- Abdominal tenderness, rigidity, guarding, bloating
- Bowel sounds

Laboratory Data

- Complete blood count (CBC)
- BUN
- *H. pylori* testing

Nursing Diagnosis and Planning

Common problem statements/nursing diagnoses, expected outcomes, and interventions for patients with a peptic ulcer are presented in **Nursing Care Plan 28-1**. Before a peptic ulcer can be successfully controlled, the patient must understand how and why the ulcer developed in the first place. Once the predisposing factors are understood, it is easier to avoid them. Unless the patient can cooperate fully, there is a strong possibility that ulcers will develop again despite medical or even surgical treatment. ☺

Think Critically

How can you increase compliance with the medication schedule prescribed for ulcers?

Nursing Care Plan 28-1

Care of a Patient With a Bleeding Peptic Ulcer

Scenario

Mr. Jackson is a 52-year-old long-distance truck driver admitted to the hospital with a diagnosis of bleeding peptic ulcer. He has had recurrent bouts of epigastric pain that is more pronounced before meals and at bedtime. Mr. Jackson states that he eats "whenever I can grab a bite." He eats mostly fried and spicy foods and he smokes two packs of cigarettes a day. He went to the provider because of fatigue and discomfort that seemed to be getting progressively worse despite antacid use. He also admits to having some vomiting episodes with blood in the secretions. Mr. Jackson is the sole support of his wife and four children and is very concerned about the expense of hospitalization and the time away from work. He is scheduled for an endoscopic examination of the esophagus, stomach, and duodenum.

Problem Statement/Nursing Diagnosis

Pain/Pain due to irritation and possible ulceration of gastric mucosa.

Supporting Assessment Data

Subjective: Recurrent bouts of epigastric pain more pronounced before meals.

Objective: Epigastric tenderness increases with gentle palpation.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will verbalize relief of pain.	Assess location and severity of pain every shift.	Provides data regarding condition and need for medication.	Pain is epigastric at 3/10 on pain scale; now occurring between meals.
Patient will verbalize ways to prevent gastric pain.	Administer ordered antacids, antispasmodics, and H ₂ inhibitors.	Medications neutralize stomach acid or decrease acid production.	Taking medications as ordered. Verbalizes rationale for medication.
	Give caffeine-free diet.	Caffeine causes more stomach acid production.	No caffeine drinks; bland diet. Verbalizes understanding of effect of caffeine on stomach pain.
	Encourage him to quit smoking.	Smoking constricts blood vessels, decreasing perfusion to stomach. Decreased perfusion makes the stomach more susceptible to inflammation.	Patient said he would think about quitting smoking. Provided community resource information for stopping smoking. Still smoking. Continue plan.
	Give frequent feedings to neutralize gastric acid.	Keeping food in the stomach helps neutralize acid.	Eating a snack every 2 hr between meals. Verbalizes understanding of how frequent meals or snacks can help control pain.

Problem Statement/Nursing Diagnosis

Anxiety/Anxiety due to expenses, time off work, and worry about what is wrong with him.

Supporting Assessment Data

Subjective: "I'm the only one working"; expresses worry over hospital expenses; worried about blood in vomitus.

Objective: Self-treated with antacids and continued to work until symptoms progressed.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will verbalize reduction in anxiety before discharge.	Encourage verbalization of concerns and fears.	Verbalizing fears may decrease their intensity.	Verbalizing specific concerns about finances and expresses fear that blood is a sign of serious illness.
Patient will devise plan to cover hospital expenses to decrease anxiety.	Advocate for financial consultation regarding hospital expenses.	A plan for meeting financial obligation will somewhat decrease anxiety.	Appointment with social worker to discuss financial situation.
Patient will verbalize understanding of diagnosis and treatment of his condition.	Explain all diagnostic procedures and medications.	Decreases the fear of the unknown and reduces anxiety.	Brochure given about endoscopic procedures and test for <i>Helicobacter pylori</i> ; reviewed purpose of each medication.
	Assess usual coping techniques and teach new ways to cope as necessary.	Establishes usual coping methods and provides data for other coping methods to be taught.	Uses smoking and television as relaxation.
	Reinforce wife's assurances that they can manage expenses at home.	Reinforcement of information helps patient remember.	Wife says he tends to be a "worry wart"; reinforced information about her ability to cope with expenses.
	Encourage relaxation techniques.	Relaxation techniques help decrease anxious feelings.	Taught relaxation exercise and encouraged to practice it. Continue plan.

Problem Statement/Nursing Diagnosis

Potential for altered tissue perfusion/Potential for decreased tissue perfusion due to increased bleeding (gastrointestinal) from irritation of gastric mucosa.

Supporting Assessment Data

Subjective: States has experienced blood-streaked vomitus; history suggestive of peptic ulcer; increasing fatigue.

Objective: Blood-tinged vomitus and blood in stool (positive guaiac test); pale conjunctiva; below-normal Hgb and Hct.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will have no signs of intestinal blood loss by discharge.	Monitor CBC count for evidence of continued bleeding.	CBC count may indicate whether bleeding is occurring.	Hgb 11.9 g/dL and Hct 32.
Hemoglobin and hematocrit will be within normal levels within 30 days.	Assess vomitus for blood.	Blood in vomitus indicates bleeding is still occurring.	No vomitus this shift.
	Check stool for occult blood as ordered.	Blood in stool indicates GI bleeding.	Stool positive for occult blood x2.
	Monitor vital signs and assess for continued or rapid blood loss as ordered.	Active bleeding will be reflected by vital signs.	Pulse 92 and BP 138/86.
	Teach about foods high in iron (i.e., meat and green leafy vegetables) to correct anemia.	Eating foods high in iron helps correct anemia.	Agrees to try and eat more spinach, chard, and lean beef.
	Administer iron supplements as ordered.	Iron supplementation helps correct anemia.	Iron supplement not ordered yet. Continue plan.

Postprocedure

Mr. Jackson's provider found a duodenal ulcer on endoscopic examination. He has prescribed sucralfate (Carafate), 1 g orally four times per day before meals and bed; ranitidine (Zantac), 300 mg at bedtime; and Mylanta II, 30 mL 30 min after meals, in hopes of healing the ulcer and preventing surgery.

Problem Statement/Nursing Diagnosis

Insufficient knowledge/Deficient knowledge due to factors that contribute to peptic ulcer and information about medications.

Supporting Assessment Data

Subjective: States was unaware that cigarette smoking contributed to ulcers; has never heard of the medications prescribed for him, except for the antacid.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will verbalize factors that contribute to ulcer formation.	Instruct in contributing factors of ulcer formation (i.e., explain how the eating behavior of "grab a bite" and eating spicy or fried foods are contributing to ulcer formation).	Understanding how behavior affects health may help the patient to make better choices.	Acknowledged that smoking, his diet, and lifestyle contribute to his ulcer. States that he will quit eating foods that cause pain (i.e., spicy foods).
Patient will attempt to quit smoking within 2 wk.	Assist him to learn new ways to cope with stress.	Practicing relaxation and deep breathing helps decrease stress.	Taught deep-breathing exercise. Will begin exercise program for stress reduction.
	Discuss smoking cessation strategies (i.e., set a stop date, enlist help of family, use of a prescribed nicotine patch, substituting an activity such as chewing gum).	Nicotine is very addictive and having a formalized plan increases success.	Expresses interest in talking to doctor about getting a prescription for the nicotine patch. Has cut smoking down to <u>½</u> pack per day, states he will try to quit.
	Discuss ways to manage proper eating when on the road (e.g., packing healthy snacks or choosing baked foods, not fried).	Knowing good food choices for his situation can help him eat properly when on the road.	Discussed food places that have appropriate choices. Wife agrees to pack fruits and whole grain crackers.
Patient will verbalize reason for each medication, dosage schedule, and side effects.	Teach action, dosage, and side effects of sucralfate (Carafate), ranitidine (Zantac), and Mylanta II. Obtain feedback for material taught.	Understanding how to take medications and what to expect, or report, helps with compliance and prevents toxic reactions.	Went over each medication and gave list with dosages. Discussed possible side effects and what to report to the provider.

Critical Thinking Questions

- How would you interact with this patient to try to help him quit smoking?
- What does he need to know about taking an antacid if he is taking other medications?
- Considering he is a truck driver and on the road a lot, what can you do to help him change his diet?

BP, Blood pressure; *CBC*, complete blood count; *GI*, gastrointestinal; *Hct*, hematocrit; *Hgb*, hemoglobin.

■ Implementation

Measure blood pressure and pulse rate regularly. Observe skin color, observe for diaphoresis or thirst, and look for other signs of continued blood loss such as restlessness. Watch for impending hypovolemic shock. Measure intake and output and note the character of vomitus, aspirated gastric fluid, and stools. Measure and record the patient's daily weight. **Melena** stools (black, tarry stools with digested blood) cause an unpleasant odor, and the room must be kept as free of odor as possible.

Diet counseling is a top priority once the patient is stable. Currently, most authorities believe that it is best to restrict only those foods that the patient identifies with the onset of symptoms. It is generally agreed that the kind of food is less important than when the food is eaten; therefore the patient is instructed to eat at frequent and regular intervals throughout the day, rather than in two or three large meals. Meals should not be skipped. Alcohol and caffeine should be excluded.

■ Evaluation

You can point out signs of improvement that will help to relieve the patient's anxiety. For example, if an NG tube is being used to lavage and decompress the stomach, there will be a decreased showing of hematemesis as the bleeding resolves. After the bleeding has apparently stopped and the patient's vital signs have stabilized, there must be continuous monitoring for signs of persistent or renewed bleeding.

Gastric Cancer

The [American Cancer Society \(2015\)](#) estimates that 24,590 cases of stomach cancer will be diagnosed in 2015 and 10,720 people will die of stomach cancer in the United States. Stomach cancer is usually discovered very late because patients often lack symptoms. The 5-year survival rate is 71% if the disease is caught fairly early, and only 4% in those with advanced disease. Metastasis to surrounding organs is common in late disease.

Etiology

The cause of gastric cancer is unknown, but pernicious anemia and **achlorhydria** (absence of hydrochloric acid) are often present. It is believed that a diet high in smoked, highly salted, or spiced foods may be a contributor. Food preservatives such as nitrates or nitrites increase the risk. The presence of *H. pylori*—particularly if present from an early age—is a definite factor. Genetic influence plays a role; the risk is increased in family members and in those with blood type A.

Pathophysiology

Gastric cancer grows primarily from the mucous glands. Most tumors arise in the antrum or pyloric area. The lesion begins as an ulcerative crater with an irregular border and a raised margin. The tumor eventually spreads through the layers of the stomach and spreads to the lymph nodes, the liver, and the ovaries in women.

Nutrition Considerations

Prevention of Gastric Cancer

Refraining from eating a diet high in smoked and salted foods or pickled vegetables helps prevent gastric cancer. Eating a diet high in fruits and vegetables, particularly those high in beta-carotene and vitamin C, decreases stomach cancer risk. People who eat a lot of red meat each week have double the risk of gastric cancer. Foods such as bacon and many “lunch meats” are high in nitrates, which are carcinogenic. When eating those foods, drinking orange juice reduces the absorption of nitrates. The ascorbic acid in the orange juice counteracts the nitrite concentration.

Cultural Considerations

Stomach Cancer Incidence

Stomach cancer is almost double in incidence in African American individuals as in non-Hispanic whites. Native Americans and Hispanic Americans are also at an increased risk for stomach cancer. *Helicobacter pylori* is more common in Hispanic and African American individuals. Research with minority populations is under way to determine how *H. pylori* is transmitted in these populations in an effort to decrease stomach cancer incidence.

Signs and Symptoms

Gastric cancer is usually asymptomatic until the disease is far advanced. Signs and symptoms may include indigestion, loss of appetite, nausea and vomiting, and weight loss but may be limited to just intermittent abdominal distress. Belching and the use of antacids may relieve the distress. The patient may become pale and weak and complain of fatigue, weakness, dizziness, and sometimes shortness of breath. Anemia is the underlying cause of those symptoms. There is often blood in the stool.

Diagnosis

Diagnosis is by upper GI series and endoscopic examination of the stomach with biopsy. Anemia, verified with a complete blood count, is usually present. Tumor markers such as carcinoembryonic antigen and carbohydrate antigen (CA) 19-9 are useful in determining the degree of invasion of the tumor and liver metastasis.

Treatment and Nursing Management

Surgical intervention may relieve symptoms such as obstruction or may debulk the tumor. The same surgical procedures are used as for peptic ulcer; lymph node dissection may be performed. There is only a 40% 5-year cure rate with surgery for gastric cancer. In Japan, laparoscopic surgery for the removal of small tumors is being studied. Adjuvant therapy of radiation and/or chemotherapy may be employed. Radiation has proved to be of value only for palliation. 5-Fluorouracil (5-FU) and cisplatin or 5-FU with epirubicin and cisplatin or other similar

combinations of chemotherapy are used. Cancer therapy and nursing care are discussed in [Chapter 8](#). Nursing care after surgery is the same as for patients after surgery for a peptic ulcer but with excision of involved lymph nodes.

Common Therapies for Disorders of the Gastrointestinal System

Gastrointestinal Decompression

Abdominal distention with increased pressure within the abdominal cavity is very uncomfortable. Excess fluids and gases also interfere with ventilation of the lungs and normal function of other nearby organs.

An NG tube to remove fluids and gas from the stomach may be inserted. Gastrointestinal tubes vary in length, design, and purpose. The Levin tube and gastric sump tube are shorter because they are intended to reach only as far as the stomach. The Miller-Abbott, Cantor, and Harris tubes are longer tubes that are directed past the stomach and into the small intestine. Intestinal tubes are described in [Chapter 29](#).

Clinical Cues

NG tube is a generic term that you may see in providers' orders or in the nurses' or providers' notes, or you may hear that term in report; however, the purpose of the therapy for the NG tube dictates the type of NG tube. Make sure that you clarify the purpose of the therapy and the type of tube before starting the care of the patient.

Nursing Management

Observe the patient for continuing signs of abdominal distention during gastric decompression, which would indicate that excess fluids and gases are not being removed as intended. **Nausea, vomiting, complaints of feeling full or bloated, increasing shortness of breath, and increase in the girth of the abdomen are signs that the stomach and intestines are not being decompressed adequately.**

Applying too much suction can pull the gastric mucosa into the drainage openings, or "eyes," of the tube, causing damage to the mucosa and traumatic ulceration.

Assignment Considerations

Caring for a Patient With a Salem Sump Tube

When assigning assisted ambulation of a patient with a Salem sump tube, remind the CNA or UAP to keep the tube above the level of the stomach to prevent leaking of stomach contents from the pigtail. The main tube should be plugged for ambulation. The assistant can be instructed to reattach the tubing to the wall suction after ambulation is completed, but the nurse is ultimately responsible to follow up and verify that the tube and suction are functioning correctly.

Using a gastric sump tube (Salem, ventral) that has an air vent can help prevent damage to the mucosa. Sump tubes are usually attached to continuous "low" suction; Levin tubes function best with intermittent suction. **Unless ordered otherwise, use the low setting for suction.** The connecting tubing leading to the suction machine works best if it is kept above the height of entry into the drainage container.

Clinical Cues

If there is leakage from the pigtail, it can be cleared by instilling a few milliliters of air; nothing but air should be instilled through it.

Irrigation of the tube with normal saline is usually ordered to keep the tube patent. The amount instilled should be added to the patient's intake count, and the amount of drainage is recorded as output for each shift. If the patient has had surgery on the intestinal tract, the irrigation procedure should be done with aseptic technique rather than clean technique.

The characteristics of the drainage are charted each shift. If coffee-ground-like material is noticed in the tube, the drainage should be tested for presence of blood by using a Hemastix strip dipped into the secretions. If blood unexpectedly appears in the drainage, the provider should be notified. Fluid and electrolyte imbalance problems that can be caused by continuous suction and irrigation are discussed in Chapter 3.

An NG tube is uncomfortable for the patient. The nares must be checked for signs of pressure, and the tube may need to be repositioned in the nares to relieve the problem. Common complaints are sore throat, dry mouth, earache (from congestion of the eustachian tube), and dry lips and nasal mucosa. Frequent mouth care and application of a lubricant to the lips and nares will help. A room humidifier can also be helpful, but this requires a provider's order. The provider may allow the patient to have limited amounts of ice chips, hard candy, or chewing gum to decrease the problem of dry mouth.

After the tube is removed, the patient is monitored for nausea, vomiting, and abdominal distention. Sometimes it is necessary to insert the tube again.

Enteral Nutrition

If a patient has long-term difficulty taking in food orally, as when in a coma, enteral feeding is indicated. Current practice calls for a nasoduodenal tube, which is a small-diameter polyurethane tube that may be weighted at the tip (Figure 28-5). The tube delivers special-formula liquid feedings into the duodenum.

Clinical Cues

When you are working with a nasoduodenal tube, always use a large syringe (10 mL or larger) to flush and to give medications because smaller syringes create too much pressure and may cause the tube to rupture.

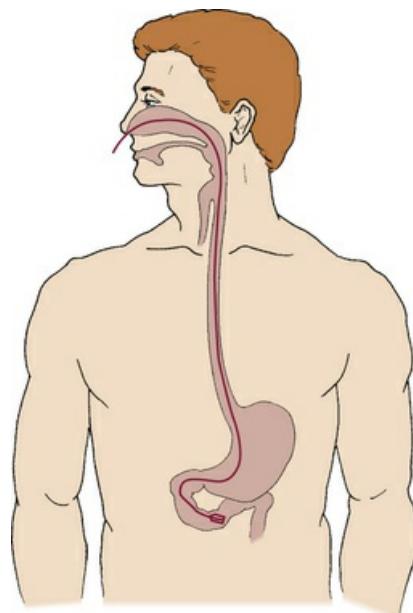

FIGURE 28-5 Small-bore feeding tube placement.

These tubes are inserted by the provider or a registered nurse, and placement in the duodenum is confirmed by x-ray film before feedings are started. Thereafter, the mark at the nares is checked to see that the tube has not slipped out of place before a feeding is begun. The feedings can be given at specified times throughout the day or on a continuous basis. If continuous tube feedings are ordered, they are administered with a feeding pump.

Patients who require long-term nutritional support for problems such as inability to swallow may undergo percutaneous endoscopic gastrostomy (PEG). A feeding gastrostomy tube is placed

endoscopically through the abdominal wall (Figure 28-6). The patient then receives enteral feedings via the gastrostomy tube. The tube is marked with indelible ink at the point of exit so that correct placement can be checked daily. The area is observed for signs of infection and cleansed daily with soap and water until healing is complete. A 4 × 4 gauze dressing is used over the outside bumper while the area is healing. Box 28-1 presents nursing interventions for patients receiving tube feedings. **Adding a feeding when there is too much residual from the last feeding may cause regurgitation and aspiration.**

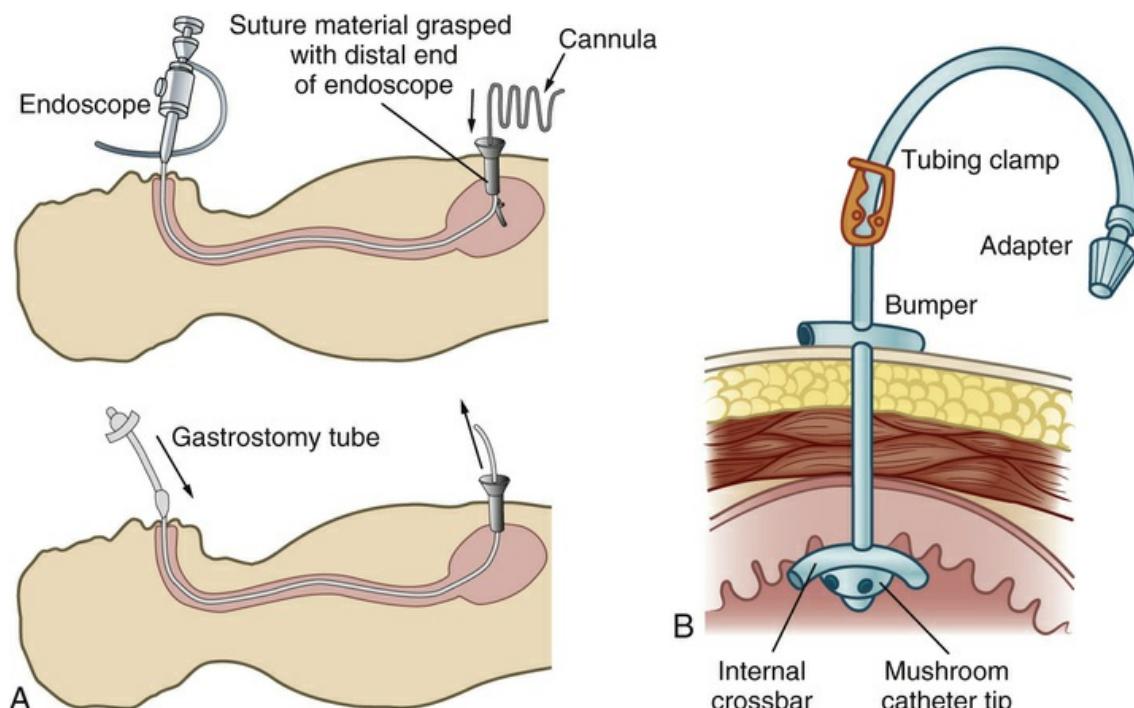

FIGURE 28-6 Percutaneous endoscopic gastrostomy. **A**, Gastrostomy tube placement via percutaneous endoscopy. The gastrostomy tube is inserted through the esophagus into the stomach and pulled through a stab wound made in the abdominal wall. **B**, A retention disk on the inside of the stomach and a bumper disk on the outside secure the tube. (From Lewis SL, Heitkemper MM, Dirksen SR, et al: *Medical-surgical nursing: Assessment and management of clinical problems*, ed. 9, St. Louis, 2015, Mosby. Redrawn from Mahan LK, Arlin M: *Krause's food, nutrition, and diet therapy*, ed 8, Philadelphia, 1992, Saunders.)

Box 28-1

Nursing Interventions for Patients Receiving Enteral (Tube) Feedings

- Be certain tube placement has been checked by x-ray and is correct.
- Check and record the residual volume every 4 hours or as ordered.
- Verify tube placement by checking the mark at the nares every 4 hours.
- Verify the order of the drip rate for the feeding.
- Assess the feeding pump to verify it is set up correctly and that the drip setting is accurate. Be certain the formula being instilled is what was ordered.
- Change the feeding bag and tubing every 24 hours. Change the irrigation set every 24 hours also.
- When continuous feeding is ordered, add only 4 hours of formula to the bag at a time to prevent

bacterial growth; a closed system may be used for 24 hours.

- Do not use food dye in the formula because it can cause complications.
- Keep the head of the bed elevated at least 30 degrees during the feeding and for 1 hour after an intermittent or bolus feeding. For continuous feeding, keep the patient in a semi-Fowler position.
- Monitor laboratory values: blood urea nitrogen, electrolytes, hematocrit, albumin, and glucose.
- Monitor for diarrhea or excessive gas.
- Monitor and record intake and output.
- Monitor and record the patient's weight at least weekly.
- Flush the tube with 30 to 60 mL of sterile water every 4 hours during continuous feeding, and before and after each intermittent feeding.
- Flush with 30 mL of sterile water before and after each individual medication; do not mix medications together or with the feeding formula. Use liquid medications whenever possible.
- If tube becomes clogged, flush with 30 mL of sterile water in a 50-mL piston syringe; use gentle pressure.
- Provide mouth care every 4 hours.
- Clean the nares and around the tube in the naris each shift or twice a day. Inspect the naris for pressure areas.
- Change the tape or tube securing device if it becomes loose or soiled.

For Gastrostomy Tube

- Assess the insertion site for signs of infection or excoriation.
- Rotate the tube 360 degrees every day and check for $\frac{1}{4}$ -inch play in and out. If tube cannot be moved, report this to the provider because the retention disk may have become embedded in the tissue.
- Change the dressing at least once a day, applying a dry sterile dressing.

For Jejunostomy Tube

- Be certain that the suture holding the tube is intact and that the mark on the tube is at the skin surface before starting or adding to a feeding. If it is not, stop the feeding and notify the provider.
- Do not attempt to aspirate a jejunostomy tube; it will collapse because of its small interior diameter.
- Inspect the insertion site and change the dressing once a day.

Sometimes the feeding tube is placed in the jejunum via a jejunostomy. If this is the case, the tube is sutured in place, and the spot where the tube enters the abdominal skin is marked. The mark and suture are checked before beginning a feeding to make certain that the tube has not been dislodged. It is difficult to aspirate anything from a jejunostomy.

Safety Alert

Jejunostomy Tube Displacement

If a jejunostomy tube has moved or the suture is broken, no feeding should be given. Peritonitis may occur if feeding formula spills into the peritoneal cavity. The tube must be replaced by the provider. Always document that placement was checked and whether the suture is intact and the mark is at the skin. If displacement has occurred, document what action was taken.

Total Parenteral Nutrition

Total parenteral nutrition (TPN) is indicated when the patient cannot ingest or digest foods normally or has a problem with malabsorption. If a patient has continued weight loss and a negative nitrogen balance, TPN is indicated. Conditions that could warrant TPN include severe trauma to the intestinal tract, as with a gunshot wound, and chronic inflammatory conditions. Regional ileitis that prevents absorption of nutrients is an example of an inflammatory condition. Other conditions not related to the intestinal tract but nevertheless capable of seriously interfering with normal nutrition over time include prolonged sepsis, fever, extensive burns, and cancer.

TPN is essentially a form of IV feeding. The amounts and kinds of nutrients needed for long-term nutrition cannot be administered using peripheral veins, so the nutrient mix is given using a larger central vein such as the superior vena cava. The provider may choose to use a direct central line into the vena cava or jugular vein, or a peripherally inserted central catheter (PICC) line may be inserted and threaded into the vena cava instead. Lipids may be given via a peripheral vein. Further information about TPN and the principles for administration are found in [Chapter 3](#).

Safety Alert

Do NOT confuse enteral feedings and TPN feedings. The solutions and routes are not interchangeable. **Infusing an enteral feeding into an IV site can result in death.** First, verify the solution and route. Trace the tube down to the patient's body to ensure that you are using the correct tube.

Care of the patient must be a team effort on the part of providers, pharmacists, dietitians, and nurses. Nursing care includes assisting with the insertion of the IV central line, changing the tubing with each new bag or bottle, changing the dressing, observing the insertion site, and removing the tubing when TPN therapy is discontinued. Day-to-day care includes monitoring vital signs, glucose levels, and fluid and electrolyte balance. The patient is weighed daily and provided frequent mouth care. The rate of TPN is slowly decreased to gradually lower the dextrose load before TPN is discontinued.

Get Ready for the NCLEX® Examination!

Key Points

- A calorie reduction diet combined with exercise and behavior modification are the initial treatments for obesity. Bariatric surgery may be considered for obese patients with a BMI over 40.
- Dysphagia may cause respiratory problems from aspiration.
- Oral cancer and esophageal cancer are associated with alcohol and tobacco use.
- Common symptoms of GERD include dyspepsia and reflux. Diet therapy, lifestyle changes, drug therapy, weight reduction, and education are the mainstays of treatment.
- A peptic ulcer (gastric or duodenal) is ulceration of the upper GI tract. Symptoms include epigastric pain before meals and during the night. Complications include hemorrhage, perforation, and obstruction.
- Monitor vital signs every 15 to 30 minutes when there is evidence of extensive GI hemorrhage. Replacement of blood and fluids may be required.
- Surgical procedures for peptic ulcer include pyloroplasty with vagotomy, subtotal gastrectomy, antrectomy, or total gastrectomy (see [Figure 28-4](#)).
- *Helicobacter pylori*, pernicious anemia, and achlorhydria are all implicated in the development of gastric cancer.
- Symptoms of dumping syndrome are nausea, weakness, abdominal pain, diarrhea, faintness, palpitations, and diaphoresis.
- An NG tube is used for gastric decompression; a nasoduodenal tube is used for enteral feeding. After NG tube removal, the patient is monitored for abdominal distention, nausea, and vomiting.
- When a patient cannot digest foods and liquids normally, total parenteral nutrition (TPN) may be required. The TPN solution must be sterile and administered at the ordered rate into a blood vessel with high-volume blood flow.

Review Questions for the NCLEX® Examination

1. When working with an obese patient who wants to lose weight, which statement would indicate that the teaching has been understood?
 1. “Starting to exercise 2 hours a day is a good beginning for me.”
 2. “Eating everything I want except for anything sweet will help me lose weight.”
 3. “A program such as Weight Watchers will help me cut calories and keep on track.”

4. "Over-the-counter diet pills are a good way to jump start my weight loss."

NCLEX Client Need: Health Promotion and Maintenance: Health Promotion/Disease Prevention

2. When screening for the presence of risk factors for oral and pharyngeal cancers, which questions would the nurse ask? (*Select all that apply.*)

1. How much alcohol do you consume?
2. Have you had any oral lesions?
3. Do you have family members who have cancer?
4. Do you smoke?
5. Have you been exposed to hepatitis virus?

NCLEX Client Need: Physiological Adaptation: Alterations in Body Systems

3. The nurse reinforces diet recommendations to a patient with GERD. Which patient statement indicates a need for further teaching?

1. "I should avoid spicy Italian sauces."
2. "Clothes should be loose around the waist and abdomen."
3. "I need to wait 30 minutes after eating before lying down."
4. "I need to consider removing caffeine from my diet."

NCLEX Client Need: Health Promotion/Disease Prevention

4. A patient who has GERD for many years is diagnosed with Barrett esophagus. Etiologic factors for Barrett esophagus include:

1. eating spicy foods and hot peppers on a regular basis.
2. long-term gastroesophageal reflux causing mucosal irritation.
3. previous history of oral cancer.
4. moderate alcohol consumption during adult years.

NCLEX Client Need: Physiological Adaptation: Basic Pathophysiology and Alterations in Body

Systems

5. A nurse is taking care of a patient who had a modified radical neck dissection surgery. The patient's spouse asks, "Why do you have to apply cold packs and elevate my husband's head?" Which response is the most appropriate?

1. "These interventions decrease the need for opiates."
2. "These interventions reduce neck swelling."
3. "These interventions promote faster healing."
4. "These interventions reduce the incidence of postoperative fever."

NCLEX Client Need: Reduction of Risk Potential: Potential for Complications from Surgical Procedures and Health Alterations

6. A nurse is reviewing signs and symptoms of esophageal cancer with people who are at risk. Which statement indicates that the participants have understood the information?

1. "A feeling of fullness in the throat is an early sign."
2. "Belching and indigestion are caused by cancerous lesions."
3. "Common symptoms are halitosis and dryness of the mouth."
4. "Choking or coughing while swallowing liquids is an early sign."

NCLEX Client Need: Health Promotion/Disease Prevention

7. A patient reports a history of gastric ulcer. Which sign or symptom indicates the need for a priority action of physician notification?

1. Epigastric pain that is described as a burning sensation.
2. Pain is most severe at bedtime.
3. Reports vomit that "looks like coffee grounds."
4. Discomfort comes for several days and then subsides.

NCLEX Client Need: Physiological Integrity: Alterations in Body Systems

8. While a nurse is obtaining a clinical history, a patient with a known history of peptic ulcers suddenly complains of a severe upper abdominal pain of increasing intensity that spread to the shoulders. The abdomen has boardlike rigidity. Which sign(s) and/or symptom(s) signal worsening related to the peptic ulcer? (*Select all that apply.*)

1. Slow, deep respirations
2. Decreased oxygen saturation
3. Increased pulse
4. Hot, dry skin
5. Belching and flatulence
6. Confusion and restlessness

NCLEX Client Need: Physiological Integrity: Alterations in Body Systems/Medical Emergencies

9. A patient is receiving continuous enteral feedings. Which intervention will address the most common problem associated with the feeding therapy?

1. Assist the patient to ambulate several times a day.
2. Assess the skin in the rectal area and apply a barrier cream.
3. Place an emesis basin and tissues within close proximity.
4. Frequently offer water, other fluids, or ice chips.

NCLEX Client Need: Physiologic Integrity: Reduction of Risk Potential: Potential Complications of Treatments

10. A nurse is supervising a nursing student during the care of a patient with a gastrostomy tube. The nurse should intervene if the student:

1. aspirates for residual contents before feeding.
2. flushes the tube after each feeding.
3. changes the tubing and bag every 4 hours.
4. cleans and dries the skin around the tube.

NCLEX Client Need: Physiologic Integrity: Reduction of Risk Potential

11. A family member tells a nurse, "Dad seems to be having some trouble swallowing lately." What is the nurse's priority action?

1. Notify the provider.

2. Consult the speech therapist for advice.
3. Initiate aspiration precautions.
4. Observe during “practice swallows.”

NCLEX Client Need: Physiologic Integrity: Reduction of Risk Potential

12. A nurse is caring for a patient who is vomiting blood. The provider orders a normal saline IV fluid bolus of 500 mL to infuse over 30 minutes. The correct pump setting in mL/hour is _____.
(Fill in the blank.)

NCLEX Client Need: Physiological Integrity: Physiological Adaptation/Fluid and Electrolyte Imbalances

Critical Thinking Questions

Scenario A

Ms. Olivera, age 56 years, is experiencing a lot of abdominal discomfort and reflux. She visits her provider, who believes she has GERD. She is 5 feet, $3\frac{1}{2}$ inches tall and weighs 158 lb.

1. What measures would be recommended to decrease the symptoms of GERD?
2. What specific instruction would you give Ms. Olivera regarding her diet?
3. Why would losing some weight help her problem?

Scenario B

Mr. Eoyang, age 47 years, is admitted to the hospital because he has epigastric pain, is vomiting blood, and has a suspected gastric ulcer.

1. What tests might be done to establish a diagnosis for Mr. Eoyang?
2. What kind of information will help Mr. Eoyang prevent difficulty with his diet after he is discharged?
3. What would Mr. Eoyang need to know to keep his ulcer under control and eventually cure it?

Scenario C

The nursing assistant tells you that Mr. Yamamoto had an episode of coughing while he was eating breakfast. You check on the patient and he is not having any respiratory distress, but you notice that there are some food stains on his shirt. He says, “Sometimes water makes me cough.” You decide to feed the patient his lunch so that you can observe him eating and inform the provider about your observations.

1. What position will you place him in before feeding?
2. Explain how to observe for problems with swallowing.
3. What dietary modifications can be made for patients who have difficulties with swallowing?

CHAPTER 29

Care of Patients With Disorders of the Lower Gastrointestinal System

Objectives

Theory

1. Discuss the characteristics of irritable bowel syndrome.
2. Explain how diverticulitis occurs.
3. Identify the causes and signs and symptoms of a strangulated (incarcerated) hernia.
4. Illustrate how the two types of intestinal obstruction occur and their symptoms.
5. Describe the pathophysiology, methods of diagnosis, and treatment for ulcerative colitis and Crohn disease.
6. Differentiate the signs and symptoms of appendicitis from peritonitis.
7. Plan nursing interventions for a patient having surgery of the lower intestine and rectum.
8. Discuss ways to help a patient psychologically adjust to having an ostomy.
9. Compare the characteristics of hemorrhoids, pilonidal sinus (cyst), and anorectal fistula.

Clinical Practice

10. Choose nursing interventions for a patient with inflammatory bowel disease.
11. Assess for the signs and symptoms of appendicitis.
12. Identify types of patients who are at risk for peritonitis.
13. Create a teaching plan for the prevention of colorectal cancer.
14. Write a nursing care plan for a patient with cancer of the colon and intestinal obstruction.
15. Evaluate a nursing care plan for a patient undergoing colostomy, considering the type of stoma and the effluent it produces.
16. Observe the equipment and procedure for changing an ostomy appliance.

Disorders of the Abdomen and Bowel

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is a functional disorder of gastrointestinal (GI) motility. In the United States more people have IBS than diabetes or asthma, and IBS is a major reason for missing workdays. In North America, IBS is far more common in women than in men.

Etiology

The cause of IBS is unknown, but is currently being researched. At this time it is thought to result from a hypersensitivity of the bowel wall that leads to disruption of the normal function of the intestinal muscles. There is a familial predisposition. Stress, caffeine, and sensitivity to certain foods such as dairy and wheat products seem to trigger IBS in some people.

Pathophysiology

An altered bowel pattern and abdominal pain with bloating are caused by altered motility of the small and large intestines. IBS can occur after a bowel infection, possibly related to changes in intestinal cells and normal GI flora. There is evidence that with IBS there is an abnormality of nerve function in the intestine. The chemical mediator 5-hydroxytryptamine (5-HT), or serotonin, plays a role in bowel motility and visceral sensitivity, and medications altering 5-HT₃ and 5-HT₄ activity have been used in treatment. Research is focusing on the neurohormonal control of the gut for answers to the pathophysiology and treatment of IBS ([Camilleri, 2014](#)).

Signs and Symptoms

IBS is a group of symptoms that together represent the most common disorder in patients who consult gastroenterologists. The three characteristics typical of this disorder are (1) alteration in bowel elimination (either constipation or diarrhea or both); (2) abdominal pain and bloating; and (3) the absence of detectable organic disease. The bloating and abdominal pain usually have a sudden onset with production of flatus. The pattern of bowel dysfunction varies from case to case, and each patient seems to have a unique pattern.

Diagnosis

Diagnosis of IBS is based on clinical manifestations and ruling out the presence of organic bowel disease. Diagnostic criteria include:

- Abdominal pain or discomfort that is:
 - Relieved by defecation
 - Associated with a change in stool frequency and/or consistency
 - Other symptoms that support the diagnosis:
 - **Mucorrhea** (mucus in the stool)
 - Abdominal bloating

No diagnostic testing is recommended unless certain additional “alarm features” are present: weight loss, iron deficiency anemia, or family history of organic GI illness ([Lehrer, 2015](#)).

Diarrhea or Constipation

Treatment and Nursing Management

A thorough general health assessment is conducted along with a focused assessment. Medications for symptom control are prescribed according to the patient's individual symptoms. Drugs that have been used include bulk-forming agents, antidiarrheals, antispasmodics, antidepressants, anticholinergics/sedatives, and mild analgesics to relieve discomfort (Table 29-1). A diet high in fiber also may be prescribed. Bulk forming agents such as Metamucil or stool softeners may be recommended.

Table 29-1
Drugs Commonly Used to Treat Gastrointestinal Disorders

CLASSIFICATION	ACTION	NURSING IMPLICATIONS	PATIENT TEACHING
Antidiarrheals			
Diphenoxylate hydrochloride (Lomotil) Loperamide (Imodium) Opium tincture (Paregoric) Kaolin-pectin combinations (Kaopectate) Bismuth subsalicylate (Pepto-Bismol)	Decrease motility, propulsion, and secretions. Decrease fluid in stool. Bind water; coat mucosa, absorb toxins.	Observe for effectiveness; should be effective within 48 hr. Observe for signs of constipation. Use cautiously in patients with prostatic enlargement; may cause urinary retention. Warn that Pepto-Bismol will make stool black.	Warn that medication will cause dry mouth. Instruct not to take more than recommended dosage; toxicity can occur. With Lomotil, warn not to operate machinery until effect on central nervous system is known. Advise to contact provider if acute diarrhea does not abate within 2 days.
Antiflatulents			
Simethicone (Phazyme, Mylicon, Di-Gel)	Defoaming action disperses gas.	Warn that the drug does not prevent gas formation, but will decrease bloating and discomfort. Gas is expelled via belching or flatus.	Instruct to chew tablets before swallowing.
Laxatives			
Bulk-Forming			
Methylcellulose (Citrucel) Psyllium (Metamucil, Konsyl)	Act like fiber, absorbing water in the bowel and hastening transit time through the bowel.	None specific; monitor effectiveness.	Instruct to take with an 8-oz glass of water to prevent esophageal or bowel obstruction.
Surfactants			
Docusate sodium (Surfak, Colace) Docusate potassium (Dialose)	Facilitate absorption of water by stool by decreasing the surface tension. Enhance secretion of fluid and electrolytes in the bowel.	Contraindicated for patients with signs of intestinal obstruction. Act in 24–48 hr. Used to prevent constipation rather than treat it.	Instruct to take with a full glass of water. Not to be used for more than 1 wk without provider's knowledge.
Contact Laxatives			
Bisacodyl (Dulcolax) Phenolphthalein (Feen-a-Mint, Ex-Lax, Modane) <i>Cascara sagrada</i> and senna (Senokot, Fletcher's Castoria) Castor oil	Act on intestinal wall to increase secretion of fluid and electrolytes into the intestine.	Most act within 6–12 hr to produce a semifluid stool. Bisacodyl is available as a rectal suppository as well as an oral tablet. Phenolphthalein may turn the urine pink. <i>Cascara sagrada</i> and senna may cause a brownish yellow or pink tinge to the urine. Castor oil acts within 2–6 hr. Castor oil should not be used routinely to treat constipation. The unpleasant taste of castor oil can be decreased by chilling or pouring over ice or mixing in chilled fruit juice.	Contact laxatives should be used only for occasional treatment of constipation. They are habit forming, decreasing the natural mechanisms for evacuation. Tablets should not be chewed. Take tablets with a full glass of water. Do not exceed recommended dosage. Take bisacodyl 1 hr after taking antacids or milk. Suppository form may cause burning sensation in the rectum.
Drugs for Inflammatory Bowel Disease (IBD)			
Sulfasalazine (Azulfidine) Mesalamine (5-ASA) Olsalazine (Dipentum) Balsalazide disodium (Colazal)	Sulfasalazine is a sulfonamide antibiotic. Mesalamine is the active agent in sulfasalazine. Olsalazine contains two molecules of 5-ASA. These drugs reduce inflammation in the bowel by suppressing prostaglandin synthesis and the migration of inflammatory cells into the affected area.	May cause muscle aches, nausea, fever, or rash. Complete blood counts needed periodically; can cause agranulocytosis and anemia. Determine whether allergy to sulfonamides exists before administration.	Caution patient to avoid direct sunlight and ultraviolet light to prevent photosensitivity reaction. Advise to use form of contraception other than oral contraceptives; these drugs interfere with their effectiveness. Warn that when used with oral hypoglycemics, an increased hypoglycemic effect may occur. Advise that urine may be tinted orange. GI upset may be minimized by taking drug after meals. Instruct to report rash or sensitivity reaction to provider promptly.
Linaclootide (Linzess)	Guanylate cyclase-C agonist causing increased fluid in the intestine and reduces nerve pain sensitivity	For treating chronic constipation and IBS in patients older than 17 years.	Should be taken in the morning on an empty stomach 30 min before the first meal of the day.
Lubiprostone (Amitiza)	Increases the volume of intestinal fluid, which makes stool easier to pass.	For treating constipation in women older than 18 years. Can cause nausea, diarrhea, and abdominal pain. In rare cases can cause dyspnea.	Teach to take with food and water to decrease side effects. Advise to seek attention immediately if dyspnea occurs.
Infliximab (Remicade)	Monoclonal antibody that neutralizes the activity of tumor necrosis factor-alpha found in Crohn disease; decreases infiltration of inflammatory cells.	Given IV over at least 2 hr. Dose repeated at 2 wk and then q6wk from first dose. Observe for anaphylactic reaction.	May initially cause increased diarrhea. Advise to report nausea, vomiting, abdominal pain, itching, or rash to provider. Need periodic blood counts. Patient should not breast-feed while taking this drug.
Antispasmodics			
Dicyclomine hydrochloride (Bentyl, Antispas) Propantheline bromide (Pro-Banthine) Oxyphenylamine hydrochloride (Daricon)	Block acetylcholine, thereby decreasing smooth-muscle spasm and GI motility and inhibiting gastric acid secretion.	These drugs interact with many other drugs; check each drug patient is taking for interactions. Most of these drugs are contraindicated in glaucoma, prostatic hypertrophy, myasthenia gravis, and other conditions; consult information on each drug individually. May predispose to drug-induced heat stroke. Monitor vital signs and urine output carefully.	Advise to take 30–60 min before meal. Patient can suck on hard candy to relieve mouth dryness unless contraindicated. Have patient drink 2500–3000 mL of fluid to prevent constipation. Warn to avoid driving or hazardous activities if drug causes dizziness, sleepiness, or blurred vision. Teach to report rash or skin eruption to provider.
Hyoscyamine (Levsin)	Inhibits action of acetylcholine at postganglionic receptor sites, decreasing spasm and abdominal pain.	May decrease absorption of antacids and antidiarrheals. May increase effects of anticholinergics. May cause urinary retention. Assess for dehydration; encourage adequate fluid intake.	May cause dry mouth. Instruct to inform provider of rash, eye pain, difficulty in urinating, or constipation. Advise to avoid hot baths and saunas. May initially cause dizziness or faintness; warn to not operate machinery until response is known.

5-ASA, 5-Aminosalicylic acid; GI, gastrointestinal; IV, intravenously.

Gas-forming foods such as legumes and those in the cabbage family should be avoided. Avoiding onions, potatoes, cucumbers, coffee, tea, carbonated beverages, and alcohol can be helpful. Milk is restricted if the patient has shown evidence of intolerance to it. Lactase tablets may be used for lactase deficiency but are not indicated if an allergic sensitivity is present. Gluten intolerance has been identified as a possible trigger for IBS symptoms. Wearing loose clothing is more comfortable if bloating or increased abdominal pressure occurs. Give instruction about medications and diet therapy.

Ineffective coping patterns in response to stress may be present in these patients. Randomized, controlled trials have shown cognitive therapy, psychotherapy, and hypnotherapy help to improve overall symptoms ([Lehrer, 2015](#)). Consultation with a psychiatric nursing specialist can help the staff nurse develop more realistic goals and effective nursing interventions to improve the patient's coping skills.

Focused Assessment

Data Collection for a Patient With Suspected Irritable Bowel Syndrome

For a patient with symptoms suggesting IBS, gather the following data:

History

- When symptoms first began
- Stool pattern: frequency, character of stool
- Presence of bloating and flatus
- Incidence of pain or cramping; location, duration, character
- Pain that awakens the patient at night
- Precipitating factors for cramping or diarrhea
- Known food intolerances
- Methods of self-treatment
- Known stressors
- Methods of coping with stress

Physical Examination

- Presence and character of bowel sounds
- Degree of firmness and tenderness of abdomen
- Location of tenderness
- Appearance of stool

Complementary and Alternative Therapies

Peppermint Oil for the Relief of Abdominal Discomfort

Peppermint oil may provide some temporary relief of abdominal pain for patients with IBS; however, those with gastroesophageal reflux disease (GERD) should avoid this alternative therapy because it can worsen heartburn ([Alam et al., 2013](#)).

Clinical Cues

Having the patient keep a food diary can be very helpful in identifying foods that cause a reaction with bloating and inflammation. If the diary is kept over a period of weeks, a pattern may be established. Food intolerance symptoms may not be evident for up to 4 days after the food is eaten. Sometimes if one food is linked to the symptoms, that food can be simply left out of the diet.

Diverticula

The term **diverticulum** refers to a small, blind pouch resulting from a protrusion of the mucous membranes of a hollow organ through weakened areas of the organ's muscular wall. Diverticula are most prevalent in older individuals and occur anywhere in the intestinal tract, but are found primarily in the colon. When diverticula are present, the patient is said to have **diverticulosis**. The exact incidence of diverticulosis is not known because most diverticula are asymptomatic. It is uncommon in people younger than 50 years and almost universal in those older than 90 years. Increases in intra-abdominal pressure from constipation and straining to defecate, obesity and a low fiber diet appear to be factors in the development of colon diverticula.

Etiology and Pathophysiology

Diverticulitis occurs when the diverticula become inflamed or infected and occurs in about 20% of those affected by diverticulosis. Food particles accumulate in the diverticula, mix with the intestinal bacteria, and can irritate the mucosal wall. The intestinal wall may become infected, and if it is not treated, perforation and peritonitis may occur.

Esophageal diverticula occur when there is herniation of esophageal mucosa and submucosa into surrounding tissue. The disorder is more common in older patients.

Signs, Symptoms, and Diagnosis

A person with diverticulosis may initially be asymptomatic; however, symptoms will develop when inflammation or infection occurs because material has lodged in diverticula. For bowel diverticula, there is usually a history of constipation. There may be rectal bleeding. **Diverticulitis of the intestine produces symptoms of diarrhea or constipation, acute left lower abdominal pain, bloating, nausea, and vomiting. The condition may be complicated by intestinal obstruction or by peritonitis if the intestinal wall ruptures.** If bleeding is massive, there will be hypotension and eventual shock. Computed tomography of the abdomen with colonic contrast is the preferred diagnostic test. Barium enema and colonoscopy should be avoided in acute cases because of the risk of bowel perforation (Shahedi, 2014).

Esophageal diverticula produce symptoms of dysphagia, regurgitation, nocturnal cough, and **halitosis** (bad breath). There is a risk of esophageal perforation.

Think Critically

What is the difference between the signs and symptoms of diverticulitis and those of irritable bowel syndrome?

Treatment and Nursing Management

Diverticulosis often can be managed conservatively. A high-fiber diet, increased fluids and bulk laxatives, or stool softeners to control constipation may be all that are needed.

For diverticulitis, antidiarrheal medication may be prescribed. The role of the LPN/LVN is to reinforce education about the diet, fluid intake, and exercise. Mild pain medication may be used for abdominal discomfort in ambulatory patients. Outpatient treatment may include clear liquids for 2 to 3 days with oral antibiotics. Diet can be advanced as tolerated. In acute cases of diverticulitis or failed outpatient treatment, parenteral antibiotics with intravenous (IV) hydration and bowel rest by placing the patient on nothing-by-mouth (NPO) status for 2 to 3 days may be necessary.

Morphine is acceptable for pain management and has fewer side effects than meperidine (Demerol). In earlier recommendations meperidine was the drug of choice based on a theoretical risk not shown in studies. (Shahedi, 2015)  Recurrent episodes of diverticulitis, or perforation and peritonitis, require surgical removal of the affected part of the colon.

Safety Alert

Meperidine Toxicity

A metabolite of meperidine is toxic, and older adults have difficulty metabolizing and eliminating it. The buildup of the toxin in the blood can cause seizures and other mental status changes such as acute confusion. Ask for an alternate analgesic for these patients.

Nutrition Considerations

Diet for Diverticular Disease

A high-fiber diet is encouraged for patients with diverticular disease. Eating whole-grain cereals and breads and fruits such as apples, seedless berries, peaches, and pears adds fiber. High-fiber vegetables—squash, broccoli, cabbage, and spinach—and legumes, including dried beans, peas, and lentils, provide bulk that decreases constipation and speeds intestinal transit time. Drinking plenty of fluids helps regularity. This diet, combined with exercise to prevent constipation, can usually control diverticular disease. Patients who have recurrent diverticulitis may be instructed to avoid foods with husks, such as peanuts, sunflower seeds, berries with seeds, tomatoes, and popcorn, as a precaution; the husks may get into the diverticulum and irritate it, causing inflammation and eventual diverticulitis. This has not been identified as a risk for diverticulitis and these foods may not need to be restricted.

Intestinal Obstruction

Intestinal obstruction is a sudden or gradual blockage of the intestinal tract that prevents the normal passage of GI contents through the intestines.

Etiology and Pathophysiology

Mechanical obstruction results in blockage of the lumen of the bowel. Examples include tumors, adhesions, strangulated hernia, twisting of the bowel (**volvulus**), telescoping of one part of the bowel into itself (**intussusception**), barium impaction, intestinal parasites, and gallstones. ([Figure 29-1](#)). Abdominal adhesions are a common cause of intestinal obstruction. Adhesions form when inflammation from abdominal trauma or surgery has occurred, and fibrous bands of scar tissue hold together two segments of bowel that are normally separated.

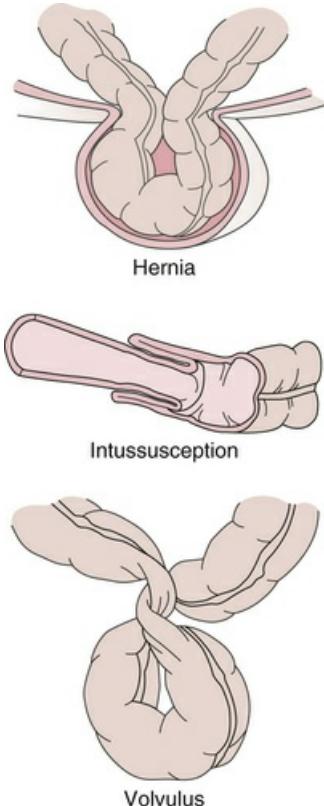

FIGURE 29-1 Mechanical causes of intestinal obstruction.

Nonmechanical obstruction results from the absence of peristalsis. Nonmechanical obstructions may occur as a result of **paralytic ileus** (failure of forward movement of bowel contents) after abdominal surgery, from infection, or as a consequence of hypokalemia. Nonmechanical obstructions may be secondary to intestinal thrombus. Infections can occur in some pelvic inflammatory diseases or peritonitis, in uremia, and in heavy-metal poisoning. All of these conditions can interfere with normal peristaltic action and produce a nonmechanical obstruction.

Older Adult Care Points

Older adults are more prone to the occurrence of volvulus and consequent intestinal obstruction, partially because of decreased muscle tone. Suspect this disorder when an older adult complains of sudden abdominal pain with vomiting, has abdominal distention with a palpable mass, has increased bowel sounds on auscultation, and shows signs of dehydration.

When obstruction occurs, fluid and gas accumulate in the intestine, increasing intraluminal pressure. Peristaltic waves above the obstruction may occur as the intestine attempts to move material down the tract. These waves may cause severe pain.

Signs and Symptoms

The symptoms of intestinal obstruction vary according to the location of the obstruction. Obstructions occurring high in the intestinal tract are characterized by sharp, brief pains in the upper abdomen. Frequent, high-pitched bowel sounds are heard above the point of obstruction, and bowel sounds are absent below the obstruction. Other symptoms include vomiting, with rapid dehydration and only slight abdominal distention. An acute intestinal obstruction in the upper abdomen can cause respiratory difficulty because of the pressure of the distended abdomen against the diaphragm.

Obstructions of the colon are characterized by a more gradual onset, with marked abdominal distention as the bowel fills, vomiting may occur (which occurs late in the process if at all), and **pains that last several minutes or longer and correspond to peristaltic waves**. Fecal odor or material in the emesis suggests a complete intestinal obstruction.

Diagnosis and Treatment

Abdominal radiographs are ordered to locate the obstruction. Insertion of a nasogastric (NG) tube relieves symptoms by decompressing or removing gas, intestinal contents and mucous. The long tube or Miller-Abbott tube has a balloon that is inflated after passage into the pylorus (Figure 29-2). Peristalsis, which is preserved above the blockage, moves the tube to the point of blockage. Use of the long tube has not been shown to be more clinically effective than a standard-length NG tube (Noble, 2014). Surgery is indicated for obstruction caused by adhesions, volvulus, hernia, or tumor. Adhesions are **lysed** (broken apart), a volvulus is untwisted, or a colectomy may be necessary if tumor is involved.

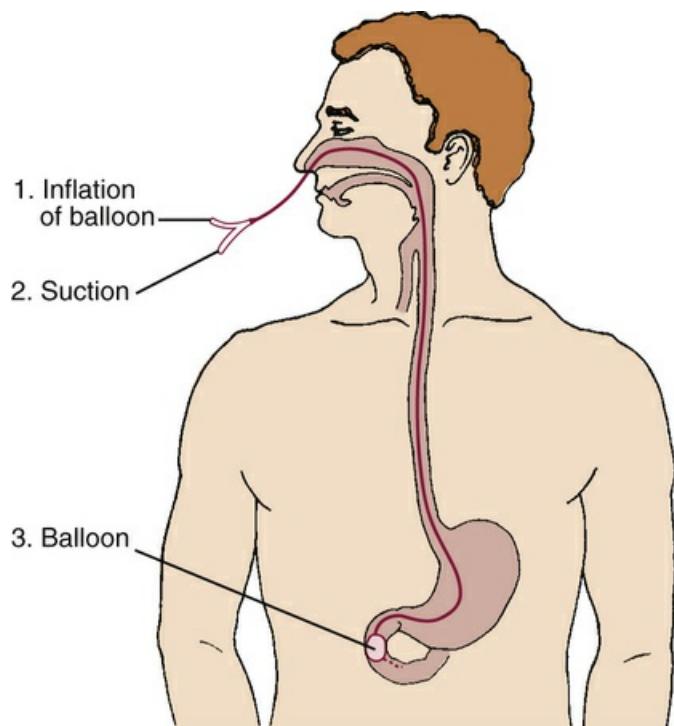

FIGURE 29-2 Miller-Abbott intestinal tube used for decompression. It is advanced through the intestines to the prescribed point. The Miller-Abbott tube has a double lumen and is weighted with tungsten. 1, Portion of the metal tip leading to the balloon. 2, Portion of the metal tip leading to the lumen that can be suctioned. 3, Balloon inflated with air.

Nursing Management

Placing the patient in a Fowler position helps relieve pressure and aids in removing gas and intestinal contents through the intestinal tube. Fluid and electrolyte status must be monitored closely. Measure abdominal girth every 2 to 4 hours by placing the tape at the same location on the abdomen each time. Pain control is essential, but worsening pain may signal an unresolved, intestinal obstruction that can lead to rupture of the intestine, peritonitis, shock, and death. If the obstruction cannot be resolved, surgical correction must be done. Postoperative care is the same as for other abdominal surgery patients (see Chapter 5, Nursing Care Plan 29-1, and Nursing Care Plan 29-2 on Evolve).

Nursing Care Plan 29-1

Care of a Patient Undergoing Colectomy for Probable Colon Cancer

Scenario

Mrs. Simpson, age 58 years, just returned from surgery and has a dressing over a colectomy site.

She has a family history of polyposis of the colon. She had the colectomy because of a malignant lesion in the upper portion of the sigmoid colon. She was NPO before surgery for a variety of tests. She has an IV running at 125 mL/hr and is on a clear liquid diet. She is experiencing pain and receiving morphine by PCA pump. She is very frightened because her father died of colon cancer. She dreads chemotherapy. Mrs. Simpson is a loan officer with a national bank, is very busy, and had put off having a physical examination and sigmoidoscopy until this month, when she noticed some blood in a loose stool. She had experienced some bouts of loose stools but thought these were a result of the stress she was experiencing on her job.

Problem Statement/Nursing Diagnosis

Pain/Pain due to abdominal surgery.

Supporting Assessment Data

Subjective: "I'm still really hurting."

Objective: Colectomy, abdominal incision with wound drain; pain at 7/10.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Pain will be controlled to a level of 3/10 with analgesia during hospitalization.	Initially assess for pain q1-2h or prn using pain scale and document location and characteristics. Monitor use of PCA pump.	Pain scale use provides more objective measure of pain. Frequency of assessment may be changed to q3-4h as condition improves. PCA allows patient better control over pain.	Pain at 2-3 with use of PCA. Using PCA appropriately.
Patient will use relaxation techniques to decrease pain before discharge.	Teach relaxation techniques to decrease anxiety. Provide comfort measures, such as a tidy odor-free room and quiet environment.	Relaxation helps decrease pain. Comfort measures help to decrease the subjective experience of pain.	Taught deep-breathing relaxation exercise. Lights dimmed and linens changed. Patient expresses appreciation. Continue plan.

Problem Statement/Nursing Diagnosis

Potential fluid volume deficit/Risk for deficient fluid volume/nutritional intake due to prior NPO status and colon surgery.

Supporting Assessment Data

Objective: NPO for several days; on clear liquids; IV infusing.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will not develop fluid or electrolyte imbalance as evidenced by good skin turgor, moist mucous membranes, and electrolyte studies within normal range.	Assess skin turgor and mucous membranes each shift. Monitor for adequate urine output. Assess for signs of dehydration (i.e., poor skin turgor, decreased amounts of and concentrated urine). Maintain IV fluid flow as ordered. Evaluate tolerance of oral fluids, so diet can be advanced to promote nutritional intake. Monitor electrolyte laboratory values.	Skin and mucous membrane assessment gives indication of fluid status. Adequate urine output indicates adequate intake. If dehydration persists or worsens, the doctor must be notified so that therapy can be adjusted. Provides fluid until the patient has adequate oral intake. GI delivery of nutrition is the most effective and efficient. Laboratory values indicate electrolyte imbalances if they occur.	Mucous membranes moist, good skin turgor. Urine output 600 mL this shift. Voiding pale yellow urine; skin dry, but no tenting. IV flowing at 125 mL/hr. Able to tolerate fluids without nausea or abdominal distention. Laboratory specimens to be obtained in A.M. No signs of electrolyte imbalance. Continue plan.

Problem Statement/Nursing Diagnosis

Potential for infection/Risk for infection due to colectomy and abdominal incision.

Supporting Assessment Data

Objective: Colectomy and abdominal incision with drain.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will not experience wound infection as evidenced by temperature and WBC count within normal range at discharge and wound clean and dry without redness, pain, or purulent drainage.	Assess surgical wounds and adjacent tissues for redness, swelling, warmth, pain, and presence of odors or drainage. Track temperature and WBC count.	Close observation is necessary to identify the beginning of infection in the early phase. Changes may indicate beginning infection.	No redness noted in surrounding tissue. Denies pain or tenderness. Temp 98.8° F (37.1° C); WBC count 9400/mm ³ .
	Reinforce dressings PRN; change every 24h or PRN when ordered. Use strict aseptic technique for dressing changes. Clean skin around incision with ordered solution.	Maintaining sterile intact dressing decreases chance of infection.	Incision clean and dry without redness. Sterile dressing changed using sterile technique.
	Maintain patency of drain.	Draining excess fluids from wound site facilitates healing.	Drain in place; small amount of serous fluid noted.

Problem Statement/Nursing Diagnosis

Potential for bleeding from surgical site/*Risk of bleeding from surgical site.*

Supporting Assessment Data

Objective: Fresh colectomy incision.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will not have excessive blood loss as evidenced by stable vital signs and adequate urine output	Assess vital signs per postoperative routine: q30min for 2 hr; q1h for 2 hr; q2h for 4 hr; then q4h until stable.	Vital signs can indicate hemorrhage.	P 86, R 18, BP 136/84.
	Notify provider for change of mental status, tachycardia with increased respirations, or blood pressure 15-20 points below preoperative baseline level; unremitting pain.	Change of mental status is usually the first sign of decreased cerebral perfusion. Tachycardia with increased respirations and falling blood pressure indicates hemorrhage.	Alert and oriented to person, place, and time. Skin is warm, pink, and dry. Vital signs stable.
	Monitor hourly urine output; report if <30 mL for 2 consecutive hours.	Decreasing urine output indicates decreased renal perfusion which can lead to renal failure if prolonged and severe.	Urine output 125 mL over 2 hr.
	Assess dressings for bleeding; check underneath patient.	Postsurgical patients have risk for hemorrhage, and blood can pool underneath the patient.	Dressings dry; no drainage under patient.
	Assess abdomen for increasing girth or rigidity.	Increasing abdominal girth or rigidity could signal internal bleeding.	Abdomen not rigid; girth not increasing. Continue plan.

Problem Statement/Nursing Diagnosis

Anxiety/*Anxiety due to fear of cancer, treatment, and possible death.*

Supporting Assessment Data

Subjective: Father died of colon cancer; expresses fear of cancer and death; dreads chemotherapy.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will openly discuss fears and concerns with nurse, family, or provider.	Establish trusting relationship with patient by active listening and attentive caring.	A trusting relationship helps patient express feelings.	Not wanting to talk yet; spent quiet time with patient.
	Assess mood, verbal, and nonverbal behaviors that suggest readiness to talk.	Expressions of anxiety and fear will manifest differently for each patient; therefore therapeutic responses are based on assessment of the behavior (i.e., crying, yelling, demanding, rejecting, withdrawn, flat affect, sad expression).	Is withdrawn and quiet; does not wish to discuss situation until pathology report is back. Sat quietly with patient for 15 min.
	Reassure patient that you are available for future discussions.	Patient needs to know that you are willing to return and support her, regardless of how she initially responds to you.	Continue plan.
	Offer to contact a cancer organization that provides visits from survivors of similar cancers.	Talking with someone that has experienced the same situation allows the patient to be with someone who understands.	Name and telephone number of volunteer given to patient for contact when the patient is ready.
	Offer to contact hospital Chaplin services or individuals of the patient's choice for spiritual support	Many people look to faith based support during times of crisis and find comfort and direction for decision making.	Patient requested her rabbi to be asked to visit her.

Problem Statement/Nursing Diagnosis

Potential altered breathing pattern/*Risk for altered breathing pattern due to anesthesia, analgesia, and postoperative pain.*

Supporting Assessment Data

Subjective: "I don't want to cough."

Objective: Underwent general anesthesia; receiving morphine via PCA; shallow breaths.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will not develop atelectasis or pneumonia as evidenced by normal breath sounds in all lobes of lungs.	Assist patient to turn, cough effectively, and deep breathe at least q2h.	Coughing and turning assists with lung expansion.	Coughing and turning q2h. Decreased breath sounds in bases of lungs.
	Monitor for proper use of incentive spirometer.	Incentive spirometer helps prevent atelectasis.	Using incentive spirometer correctly q2h.
	Auscultate lungs every shift. Monitor pulse oximetry.	Auscultation tells whether all areas of the lungs are aerating.	Decreased breath sounds in bases bilaterally; no adventitious sounds. SpO ₂ 98%.
	Assist to get out of bed to sit in chair or ambulate as ordered.	Early mobility improves lung function and decreases complications such as pneumonia.	Able to move, stand, pivot, and sit in chair with one-person assist. Continue plan.

Critical Thinking Questions

1. Why is it significant that Mrs. Simpson has familial polyposis?
2. What should other family members be told? What is the nurse's role in disclosing information?

3. Why is a patient such as Mrs. Simpson likely to have IV therapy ordered?

BP, Blood pressure; CBC, complete blood count; GI, gastrointestinal; I&O, intake and output; IV, intravenous; NG, nasogastric; NPO, nothing by mouth; P, pulse; PCA, patient-controlled analgesia; PRN, as needed; R, respirations; WBC, white blood cell.

Abdominal and Inguinal Hernia

Etiology and Pathophysiology

If there is a defect in the muscular wall of the abdomen, the intestine may break through the defect. This protrusion is called a **hernia** or a *rupture*.

The most common locations for a hernia are in areas where the abdominal wall is normally weaker and more likely to allow a segment of intestine to protrude (Figure 29-3). These include the center of the abdomen at the site of the umbilicus and the lower abdomen at the points where the inguinal ring and the femoral canal begin. A hernia may form at an old abdominal surgical incision. The most common contributing factors in the development of a hernia are straining to lift heavy objects, chronic cough, straining to void or pass stool, and ascites. Inguinal hernias are more common in men. Hernias are classified as **reducible**, in which the protruding organ can be returned to its proper place by pressing on the organ, and **irreducible** or **incarcerated**, in which the protruding part of the organ is tightly wedged outside the cavity and cannot be pushed back through the opening. If the protruding part of the organ is not replaced and its blood supply is cut off, the hernia is **strangulated** or **incarcerated**.

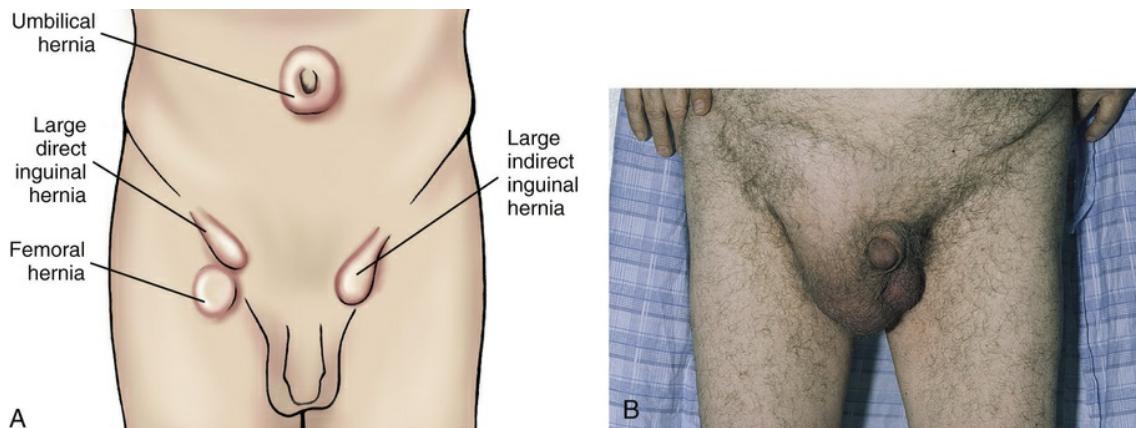

FIGURE 29-3 **A**, Umbilical hernia. **B**, Indirect inguinal hernia. (**A**, From Lewis SL, Heitkemper MM, Dirksen SR, et al: *Medical-surgical nursing: Assessment and management of clinical problems*, ed 9, St. Louis, 2015, Mosby. **B**, From Swartz MH: *Textbook of physical diagnosis: History and examination*, ed 6, Philadelphia, 2010, Saunders.)

Signs and Symptoms

If the hernia is not incarcerated, there will just be an abnormal pouching, a “lump” or local swelling out from the abdominal wall or in the groin area (inguinal or femoral hernia). When pressure on the abdominal wall is removed by lying down, the swelling disappears. Lifting of heavy objects, coughing, or any activity that puts a strain on the abdominal muscles may force the organ back through the opening, and the swelling reappears.

Some discomfort may accompany the hernia. Pain occurs when the peritoneum becomes irritated or when the hernia is incarcerated or strangulated. The flow of intestinal contents can be blocked by an incarcerated hernia, causing symptoms of intestinal obstruction. **This is an emergency because when the blood supply is restricted, part of the intestine may die.**

Treatment

The surgical procedure used in the treatment of a hernia is called a **herniorrhaphy**. The defect in the muscle is closed with sutures. If the area of weakness is very large, a **hernioplasty** is done. In this procedure, some type of strong synthetic material is sewn over the defect to reinforce the area. The

material used is a mesh product; it has potential for complications because a foreign object is being implanted. Studies show the recurrence of a hernia is significantly decreased with the mesh implant. The procedure can be done on an outpatient basis as an open or laparoscopic procedure. Local or regional anesthesia is used instead of general anesthesia for uncomplicated and minimally invasive cases.

If surgery is not possible because of age or high surgical risk, the patient may be fitted with an appliance called a *truss*, which simply reinforces the weakened cavity wall and prevents protrusion of the intestines. The truss is put on in the morning before the patient gets out of bed because the hernia is more likely to be reduced at that time. It is only a symptomatic measure and does not cure the hernia.

Nursing Management

Care after hernia repair is directed at pain control and preventing recurrence of the hernia. The patient is cautioned not to do heavy lifting, pulling, or pushing that increases intra-abdominal pressure. Postoperative care is similar to other surgical patients (see [Chapter 5](#)).

Careful discharge instructions are given to the patient to prevent problems at the surgical site. Guidelines on signs and symptoms of complications are sent home with the patient, along with a written list of activities to avoid until healing is complete. Lifting restrictions are usually implemented for 1 to 2 weeks, and the patient is instructed to support the site with the hand if coughing or sneezing.

Think Critically

What would you say to a family member who mentions to you that he has a swelling in the groin area and thinks he may have a hernia?

Bowel Ischemia

Bowel ischemia occurs when the blood supply to the bowel is insufficient to support metabolic needs. It can be an acute process with a sudden onset of symptoms or a chronic condition.

Etiology and Pathophysiology

The problem may involve the arterial or the venous blood supply in the form of emboli, thrombosis, or the gradual narrowing and occlusion of vessels. Ischemia can occur as the result of a bowel obstruction or as the result of hypovolemic shock. In 95% of chronic conditions, diffuse atherosclerotic disease of the mesenteric vessels is the source of decreased blood flow. Chronic mesenteric ischemia (CMI) is a rare diagnosis. Most episodes of bowel ischemia result from an acute event.

Acute mesenteric ischemia can result from arterial emboli or thrombosis. Emboli can originate in the heart chambers or plaque inflammation in major vessels, leading to clot formation. Acute events not involving obstruction of blood flow include those that decrease blood flow, such as hypotension, sepsis, or severe liver or renal disease. When blood flow is limited, the gut is bypassed in favor of the brain, heart, lungs, and kidneys so hypotension has more of an effect on the blood flow to the intestines than to other organs.

Signs, Symptoms, and Diagnosis

A careful history is necessary because the symptoms are similar to many other abdominal disorders. The sudden onset of severe abdominal pain signals an acute condition. Nausea, vomiting, diarrhea, and abdominal cramps may also be present. The abdomen is tender to palpation, and the patient will exhibit guarding. Bowel sounds will be minimal or absent. The white blood cell count is likely to be elevated. Computed tomography angiography or magnetic resonance angiography is used to confirm the medical diagnosis.

Treatment and Nursing Management

The patient will be NPO and an NG tube will be inserted to relieve distention. Intravenous hydration is usually ordered, and a Foley catheter may be used to monitor output in the acute phase. Ischemia from an obstructive cause, either thrombus or embolus, may be treated with intra-

arterial infusions of a vascular smooth muscle relaxant at the site of the blockage, or thrombolytic therapy may be used. The standard treatment is IV heparin. If bowel tissue has become necrotic, surgery is indicated.

Inflammatory Bowel Disease

Ulcerative Colitis and Crohn Disease

Inflammatory bowel disease (IBD) includes both ulcerative colitis (UC) and Crohn disease (regional ileitis). UC is an inflammation with formation of ulcers of the mucosa of the colon. It frequently is a chronic disease, and the patient is usually asymptomatic between acute flare-ups. People with UC have a 40% higher incidence of some types of arthritis. Crohn disease is a chronic inflammatory disease that can involve any part of the GI tract but most commonly affects the distal ileum and proximal colon. Both diseases are idiopathic, meaning the cause is not known. There are theories and research being conducted but no proof of a cause.

Etiology

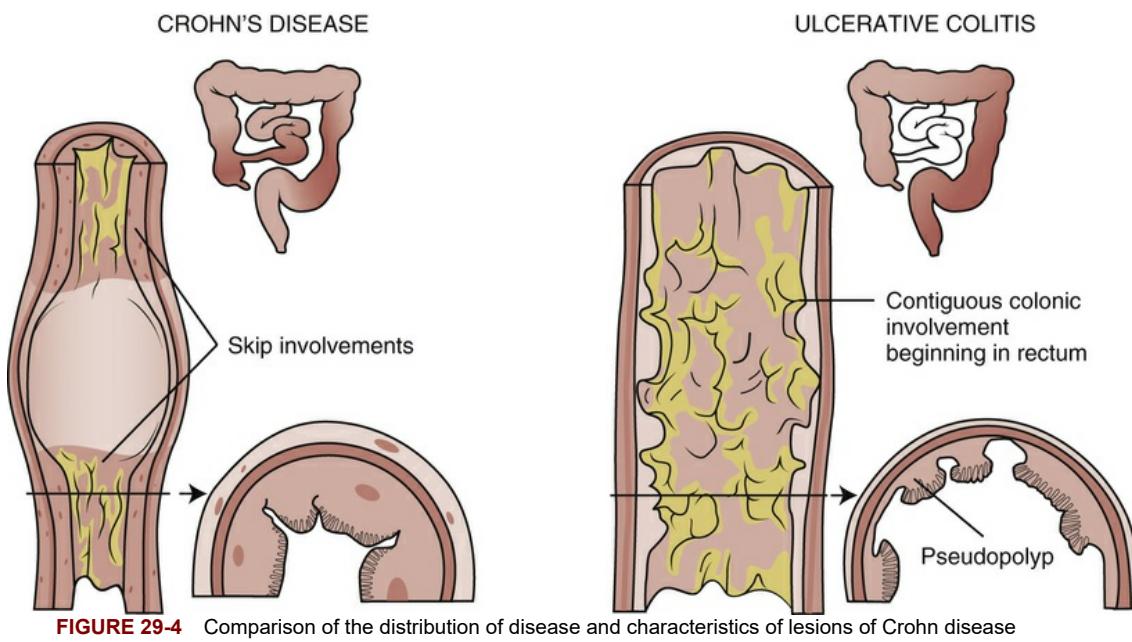

Crohn disease and UC have a genetic predisposition; UC is three times more common than Crohn disease. Both disorders also have an ethnic correlation: they are more common among the Jewish population. Immunologic activity is thought to be involved as well because anticolon antibodies are often present in the blood. With UC, infections and emotional tension often bring about acute attacks.

Pathophysiology

The pathophysiology of IBD is being investigated. It is suspected that UC and Crohn disease are immunologic responses to the same (as-yet-unknown) etiologic agent. The end result is inflammation of the mucosal lining of the intestinal tract, causing ulceration, edema, bleeding, and fluid and electrolyte loss. UC and Crohn disease share many of the same characteristics ([Table 29-2](#)). One difference is that the inflammatory changes in UC are nonspecific, whereas those in Crohn disease are granulomatous (a mass of inflamed tissue characterized by the presence of small granules). Patients with long-standing chronic UC are at 10 to 20 times greater risk for developing cancer of the colon than patients with Crohn disease. The constant inflammation disrupts normal cell function, and cellular mutations may occur. Crohn disease can affect any area of the intestine, although it more often affects the ascending colon and can affect the small intestine ([Figure 29-4](#)). UC typically affects the rectosigmoid and left colon. Changes caused by UC tend to be continuous along the affected portion of the bowel, whereas changes caused by Crohn disease are segmental, leaving healthy sections of bowel in between diseased portions ("skip lesions"). With Crohn disease, radiography reveals a cobblestone appearance to the mucosa.

Table 29-2
Comparison of Ulcerative Colitis and Crohn Disease

	ULCERATIVE COLITIS	CROHN DISEASE
Area affected	Mucosa only; usually involves rectum and proceeds up the colon.	Full thickness of the intestine; most common in small intestine.
Characteristics	Mucosa is red; intestinal wall is edematous and friable, bleeding easily; pseudopolyps are present.	Edematous bowel wall, inflammatory cells, mucosal ulcerations, granulomas, and "skip" lesions (normal areas).
Signs and symptoms	Diarrhea, frequently bloody; abdominal cramping relieved by defecation; rectal bleeding.	Fever, malaise, fatigue, weight loss, intermittent diarrhea, cramping or steady right lower quadrant or periumbilical pain, postprandial bloating.
Complications	Massive hemorrhage; hypovolemia; toxic megacolon (rapid dilation of the intestines); cancer of the colon.	Fistulas, anal fissures, perianal disease, bowel obstruction or perforation.

Signs and Symptoms

Patients with IBD have attacks of diarrhea that may be **bloody and contain mucus; abdominal pain with cramping; malaise; fever; and weight loss**. The color of blood in the stool depends on the degree and rapidity of the bleed. Slow bleeding and oozing will show a black, tarry stool. If diarrhea is frequent, the blood may be more reddish. The stool color is also dependent on where in the intestine the bleeding is occurring. Blood tends to be redder when the bleeding location is lower in the intestine. The bouts of IBD symptoms often are precipitated by events that cause physical or emotional stress. An acute attack can last for days, weeks, or even months, followed by periods of remission extending from a few weeks to several decades. A few patients experience only one attack, and then remain free of symptoms for the rest of their lives. Others have serious intestinal hemorrhage with fluid and electrolyte imbalances.

Safety Alert

Opioids and Anticholinergic Medications

If your patient has ulcerative colitis, opioid medications or anticholinergic medications should be avoided if there is fever, leukocytosis, or worsening symptoms because these medications will further reduce the tone of the colon ([Peppercorn and Farrell, 2013](#)).

Diagnosis

Medical diagnosis of IBD usually is based on the patient's medical history and symptoms. Colonoscopy, flexible sigmoidoscopy, mucosal biopsy, barium enema, and stool analysis may be performed to confirm the diagnosis.

Treatment

Treatment for UC and Crohn disease varies according to severity and frequency of symptoms. Conservative approaches to medical treatment include administration of antidiarrheal drugs, long-term sulfasalazine therapy, and medications to relieve abdominal cramps. The recommended diet consists of low-fat, low-fiber foods that are high in protein and calories. Small frequent feedings are best. Lactose avoidance helps some patients. Corticosteroids are used for moderate to severe cases to decrease the inflammation. During acute attacks, fluid replacement may be necessary. Blood transfusions are given when anemia is present. Oral 5-aminosalicylic acid (5-ASA) derivatives, such

as olsalazine sodium (Dipentum), are useful for those patients who cannot tolerate sulfasalazine (see [Table 29-1](#)). Budesonide (Entocort) is used to help control disease in the ileum. Patients with advanced disease who are not surgical candidates may be given azathioprine, 6-mercaptopurine, methotrexate, levamisole, or cyclosporine to help control the disease ([Rowe, 2015](#)).

Infliximab (Remicade), a monoclonal antibody against tumor necrosis factor, has greater than 80% response rate for Crohn disease, but only about a 50% success rate with UC. The drug is extremely expensive and is given IV by a set protocol. Certolizumab pegol (Cimzia) is a drug for patients with moderate to severe Crohn disease who have not responded to conventional treatments.

Surgical intervention is an alternative treatment for some patients. The surgical procedure usually involves removing the affected portion of the bowel, often by proctocolectomy, and creating an ileostomy. A patient with UC may be a candidate for an ileal reservoir (Kock pouch) or an ileoanal anastomosis rather than a standard ileostomy. Both of these procedures allow the patient control over the discharge of wastes from the reservoir, and consequently a collection pouch is not necessary. The patient uses a catheter to empty the reservoir after the Kock procedure. With an ileoanal anastomosis, the patient retains control over the anal sphincter with voluntary defecation. These procedures are not usually performed for Crohn disease because as the disease progresses, the area of the reservoir becomes involved.

❖Nursing Management

■ Assessment (Data Collection)

A complete health assessment is performed with particular attention to nutritional, fluid, and electrolyte status. A thorough abdominal assessment is performed, identifying pain location.

■ Nursing Diagnosis and Planning

Problem statements/nursing diagnoses might include:

- Acute or chronic pain due to intestinal inflammation.
- Fluid volume deficit due to diarrhea fluid loss.
- Diarrhea.

Other problem statements are listed in [Table 27-2](#). Specific NANDA-I nursing diagnoses are chosen from the NANDA-I list (see inside back cover).

Expected outcomes might include:

- Patient's pain will be controlled with analgesia within 8 hours.
- Patient will regain fluid balance within 24 hours.
- Patient will experience decreased number of diarrhea bowel movements within 24 hours.

Long-term goals are to help the patient adhere to the prescribed regimen, develop effective coping mechanisms, and participate in prescribed psychotherapy.

■ Implementation and Evaluation

For an acute attack of IBD, care includes monitoring the number and character of stools, periodic auscultation of bowel sounds, measurement of intake and output, and daily weight measurement. Check for signs of internal bleeding and monitor laboratory data for evidence of electrolyte imbalances and anemia. Indicators of successful therapy include a decrease in abdominal cramping and discomfort and return of typical bowel pattern.

❑ Think Critically

Can you describe three key differences between Crohn disease and UC?

Appendicitis

Etiology and Pathophysiology

Appendicitis is an inflammation of the appendix, which is a blind pouch and is therefore easily infected by bacteria passing through the intestinal tract.

Signs, Symptoms, and Diagnosis

Pain in the lower right side, halfway between the umbilicus and the crest of the ileum at McBurney point, is the best-known symptom of appendicitis. It is usually accompanied by muscle guarding. However, the location of the pain may—and often does—vary among individuals. The patient may rest with the right thigh drawn up. Extending the leg causes pain. **A slight temperature elevation (1° F), nausea and vomiting, and an increase in the white cell count also are characteristic of appendicitis.** Oral contrast-enhanced computed tomography (CT) scan or ultrasound are used for diagnosis. Concerns about radiation exposure have made ultrasound the preferred imaging technique. CT is used if the ultrasound is negative or inconclusive. Ultrasound should be used to make the diagnosis if the patient is pregnant ([Craig, 2014](#)). Laboratory testing may be performed to rule out other causes of the presenting symptoms.

Treatment

Appendicitis is treated by surgically removing the appendix (**appendectomy**). This procedure may be performed laparoscopically or require an open laparotomy. Patients may be observed for 6 to 10 hours if there is no immediate need for surgery. Before surgery, the patient is NPO. If an abscess is present, IV antibiotics may be given for several days or weeks before appendectomy is performed. If the infection is widespread immediate surgical intervention is indicated. **Under no circumstances should laxatives be given when appendicitis is suspected because of the increased risk for rupture.**

Safety Alert

Cold, Not Heat, for Appendicitis

Never use heat to relieve abdominal pain if appendicitis is suspected. Heat might bring enough blood and fluid to the appendix to cause it to rupture and cause peritonitis. An ice bag may be placed on the abdomen to slow down the inflammation and thus prevent rupture of the swollen and inflamed appendix.

The patient is usually encouraged to be out of bed within several hours of surgery, if there are no complications. The patient undergoing an uncomplicated laparoscopic appendectomy may be discharged the same day after an adequate anesthesia recovery period. The convalescent period is usually uneventful, and the patient may return to her former activities within 1 to 2 weeks. Recovery from an open laparotomy takes 2 to 4 weeks.

Nursing Management

Assess for nausea, determine pain level, take vital signs, and check the abdomen for rigidity that might indicate a ruptured appendix. A diet history for the previous 24 to 48 hours is obtained to help determine whether food poisoning is a cause of the symptoms. Date and character of the last bowel movement and usual bowel pattern are obtained. Common problem statements are listed in **Table 27-2**. Preoperatively, *Pain* is the primary problem. Postoperatively, pain control and prevention of infection at the surgical site are nursing priorities.

Older Adult Care Points

Peritoneal inflammation does not necessarily cause abdominal rigidity in older adults. These patients often have only diffuse abdominal pain, malaise, and weakness. Confusion may be present, and older adults have an increased risk for falls.

Peritonitis

Etiology

Peritonitis is an inflammation of the peritoneum. It usually occurs when one of the organs it encloses ruptures or is perforated so that the organ's contents (including bacteria) are spilled into the abdominal cavity. Examples of common causes of peritonitis are ruptured appendix; perforated

duodenal or gastric ulcer; ruptured ectopic (tubal) pregnancy; diverticulitis with perforation; and traumatic rupture of the colon, spleen, or liver. Patients receiving peritoneal dialysis have a constant risk of developing peritonitis from pathogens entering the abdominal cavity via their dialysis catheter.

Pathophysiology

As the peritoneum becomes inflamed, there is local redness and swelling of the membrane and production of serous fluid that becomes increasingly purulent as the bacteria multiply. Normal peristaltic action of the intestines slows or ceases, and symptoms of paralytic ileus occur.

Signs and Symptoms

The patient experiences nausea, vomiting, and severe abdominal pain and distention. Fever, chills, tachycardia, and pallor occur, and other symptoms of shock may emerge. Unless the condition is treated promptly and successfully, peritonitis can be fatal.

Diagnosis and Treatment

Diagnosis of peritonitis is by history, physical examination, and results of a complete blood count (CBC). A CT scan of the abdomen may be performed to rule out structural problems or tumor. Broad-spectrum antibiotics are given IV, IV fluids and electrolytes are administered to restore a normal balance, and gastric or intestinal decompression is initiated to relieve distention. Surgical procedures needed to repair a ruptured organ are performed as soon as the patient's condition will permit. Complex situations may require multiple surgical interventions. The abdominal incision may be closed temporarily to protect from contamination. In some cases the wound may be left open with packing and dressings as the only covering.

Nursing Management

Frequent assessment and prompt and accurate reporting of unexpected changes in condition are required. The patient is usually placed in the semi-Fowler position to facilitate breathing, prevent respiratory complications, and aid in localizing the purulent material in the lower abdomen or pelvis. Vital signs are taken and recorded as frequently as every 15 minutes during the critical stage. If vomiting occurs, the characteristics and amount of vomitus are noted. Pain management is also important because this is one of the primary presenting symptoms.

A common complication of peritonitis is paralytic ileus. Auscultate at least once a shift for the return of bowel sounds. If the patient passes flatus or feces rectally, this should be recorded on the chart because it indicates return of peristalsis.

Because of the high fever and toxicity that accompany peritonitis, the patient may be delirious or disoriented and must be protected from self-injury. This includes putting side rails up, activating the bed alarm, or having someone at the bedside at all times. The patient should be turned **very gently** and moved in the bed with care because of extreme tenderness in the abdominal region. A high fever and the presence of a gastric tube demand frequent mouth care to protect the lips, prevent halitosis, and cleanse the mouth.

Malabsorption

Etiology and Pathophysiology

Many disorders interfere with the normal absorption of nutrients, water, and vitamins from the intestine. Adult celiac disease (**sprue**), in which the patient cannot properly metabolize gluten (a protein found in all wheat products, barley, and rye), is one cause. Lactose intolerance is another cause because it results in diarrhea. Pancreatic disease with interference in secretion of pancreatic digestive enzymes also causes malabsorption. Some patients who have undergone chemotherapy for treatment of cancer experience alteration of the intestinal mucosa that causes malabsorption. **Whatever the cause, malabsorption creates a nutritional deficiency.** Pathophysiologically, there is irritation of the intestinal mucosa and consequent diarrhea. Both problems limit the ability of the intestine to absorb nutrients.

Cultural Considerations

Lactose Intolerance

Lactose intolerance is most common in Native Americans, African American, Hispanic, and Asian populations, but it can affect people at any age and any ethnicity. It is caused by lack of the enzyme lactase, which is needed to digest lactose. Assess for bloating, flatulence, cramps, and loose stools or diarrhea after consuming milk or milk products.

Signs, Symptoms, and Diagnosis

A key sign of fat malabsorption is **steatorrhea**, or passage of stool that is bulky, frothy, and foul smelling and usually floats in the toilet. Other signs and symptoms include weight loss, weakness, and various signs of vitamin deficiency, depending on the type of malabsorption the patient is experiencing. Diagnosis is by history, upper and lower GI series, and endoscopy with biopsy. Gluten intolerance is diagnosed by blood tests for gluten antibodies and small bowel biopsy.

Clinical Cues

If your patient is to undergo testing for gluten intolerance, she must eat wheat and gluten products for a minimum of 2 weeks before testing. The gluten load should be the equivalent of 2 slices of bread per day; otherwise, the tests will not be accurate.

Treatment and Nursing Management

Treatment is directed at the underlying cause. Pancreatic insufficiency can be treated by administering pancreatic enzymes with meals. Celiac disease is treated by completely omitting gluten from the diet. Lactose intolerance is treated primarily by diet adjustment, limiting intake of lactose. Lactase enzyme preparations are available over the counter and relieve symptoms in some patients. Nursing management consists of supporting the patient through the diagnostic process and reinforcing teaching about diet and medications. The patient is often required to take supplements of vitamins and minerals as a lifetime therapy.

Cancer of the Colon

Cancer of the large intestine, also called colorectal cancer, is the third most common malignancy in both men and women in the United States. Certain forms of colon cancer have been identified as having a genetic link and definitely show a familial tendency for occurrence. Approximately 93,090 colorectal cancer cases were expected to occur in 2015 ([American Cancer Society, 2015](#)). Colorectal cancer is one of the most preventable and curable of all cancers if it is found in the early stages, and mortality rates have fallen over the last 30 years as detection has become easier. *Healthy People 2020* objectives include the reduction of deaths by colorectal cancer and a decrease in the incidence of invasive^E colorectal cancer.

Cultural Considerations

Colorectal Cancer Incidence

Colorectal cancer incidence is highest in African American men and women. Mortality rates in African Americans also are higher than in the white population. It is not certain whether this is because of limited access to health care or other reasons. Always assess an African American older than 40 years for risk factors and signs and symptoms of colorectal cancer. Encourage annual screening after age 50 years. High-risk patients need individualized counseling for screening and follow-up ([American Cancer Society, 2015a](#)).

Etiology

The cause of colorectal cancer has not been established but is generally believed to be a mutation of

a naturally occurring process of colon tissue repair and replacement. The disease mainly occurs in people older than 50 years, although there is a type that occurs in young people. People most at risk include those with disorders of the intestinal tract, especially UC and familial polyposis. Other risk factors are smoking, alcohol consumption, physical inactivity, obesity, and a diet high in saturated fat and/or red meat, as well as inadequate intake of fruits and vegetables (American Cancer Society, 2015a).

Nutrition Considerations

The Colon and Conjugated Linoleic Acid

In research studies with animals, conjugated linoleic acid (CLA) was found to have a protective effect against inflammation-induced colon cancer. Human studies have found that the action of CLA in modifying the immune response decreased symptoms in patients with IBD. CLA is found in high-fat nonpasteurized dairy foods, grass-fed beef, and lamb with a diet supplemented by safflower oil (Bassaganya-Riera et al., 2012).

Health Promotion

Colon Cancer Preventive Measures

Preventive measures include a diet that is high in fiber and low in red meat and animal fat. Nutrients that offer protection against colon cancer are fiber, calcium carbonate, selenium, and vitamin C.

Pathophysiology

The cancerous tumor tissue may be polypoid, protruding into the bowel lumen, or it may be annular and extend around the bowel, causing stricture. Most large bowel tumors are adenocarcinomas and are believed to arise from adenomatous polyps that visibly protrude from the mucosal surface of the bowel. The tumor may spread into adjacent structures or via the lymphatics or the bloodstream.

Complementary and Alternative Therapies

Aspirin, Folic Acid, and Calcium

Some studies suggest that polyp formation can be reduced by taking a baby aspirin each day and diet supplementation with folic acid and calcium. A diet high in fruits, vegetables, and whole grains and adequate exercise are still the recommendations for maintaining colon health (American Cancer Society, 2015a).

Signs and Symptoms

In the early stages, symptoms are typically mild and vague and depend on the location of the tumor and the function of the affected area. Weight loss may be the first sign. Later signs of colorectal cancer are the result of obstruction of the bowel and extension of the growth to adjacent structures.

Any change in bowel habits, either diarrhea or constipation, could be a sign of colon cancer (American Cancer Society, 2015a).

Other symptoms include red blood in the stool, black tarry stools, change in stool shape (ribbonlike stool), abdominal distention without weight gain, sensation of incomplete evacuation after a bowel movement, and anemia resulting from intestinal bleeding. Abdominal pain and a sensation of pressure in the lower abdomen or rectum usually are present. Digital examination may reveal a mass in the anus.

Diagnosis

Screening tests include an annual stool guaiac test or fecal immunochemical test or stool DNA test

(the ideal frequency for the DNA test is undetermined). Beginning at age 50 years, flexible sigmoidoscopy is recommended every 5 years, colonoscopy every 10 years, double contrast barium x-ray every 5 years, or CT colonography (virtual colonoscopy) every 5 years. Colonoscopy is recommended if any of the screening tests are positive ([American Cancer Society, 2015a](#)). If adenomatous polyps are discovered early and removed, colon cancer could be prevented. Tumors of the rectum or lower sigmoid colon are seen by proctosigmoidoscopy. Transrectal ultrasound may be used to determine the extent of a small rectal lesion. Carcinoembryonic antigen (CEA) is elevated in 70% of patients with colorectal cancer, but because it is nonspecific to this type of cancer, it is mainly used to monitor the effectiveness of treatment.

Treatment

Treatment of colorectal cancer usually involves surgical removal of the affected portion of the intestine. Reconnection of the remaining intestine portions (**anastomosis**) is done if the lesion is small and localized (**hemicolectomy**). Alvimopan (Entereg), may be used short term to speed the healing process of the bowel in cases when there is resection and anastomosis. Larger tumors are treated by excising the affected portion of the colon. Occasionally, a surgically created opening on the abdomen (**colostomy**) is needed to provide for elimination of fecal matter. A permanent colostomy is rarely needed for cancer of the colon. After healing takes place, the colon is reconnected.

Most tumors are resected with an open approach, but laparoscopic surgery is an option for a small, localized tumor. Further treatment depends on the stage of the cancer—whether the tumor is through the bowel mucosa, through the bowel wall, or affecting lymph nodes or has metastasized to other organs.

Coleectomy or hemicolectomy.

Coleectomy is the removal of the diseased portion of the colon. The remaining ends of the colon are reattached (anastomosed). **Hemicolectomy** is removal of one half of the colon.

Abdominoperineal resection.

Abdominal resection is performed for cancer in the rectum or low sigmoid colon. It is a very extensive surgical procedure in which part of the colon and the entire rectum, anus, and regional lymph nodes are removed. Both an abdominal and a perineal incision are necessary for this procedure. Because of the nature of the surgery, a permanent colostomy is necessary.

Adjunctive treatment.

Preoperative, intraoperative, or postoperative radiation and chemotherapy may be given for cancer of the rectum. Use of radiation or chemotherapy for colon cancer depends on the stage of the tumor and the presence of metastasis. These therapies may be used preoperatively to shrink a mass so it is more easily addressed surgically. When metastasis is present, the patient is usually treated with 5-fluorouracil (5-FU) with or without leucovorin (folic acid). Oxaliplatin (Eloxatin) is used with 5-FU and leucovorin for treatment-resistant tumors. Intra-arterial chemotherapy may be directed into the liver if metastasis has occurred. Two other drugs may be used as well. Bevacizumab (Avastin) is an antiangiogenesis medication that reduces blood flow to the growing tumor cells, depriving them of nutrients needed for replication. Cetuximab (Erbitux) and panitumumab (Vectibix) are monoclonal antibodies that bind to protein to slow cell growth. Both are used with other chemotherapy drugs. Irinotecan (Camptosar) is available to treat recurrent colon cancer. Capecitabine (Xeloda) is given orally when the tumor has not penetrated the colon wall.

Nursing Management

An abdominal assessment is performed. Questions are asked regarding bowel pattern and changes, diet pattern, and amounts of red meat and charred or grilled food usually eaten. Determine the amount of alcohol consumption and the degree of cigarette smoking. Assess for a family history of colon cancer. Check diagnostic test results such as the CBC for anemia, liver enzymes, and amylase for signs of possible metastatic involvement of the liver or pancreas.

The patient is likely to be very anxious once a diagnosis of colon cancer has been made. Before surgery, focus on the preoperative care and what the patient needs to be taught. Cover what to

expect and provide information about postoperative care. [Nursing Care Plan 29-1](#) describes postoperative care of a patient who has had abdominal surgery with a colectomy.

Health Promotion

Quadrivalent human papilloma virus (HPV) vaccine is FDA approved for use in prevention of anal cancer. HPV is associated with about 90% of anal cancer in homosexual males ([Cagir, 2014](#)).

Common problem statements are located in [Table 27-2](#), but diagnoses specific to cancer (see [Chapter 8](#)) are also relevant. The patient will experience multiple physical and psychological challenges through the diagnosis and treatment process; if interventions are not working, the plan should be changed.

Ostomy Surgery and Care

In an ostomy procedure, an abdominal incision is made, and either the colon (**colostomy**) or the ileum (**ileostomy**) is brought to the outside to drain fecal material.

Colostomy

A colostomy may be required after a colectomy. The colostomy may be permanent or temporary. For a temporary colostomy, the patient will have surgery later for anastomosis of the open ends.

Types of Colostomies

Colostomies are identified by their location and whether one or two lumens are visible. Transverse colostomies may be a **loop colostomy** or **double-barreled colostomy**. Usually these techniques are used when there are plans for reversing the colostomy. Colostomies are also located on the ascending and descending colon and can be double lumen or single lumen. Single opening colostomies are called **single-barreled** or **end colostomy**. **Sigmoid colostomies are the most common location.**

Think Critically

What do you think might be psychological concerns for a person who is to have a colostomy?

Loop colostomy.

During surgery, a loop of the colon is brought through an abdominal incision and onto the surface of the body. An open or laparoscopic approach is used. The colon is transected and the edges sutured to the abdominal skin (Figure 29-5).

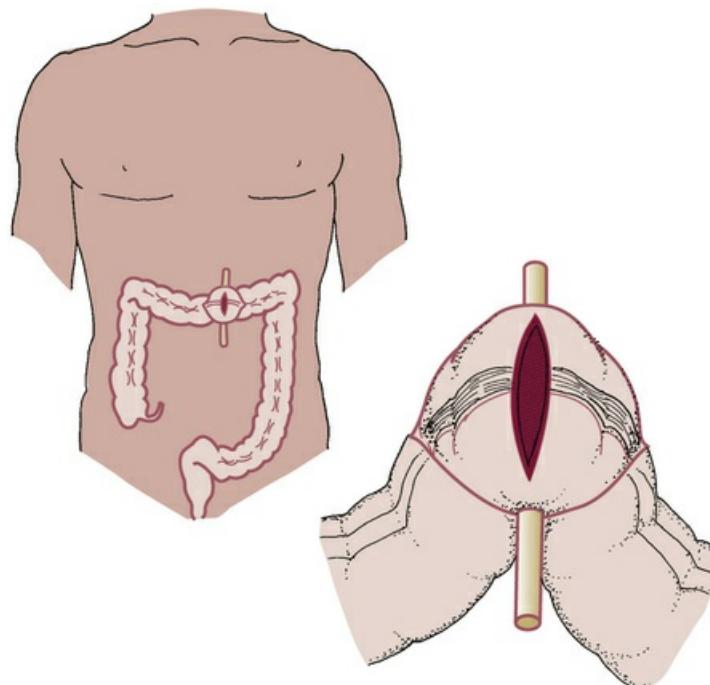

FIGURE 29-5 First stage of loop transverse colostomy. A segment of transverse colon is brought out through the abdominal wall and supported by a bridge. A slit in the bowel allows feces to drain from the proximal colon. The support is removed 5 to 7 days after surgery or when the bowel adheres to the abdominal wall.

An appliance for collection of fecal material is attached over the entire exposed colon.

Double-barreled colostomy.

In a double-barreled colostomy, there are two separate stomas (Figure 29-6). The loop of intestine is completely severed, creating a **proximal stoma** and a **distal stoma**. The proximal stoma is the one closer to the small intestine, so fecal material passes through it to the outside. The distal stoma leads to the rectum and should discharge only small amounts of mucus. The distance between the stomas varies; if they are too close together, it is difficult to get a good seal for the collection device around each one. Eventually the colon ends will be reattached.

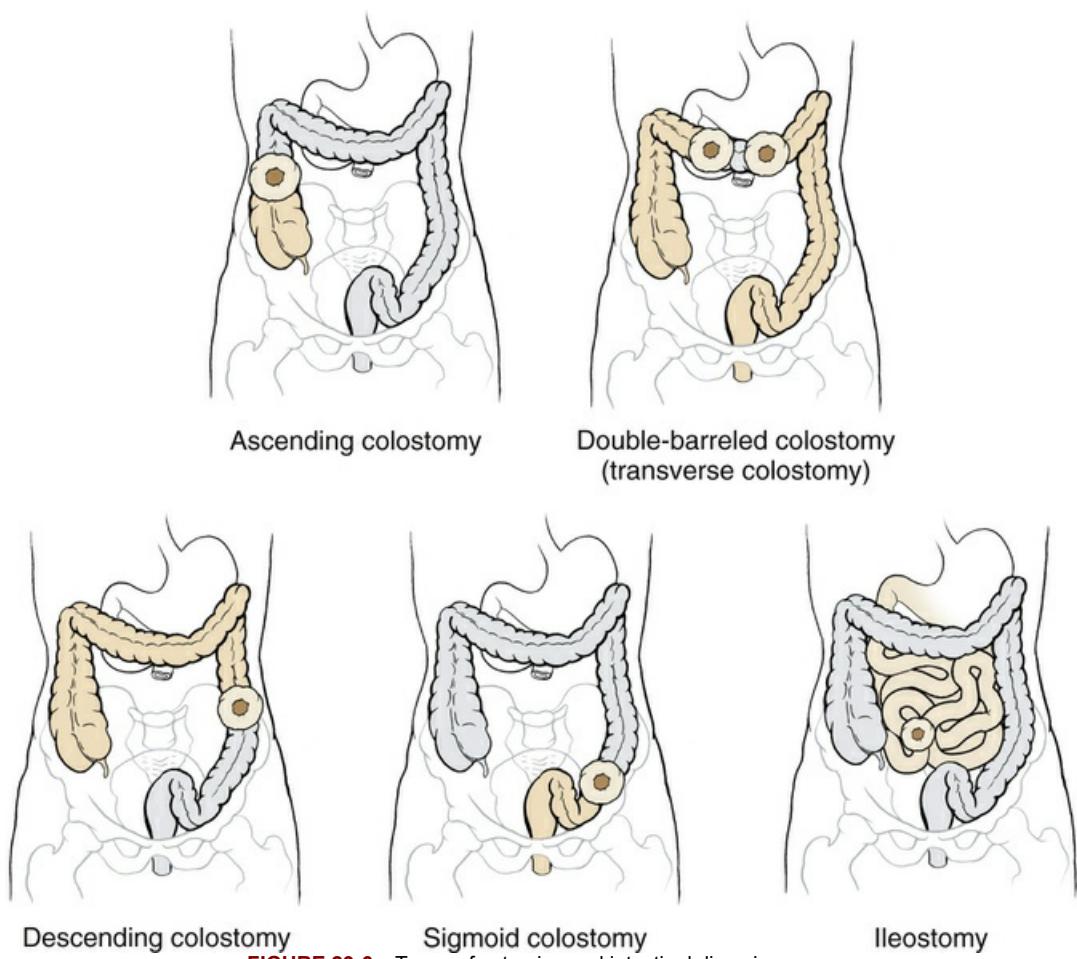

FIGURE 29-6 Types of ostomies and intestinal diversions.

Single-barreled or end colostomy.

There is only one stoma in a single-barreled colostomy. The end is brought to the abdominal surface, **effaced** (cuffed over itself), and sutured to the skin, making what is called a *surgically matured stoma*. If the colostomy is temporary, the remaining portion of bowel and rectum are left intact. If the colostomy is permanent, an abdominal perineal resection may be performed to remove the freed bowel, anus, and rectum, or the end of the bowel is closed and returned to the abdomen. It will continue to produce mucous and expel it from the anus.

Colostomy Locations

An ascending colostomy is one in which either one end or a loop of a portion of the ascending colon is brought to the surface of the abdomen to form a stoma. The stool from an ascending colostomy is thus watery and unformed.

An ascending colostomy usually is temporary and is performed to allow the bowel distal to the ostomy to rest and heal. This is sometimes necessary for patients with IBD, to reconstruct an

intestinal birth defect, or for patients who have experienced an intestinal tear from trauma. After the rest and healing period, the surgeon will replace and reattach the intestine ends, and fecal material can be defecated normally.

A transverse colostomy is situated toward the middle of the abdomen (location of transverse colon). This kind of colostomy usually is temporary. The stool from a transverse colostomy is soft and is discharged unpredictably.

A sigmoid (descending) colostomy is located on the surface of the lower quadrant of the abdomen (see [Figure 29-6](#)). It is the most common type of permanent colostomy and usually is done to treat cancer of the rectum. The stool from a sigmoid colostomy is more solid and well formed and may be discharged no more often than once a day or every 2 days. It is therefore much easier to establish a pattern of evacuation to control the flow of fecal material through a sigmoid colostomy.

Ileostomy

An [ileostomy](#) is performed to drain fecal material from the ileum. It is indicated when disease, congenital defects, or trauma require bypassing the entire colon. The most common indications for ileostomy are chronic IBD, such as UC and Crohn disease; malignancy; and the presence of many polyps in the colon (multiple polyposes). The latter disease is hereditary, and the polyps have a high potential for malignancy.

The site for the stoma of an ileostomy must be carefully selected so that it is not near any bony prominences, folds of skin, or scars and is in a place where the patient can see it and care for it (see [Figure 29-6](#)). The stool from an ileostomy is liquid, and although digestion is completed by the time the fecal material reaches the stoma, it still contains digestive enzymes that are highly irritating to the skin. Skin protection is very important for long-term management.

Surgeons may choose from several techniques to create an ileostomy. The pouch ileostomy or continent ileostomy frees the ileostomy patient from the need to wear a collection device. A small segment of the ileum is looped back on itself to form a pouch (Kock pouch), and a nipple effect is created ([Figure 29-7, A](#)). Pressure from the accumulating feces closes the nipple valve, preventing constant drainage through the stoma. The patient empties the pouch every 3 to 4 hours during the day by inserting a catheter into the stoma.

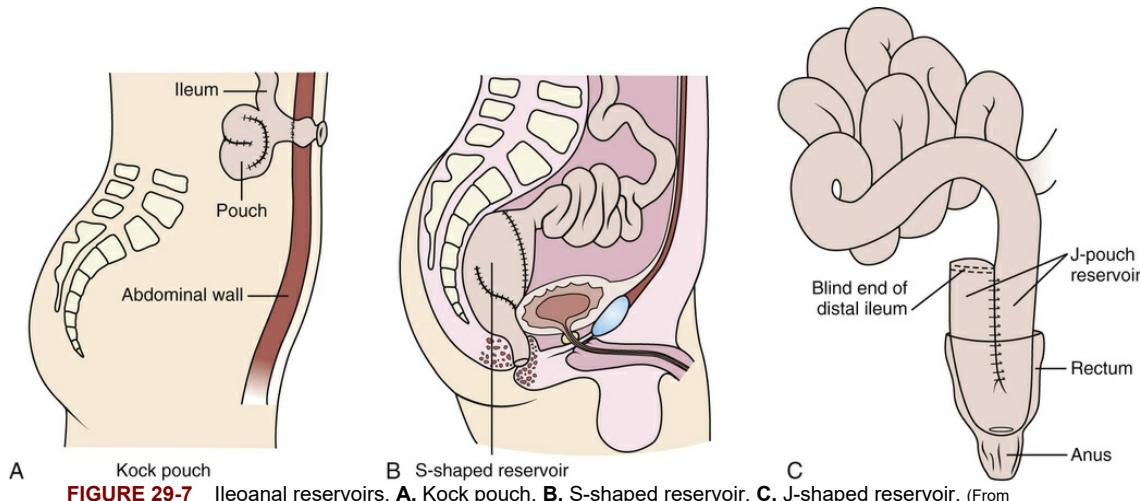

FIGURE 29-7 Ileoanal reservoirs. **A**, Kock pouch. **B**, S-shaped reservoir. **C**, J-shaped reservoir. (From deWit SC: *Fundamental concepts and skills for nursing*, ed. 2, Philadelphia, 2005, Saunders.)

Not every patient can be treated by this surgical technique. It has some disadvantages and must be performed by a surgeon skilled in the procedure. Among those who are not good candidates for a continent ileostomy are patients with chronic inflammatory disease, because the disease tends to recur. Another consideration is the patient's potential for self-care; a catheter must be inserted for periodic drainage of the Kock pouch, and the patient must be able to understand instructions and perform self-care. A third contraindication is related to previous surgery. Patients who have had a conventional ileostomy cannot have a continent ileostomy done if they have less than 29 mm of terminal ileum remaining. This much is needed to construct the nipple valve.

The preferred procedure for UC is the creation of a pouch from the terminal ileum; the pouch is sutured directly to the anus (**ileoanal pouch**). The anal sphincter is left intact and functional. It is a two-stage surgical procedure in which a loop ileostomy is performed and then is closed 3 or 4 months later, when healing is complete. The reservoir may be S-shaped or J-shaped (see [Figure 29-7, B and C](#)). Most patients then have three to eight bowel movements a day. Slight fecal incontinence may be a problem, particularly at night. This procedure is performed only on those patients younger than 55 years who do not have any anal sphincter deterioration. The mucosa is stripped from the small segment of the rectum that is retained to prevent recurrent UC. "Pouchitis" occurs in about 29% of patients and tends to be recurrent. A course of metronidazole (Flagyl) may adequately treat pouchitis. Otherwise, alternate antibiotics and/or steroids are used.

Although not every patient needing an ileostomy can have a continent ileostomy, it is a safe and effective procedure for many. It eliminates the need for an external appliance, is a more natural way to handle waste, greatly reduces fear of embarrassment from leakage of gas and feces, and minimizes peristomal skin problems.

Preoperative Nursing Care

Before surgery of the large intestine, fecal material is removed from the colon. To accomplish this, the patient usually takes oral laxatives the night before surgery and ingests only clear liquids. An enema may also be indicated. In certain cases oral antibiotics may be started.

The contents of the stomach are removed by inserting an NG tube and connecting the tube to a suction apparatus in the operating room. The tube may be left in place after surgery to remove accumulations of mucus and gas that may cause distention and strain on the sutures, but is usually removed in the operating room or recovery room. Postoperative ileus occurs in approximately 5% of patients, in which case the tube is replaced.

❖Nursing Management

■ Assessment (Data Collection)

The immediate postoperative care for a patient who has had intestinal surgery is the same as for other patients having major abdominal surgery. Frequent assessment of vital signs, surgical site, bowel sounds, and IV site is conducted. The patient is assessed for nausea and treated in the early postoperative period because vomiting places a strain on suture lines. Intake and output are tracked, and fluid balance is assessed.

Psychosocial assessment postoperatively focuses on the patient's perception of her altered body image; the meaning of the altered body part; her usual and current coping skills, emotional state, support systems, and presurgery lifestyle; and her perception of physical prognosis and its effect on her life.

■ Nursing Diagnosis and Planning

Problem statements/nursing diagnoses concerning the surgical procedure are similar to abdominal surgery (see [Nursing Care Plan 29-1](#); see also [Table 27-2](#)).[©] Nursing Care Plan 29-2 (on Evolve) presents problem statements/nursing diagnoses and expected outcomes for a patient with an ostomy.

■ Implementation

The patient is started on liquids when tolerated, and the diet is slowly advanced. Early feeding encourages peristalsis in the gut, decreasing ileus.

▣ Complementary and Alternative Therapies

Chewing Gum Postoperatively

"Current best evidence suggests that chewing gum should be offered to selected patients with the intent of decreasing^Q postoperative ileus" ([Keenan, 2014](#)).

The passing of gas, liquids, or solids through the rectum (or stoma) is an indication of active peristalsis. Observe patients carefully for evidence of the return of peristalsis, and chart it in the medical record. The IV site, fluids, and electrolyte levels are monitored very carefully because the patient is especially prone to fluid and electrolyte imbalances. Pain assessment is ongoing, and the effectiveness of analgesia should be assessed after administering pain medication.

Think Critically

How does the effluent from a transverse colostomy, from a sigmoid colostomy, and from an ileostomy differ?

Care of the stoma.

The stoma is inspected for a normal pink or deep red color, which indicates adequate blood supply. It should look like healthy mucous membrane such as that inside the mouth. Later, the stoma will shrink in size and may be less highly colored. There may be slight bleeding around the stoma and its stem, but any more than slight bleeding should be reported. Most collection devices are transparent, so checking for color and bleeding does not require removal of the appliance. Dark purple or black stoma color should be reported immediately. The skin around the stoma is assessed for irritation or signs of breakdown.

Observe the stoma for signs of edema. In the early postoperative period, the stoma will be slightly edematous and larger than it will be after complete healing has taken place. Stoma edema can be caused by a collection device whose opening is too narrow to accommodate the stoma. The opening of the collection device should be at least $\frac{1}{8}$ -inch larger than the circumference of the stoma. There are a variety of appliances available, one- and two-piece devices. The two-piece systems allow for changing the collection bag without removing the appliance from the skin. This allows for direct visualization of the stoma.

Fecal output from the colostomy stoma does not occur for 2 to 4 days, because of the preoperative bowel evacuation and clear liquid diet postoperatively. If there is a perineal wound, the appearance, amount, and character of drainage are assessed and charted. Carefully inspect for signs of infection. Such a wound may be left open to heal by secondary intention, in which case it may be 3 months before it is completely healed. Initially there will be a drain in the wound. Antibiotic therapy is usually given for 24 hours postoperatively for antimicrobial prophylaxis or longer if there is a known infection.

A surgical dressing is never placed over an ileal stoma. If there is a significant decrease in ileal output accompanied by stomach cramping, the ileum may be obstructed. Such symptoms should be reported to the surgeon immediately. If the condition is not relieved, perforation or rupture of the intestine eventually may occur.

Older Adult Care Points

Older adults may require assistance with ostomy care because of poor vision or severe arthritis in the hands. In this case a family member must be taught the techniques of care. Older adults should be given easy-to-follow, large-print instructions for care.

Measurement of intake and output.

Accurate recording of intake and output is especially important in the care of an ostomy patient. Total output of fecal material is calculated every 8 hours. If the stool is liquid, the accuracy of measurement is very important. When the patient's condition is stable, ostomy output is regular, and the patient's nutrition and hydration status are normal, intake and output recording is discontinued.

A patient who has had an ileostomy must always be watched for signs of dehydration and fluid imbalance. This is especially important during the immediate postoperative period, but remains a concern as long as the patient has the ileostomy. To prevent dehydration, fluid intake should be sufficient to compensate for the loss of fluid through the feces.

Evacuation and irrigation.

Once the patient is eating again, ileostomy drainage is usually emptied every 2 or 3 hours. The pouch should be emptied when it is half full. The patient sits on the toilet, unclamps the drainage device, and allows the effluent to drain into the bowl. The clamp is then closed, and the outside of the bag is cleansed of any debris. Ileostomies are not usually irrigated unless there is blockage by large particles of undigested food; then irrigation is done by a provider or enterostomal therapist.

A continent ileostomy with a Kock pouch has a drainage tube inserted with gravity drainage maintained in the immediate postoperative period to prevent distention and allow the pouch to heal. In about 2 weeks, the patient is taught to insert a catheter into the pouch to drain the contents. As the pouch matures and its capacity increases, the time between drainings will lengthen. The pouch may be irrigated occasionally to remove fecal residue.

A sigmoid colostomy will usually expel formed stool on a relatively regular schedule. Irrigation of the colostomy gives the patient some control over when elimination takes place. The procedure is done daily or every other day at about the same time and takes close to an hour. A catheter with a cone tip is attached to a bag, which is filled with 500 to 1000 mL of warm (not hot) tap water. The bag is positioned 18 to 20 inches above the height of the stoma. The colostomy appliance is removed, and an irrigating sleeve is attached to direct the drainage into the toilet. The cone tip is lubricated and inserted gently into the ostomy stoma, and the water is infused slowly to prevent cramping and distention. The cone tip is removed, and the drainage flows through the sleeve into the toilet. When drainage is complete, the sleeve is removed, skin care is performed, and a clean appliance is secured in place. If the patient has a regular evacuation pattern, irrigation is not necessary. If the patient has a regular evacuation schedule whether irrigated or natural, they may be able to use a stoma cap and not need an appliance.

The major reason for irrigating a colostomy is to establish a pattern of predictable bowel movements at the patient's convenience. If the patient prefers not to irrigate, suppositories can be used to stimulate evacuation. Patients who do not irrigate must wear a drainable pouch, because evacuation can be unpredictable.

Cultural Considerations

Cultural Issues for Ostomy Patients

Be aware that cultural and religious considerations for hygiene and fasting may be important for your ostomy patient. For example, on the Jewish Shabbat, strictly observant practice may prohibit the use of running water or electricity; therefore hygiene must be accomplished before the start of Shabbat. A Muslim patient may observe a strict fasting practice for Ramadan that lasts 28 days, when no food or fluid is consumed between sunrise and sunset. An ileostomy patient could be at risk for dehydration, or change of eating patterns could lead to diarrhea or constipation (Black, 2009).

Assignment Considerations

Ostomy Care

The care of a new postoperative ostomy should not be assigned to UAP, because assessments of the stoma, incision, and skin are essential. When ostomy care for a mature ostomy is assigned to a CNA or UAP, remind the person to note the color of the stoma and to immediately report if the stoma appearance is not rosy pink or if there is excoriation of the skin. Documenting the appearance of the stoma, the condition of the skin, and the type and amount of effluent is your responsibility regardless of whether the patient or assistive personnel does the actual cleaning and appliance change.

Peristomal skin care.

Drainage from an ileostomy contains enzymes and bile salts that are highly damaging to the skin. The area of skin around the stoma must be kept clean and protected; fecal material should not be allowed to seep around the opening of the collection device and pool on the skin. In the immediate postoperative period, the pouch should not be changed any more than is necessary to prevent

trauma to the skin.

Clinical Cues

Gently placing a cotton tamponade into the stoma opening after removing the appliance will prevent ileostomy contents from getting on the skin and causing irritation.

The two major principles to follow to protect the skin are cleanliness and the provision of a protective barrier to prevent contact between the skin and the discharge from the stoma. If there is a proper seal to prevent seepage of feces around the stoma, irritation and breakdown of the skin occur much less frequently.

Appliances are generally changed twice a week to maintain an effective seal. When the appliance is changed, it should be removed carefully and the skin washed gently with soap and water so that skin is not damaged by vigorous rubbing and scrubbing. The area should be rinsed thoroughly and dried by patting, not rubbing, the skin. In humid weather, a hair dryer on the low setting may be used to dry the skin. Possible causes of skin problems are allergic reactions, yeast infections, or irritation from changing the faceplate too frequently. After cleansing, a protective skin barrier paste, wipe, or spray—which serves to prevent contact between the skin and the waste being discharged through the stoma—is applied. This may or may not be used for a sigmoid colostomy stoma.

Protective barriers are available in a number of forms and types. The enterostomal therapist or surgeon will indicate which type of barrier is most effective for the individual patient. Should the skin become highly irritated despite efforts to protect it, the provider will prescribe topical medications. Fungal infection of the skin sometimes occurs.

Older Adult Care Points

The changes related to aging reduce reaction time and manual dexterity, decrease visual and hearing acuity, and cause memory loss and fatigue. In addition, changes in body contour such as loss of supporting subcutaneous tissues, wrinkling, and fragility of skin may result in improper fit of appliances. An older adult may have been “educated” about self-care when the ostomy was first established; however, she may have had no follow-up because of transportation issues or because she “didn’t want to bother anybody.” Nurses should advocate for regular follow-up appointments.

Changing the collection device.

There are two kinds of pouches or appliances: the drainable or closed-ended. Each is attached to a faceplate that is secured to the skin around the stoma with a special adhesive. Drainable pouches are used when the flow of waste cannot be regulated and the contents must be emptied frequently (Figure 29-8). Closed-end pouches are used only for security once bowel movements have been regulated. Either new appliance is trimmed to size using a template drawn from the dimensions of the stoma plus $\frac{1}{8}$ inch. The appliance should not be constricting to the stoma but must be tight enough so that skin is not exposed to effluent.

FIGURE 29-8 Ostomy collection appliance in place and sealed around the stoma. (From deWit SC, O'Neill P: *Fundamental concepts and skills for nursing*, ed. 4, St. Louis, 2013, Saunders.)

Psychosocial concerns.

Patients with an ostomy usually go through the stages of grief and loss (see [Chapter 8](#)). Your attitude toward the patient, the stoma, and care has a major effect on the attitude the patient develops about body image changes and self-care. Disposing of body waste is not a pleasant nursing task, but a matter-of-fact, efficient approach is best when caring for the stoma, the effluent, and the drainage device.

Encourage social interaction, and contact available support groups. **As soon as postoperative pain is well controlled, it is best if the patient can talk with another person who has fully adjusted to her ostomy and is living a full and active life.** A series of such visits allows time to formulate and address questions. Such visits do require an order by the provider.

The patient should be guided to express her concerns about the physical and social problems she might encounter as a result of her ostomy. Most patients have concerns about odor, leakage, and noise from the passing of flatus. The nurse and patient should jointly explore changes in lifestyle and realistic alternatives. For example, a patient with a colostomy might be interested in trying a stoma cap, which is a small flat absorbent device that is placed directly over the stoma. The cap will absorb mucus but has no capacity to collect stool or fluids; thus irrigation must be done immediately before application. This option might be used for sexual relations or sports ([Burch, 2009](#)).

The nurse should indicate that concerns about sexual function are expected. Concerns should be addressed matter-of-factly, and the patient's sexual partner should be included in discussions. The enterostomal therapist is a good resource for specific information and suggestions in this area.

When the patient has prolonged dysfunctional grieving, becomes clinically depressed, or cannot accept her altered body image, referral for professional counseling is appropriate.

Patient Education

After teaching the patient about the physiology of her ostomy and the steps involved in taking care of the stoma and skin, teach the patient how to control odor. There will be odor when the drainage pouch is changed or emptied, just as there is with normal bowel movements.

Good basic hygiene is essential. Another measure to control odor is to eliminate from the diet foods known to cause odor or gas. Such foods include eggs, fish, garlic, raw onions, cucumbers, radishes, sauerkraut, corn, broccoli, cabbage, cauliflower, asparagus, dairy products, beans and other legumes, soy, some spices, and chewing gum. Eating too quickly and not chewing food well can cause gas. Carbonated and alcoholic beverages also contribute to the problem.

Gas entering the pouch from the stoma will accumulate there until the pouch is opened and the gas is released (called "burping" the bag). To release gas, open the lower end of the pouch and gently press against its sides. If not released, the gas may cause enough pressure to make the device separate from the stoma. Newer pouches have a charcoal-filtered valve that allows gas to escape.

There are deodorizing sprays and tablets that can be put in the bag that can reduce odor.

Patients with a colostomy slowly resume a regular diet. All ostomy patients are taught to prevent problems with diarrhea, constipation, and blockage. Dietary guidelines are more important for the ileostomy patient.

Patient Teaching

Measures to Prevent Intestinal Blockage for Ileostomy Patients

Teach the patient the following:

- Eat six small meals a day.
- Eat a soft diet during the healing period.
- Chew food very thoroughly.
- Add other foods to your diet gradually.
- Drink more than 8 cups of fluid per day.
- Avoid the following foods:
 - Dried fruits
 - Corn, including popcorn
 - Nuts
 - Sunflower and other seeds
 - Sausages and foods with casings
 - Apple peel
 - Oranges
 - Pineapple
 - Raw cabbage
 - Celery
 - Chinese vegetables
 - Coconut
 - Mushrooms
- If you experience a blockage in the intestine or of the ostomy:

- Begin a liquid diet.
- Cut the opening in your faceplate a little larger than normal, because the stoma may swell.
- Take a warm bath to relax the abdominal muscles.
- Massage the abdomen and area around the stoma; this might increase the pressure behind the blockage and help it to “pop out.” Most food blockages occur just below the stoma.
- Try different body positions, such as a knee-chest position, to move the blockage forward.
- Take oral enzymes to encourage digestion.
- If you still have a blockage or have no stomal output for several hours:
- Call your provider or enterostomal nurse and report the problems.
- If you cannot reach your provider or the enterostomal nurse, go to the emergency department. Take all of your pouch changing supplies with you.
- **Do not try to lavage the ileostomy.**
- **Do not take a laxative.**
- Other pointers:
 - **Ileostomy patients should not take time-release capsules and enteric-coated tablets, because there is not enough time for adequate absorption before the medication is expelled through the stoma.**
 - **Adequate intake of fluids is important for all ostomy patients, to prevent dehydration and electrolyte imbalance.**

Many sources of information are available for ostomy patients (see [Online Resources](#)). These include the local branches of the American Cancer Society, ostomate clubs, enterostomal therapists, and other members of the health care team who have expertise in managing a stoma. Enterostomal therapists are wound care specialists (often with a master's degree, but with certification in wound and ostomy care).

Evaluation

The patient should demonstrate an ability to perform ostomy care and an understanding of how to

manage diet and to prevent potential complications such as fluid and electrolyte imbalance, skin breakdown, and blockage of the ostomy. In addition, the patient should demonstrate psychological adjustment to changes in body image. The plan is adjusted if goals are not being met.

Anorectal Disorders

Hemorrhoids

Hemorrhoids are varicosities of the veins of the rectum. They may be **internal** (inside the sphincter muscles of the anus) or **external** (outside the sphincter muscles) (Figure 29-9).

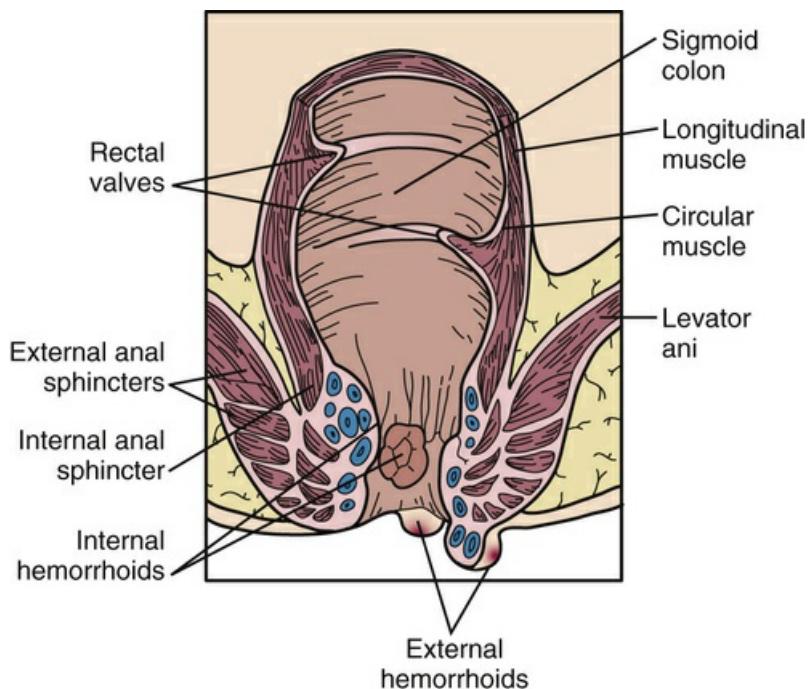

FIGURE 29-9 Hemorrhoids. (From deWit SC, and O'Neill, P.: *Fundamental concepts and skills for nursing*, ed. 4, Philadelphia, 2014, Saunders.)

Etiology and Pathophysiology

Venous congestion from interference with venous return from the hemorrhoidal vessels leads to the development of hemorrhoids. Constipation, obesity, prolonged standing or sitting, and pregnancy are predisposing causes of hemorrhoids. The habit of sitting on the toilet and straining at the stool for long periods is one of the primary factors responsible for many cases of hemorrhoids. Enlargement of the prostate, uterine fibroids, and rectal tumors are other contributing factors. Chronic liver disease with portal hypertension is another cause.

Signs, Symptoms, and Diagnosis

Local pain and itching are the most common symptoms of hemorrhoids. Bleeding from the rectum at the time of defecation may also occur. Hemorrhoidal blood is usually bright to dark red and is located on the outside of the stool. External hemorrhoids are less likely to bleed, but they are more evident, because they appear as tumorlike projections around the rectum. Diagnosis is by physical examination.

Treatment

The symptoms of hemorrhoids may be relieved by correcting constipation, local applications of heat or cold, and sitz baths. The use of ointments that contain a local anesthetic helps relieve the itching and pain. Hydrocortisone ointment and suppositories help decrease the swelling. The patient also should be instructed to wash the anal region with warm water after each bowel movement to prevent infection at the breaks in the mucosa. Wipes not containing alcohol may be used for cleaning without the mucosal drying that soap causes.

Hemorrhoids can be treated by **sclerotherapy** (injection of a solution that causes the vessel to dry up and disintegrate), **cryotherapy** (freezing), **photocoagulation** (burning), or infrared coagulation (IRC). **Hemorrhoidectomy** using a laser or standard surgical procedure may be performed. Another treatment method is rubber band ligation, in which a rubber band is slipped around the hemorrhoidal vessel, cutting off the blood supply. This causes the hemorrhoid to shrivel and disintegrate. All of these methods are usually done as outpatient treatments. Hemorrhoidectomy may occasionally be done as an inpatient procedure.

Nursing Management

Preoperatively, instruct the patient on rectal hygiene and the use of hydrocortisone suppositories or cream and sitz baths to decrease swelling. Teach the patient ways to prevent constipation and to promote regular bowel evacuation.

After surgery, the patient receives a prescription for analgesics. A air-filled or foam pillow may be used while the patient is sitting down to decrease pain and pressure on the rectal area. The patient should not use a ring-shaped device, because it increases stress to the surgical site. Sitz baths are usually ordered three times a day and cold or warm compresses are a comfort measure. Mild, wet nonalcohol dressings also may be used on the surgical site. These dressings have a glycerin base and contain a mild astringent that reduces swelling and relieves pain.

Bowel movements after a hemorrhoidectomy will cause some pain, and the standard procedure is to administer a stool softener to make defecation less traumatic. The patient and family should be warned that the patient may become faint, and someone should stay close by.

A high-fiber diet is started right away, because it is best if formed stool is passed regularly. A sitz bath after each bowel movement will offer relief and also cleanses the affected area, keeping it free from irritation. The patient should continue warm water cleansing after bowel movements until healing is complete.

Pilonidal Sinus (Pilonidal Cyst)

Etiology and Pathophysiology

The word **pilonidal** means "having a nest of hair." A pilonidal sinus is a lesion located in the cleft of the buttocks at the sacrococcygeal region. It is sometimes called a *pilonidal cyst*, but it is believed to be a subcutaneous canal (sinus) with one or more openings into the skin (rather than a true cyst or fluid-filled sac). The condition occurs when the stiff hairs in the sacrococcygeal region irritate and eventually penetrate the soft skin in the cleft of the buttocks. Factors that can lead to development of such a sinus include local injury, improper cleaning of the area, and obesity. People who have more than the average amount of body hair are particularly susceptible.

Signs, Symptoms, and Diagnosis

A pilonidal sinus may cause no trouble until it becomes infected, and then the patient experiences pain in the area, with swelling and a purulent drainage. Diagnosis is by history and examination.

Treatment and Nursing Management

When symptoms are severe or persistent, with abscess formation, the area must be incised surgically and the connecting canals opened and drained. Hairs and necrotic tissue must be removed so the area can heal. This is usually performed as an outpatient surgical procedure. Packing is left in the cavity so drainage can continue.

Postoperative care includes removal of wound packing, cleansing with warm water 2 to 3 times a day, and redressing the wound. Site care continues until the wound has closed. Good hygiene and shaving the site every few weeks may prevent future infections. Antibiotics do not heal a pilonidal cyst.

Anorectal Abscess and Fistula

Etiology and Pathophysiology

An abscess may form where there has been irritation with breaks in the skin or mucosa. Localized infection with a collection of pus forms an anorectal abscess. Tears in the mucosa of the rectum from

hard, constipated stools may predispose to abscess and fistula formation. A fistula is a chronic granulomatous tract that travels in a line from the anal canal to the skin outside the anus, or from an anorectal abscess to the anal canal or the area around the anus.

Signs, Symptoms, and Diagnosis

A discharge of pus from the fistula opening may be the first sign of an abscess or fistula. Both abscess and fistula are painful, and sitting or coughing aggravates the pain. If a fistula is accompanied by diarrhea, Crohn disease is suspected; 50% of patients with Crohn disease develop a rectal fistula. Diagnosis is by history and physical examination.

Treatment and Nursing Management

Antibiotics are usually not administered unless other conditions are present. Medication for pain is prescribed. Incision and drainage of an abscess may be necessary. A fistula usually requires surgical excision and repair. Nursing management involves teaching measures to prevent further incidence of constipation and infection and rectal hygiene measures. Sitz baths are used to decrease inflammation. Education about pain medication and possible complications is provided.

Community Care

Nurses in the community should teach self-care and habits that promote healthy function of the GI system. A healthy diet with appropriate quantities of fiber and fluid, counseling regarding exercise programs, and teaching about the warning signs of colon cancer are all appropriate nursing interventions, to be used whenever possible. Nurses should be a role model for a healthy diet and exercise program to maintain weight within normal limits.

Nurses who work in long-term care facilities and in home settings must be vigilant to spot problems of the GI system. Monitoring nutritional and bowel status is standard practice for every patient. On a continuing basis it is important to assess bowel changes that might indicate colon cancer. Remember that patients who are under care for other disorders still need to have regular cancer screenings.

Get Ready for the NCLEX® Examination!

Key Points

- IBD includes UC and Crohn disease. An altered bowel pattern, abdominal pain with bloating, and diarrhea or constipation are typical. Problems include ulceration, edema, bleeding, and fluid and electrolyte loss. Drug therapy includes antidiarrheals, sulfasalazine, drugs to relieve abdominal cramping, and corticosteroids.
- Surgery for ulcerative colitis usually involves a proctocolectomy with ileostomy, a Kock pouch creation, or an ileoanal reservoir.
- A hernia can become incarcerated, trapping intestine and cutting off its blood supply and causing intestinal obstruction.
- Diverticulitis produces diarrhea or constipation, left lower abdominal pain, fever, and rectal bleeding. Treatment of diverticulitis includes antibiotics, NPO or a liquid diet, IV hydration, and surgical hemicolectomy.
- A high-fiber diet and lots of fluid are prescribed for patients with diverticular disease.
- Mechanical bowel obstruction is mainly caused by adhesions, volvulus, intussusception, and strangulated hernia. Nonmechanical bowel obstruction may be a result of paralytic ileus after surgery, hypokalemia, infection, uremia, or heavy-metal poisoning.
- Appendicitis (inflammation of the appendix) classically causes right lower quadrant pain accompanied by muscle guarding. Nausea and vomiting, a slight temperature elevation, and an increase in the white blood cell count may also occur.
- Peritonitis is an inflammation of the peritoneum. Serous fluid is purulent, and normal peristaltic action slows or ceases.
- Malabsorption in adults is usually from sprue or lactose intolerance, radiation therapy, or chemotherapy. Malabsorption can also occur with IBD or diarrhea when transit through the intestines is too rapid.
- Ulcerative colitis, familial polyposis, smoking, alcohol consumption, obesity, physical inactivity, and a diet high in saturated fat or red meat are risk factors for colon cancer.
- Cancer treatment depends on tumor stage and may include surgery, chemotherapy, and radiation. Abdominoperineal resection is performed for rectal cancer and may include a colostomy.
- An ileostomy drains fecal material from the ileum and is usually performed for IBD problems. Fluid and electrolyte monitoring is crucial when there is an ileostomy.
- The stoma should be a normal pink or red color. Protective powders, sprays, and skin paste and a proper fit of the appliance will help to protect the skin. The opening should be cut $\frac{1}{8}$ -inch larger than the stoma.
- Hemorrhoids are caused by straining at stool for long periods while sitting on the toilet, prolonged standing, prolonged sitting, or pregnancy.
- Anorectal abscess or fistula may be treated with incision and drainage or surgery. Nursing measures include teaching to prevent further constipation and infection.

Review Questions for the NCLEX® Examination

1. A nurse encourages a patient with IBS to keep a food diary. What is the best nursing response to

the patient regarding the importance of keeping the diary?

1. "The diary will monitor caloric intake."
2. "The diary will help identify foods that cause bloating."
3. "The diary will determine food preferences."
4. "The diary will reinforce the need for better food choices."

NCLEX Client Need: Health Promotion and Maintenance

2. A 68-year-old patient complains of mild left lower abdominal pain that is accompanied by frequent diarrhea, slight fever, and rectal bleeding. Which treatment measure should the nurse anticipate?

1. Administration of a bulk-forming stool softener
2. Increasing fluid intake
3. Encouraging solid foods
4. Increasing physical activity

NCLEX Client Need: Basic Care and Comfort

3. A patient admitted with a bowel obstruction is complaining of severe pain, his abdominal girth has increased 4 inches in the past hour, and his blood pressure is now 80/50. List in priority order the actions of the nurse.

1. Assess breathing.
2. Notify the provider.
3. Position to support blood pressure.
4. Ensure IV patency.

NCLEX Client Need: Physiological Adaptation

4. During a home visit, a nurse provides verbal instructions to a patient with a possible blockage of an ostomy. What would be an appropriate instruction for the nurse to give?

1. Massage the stoma.
2. Try different body positions.

3. Take a cold bath.
4. Begin a high-fiber diet.

NCLEX Client Need: Physiological Adaptation

5. A nurse is caring for a patient who is postoperative after an ileostomy. Which order should the nurse question?

1. Strict intake and output recording for 8 hours
2. Clear liquid diet
3. IV fluids 125 mL/hr
4. Occlusive dressing over stoma

NCLEX Client Need: Physiological Adaptation

6. In caring for a patient with an ostomy, which statement is true regarding medication administration?

1. Time-release capsules can be given to patients with an ileostomy.
2. Enteric-coated tablets are adequately absorbed by patients with ileostomy.
3. Glycerin suppositories are readily evacuated in the distal colostomy stoma.
4. An antiemetic suppository can be effectively absorbed when inserted in the distal colostomy stoma.

NCLEX Client Need: Pharmacological Therapies

7. A patient has a new colostomy. Which behavior is an early sign of acceptance in the change of body image?

1. The patient allows the nurse to empty the colostomy bag.
2. The patient refuses to look at the ostomy site.
3. The patient holds and examines a new appliance bag.
4. The patient continues to ask for bedpan to have a bowel

movement.

NCLEX Client Need: Psychosocial Integrity

8. A patient develops a paralytic ileus as a complication of peritonitis. Which patient comment suggests a return of peristalsis?

1. "I feel thirsty; may I have some water?"
2. "I would like to try and walk to the toilet."
3. "When will I be allowed to have solid food?"
4. "I am sorry to pass gas while you are here."

NCLEX Client Need: Reduction of Risk Potential

9. What would be included in the recommended diet for patients with IBD? (*Select all that apply.*)

1. Low fat
2. High fiber
3. High protein
4. Low calorie
5. Lactose avoidance

NCLEX Client Need: Reduction of Risk Potential

10. A nurse admits a 23-year-old patient with possible appendicitis. The nurse anticipates which sign(s) and/or symptom(s)? (*Select all that apply.*)

1. Increased red cell count
2. Abdominal tenderness
3. Anorexia and vomiting
4. Mild fever
5. Dark black stools

NCLEX Client Need: Physiological Adaptation

Critical Thinking Questions

Scenario A

Mrs. Blein, age 29 years, has had frequent bouts of diarrhea associated with physical and emotional stress since her early teens. She is admitted to the hospital with a diagnosis of UC. Her admitting physician, a gastroenterologist, feels certain that she will benefit from an ileostomy, because previous efforts on the part of several other providers have brought no lasting relief from Mrs. Blein's symptoms. She is admitted to the hospital to rehydrate and improve her nutritional status for surgery. Mrs. Blein is 40 pounds underweight and is suffering from severe diarrhea and fluid deficit.

1. What questions would be relevant when taking Mrs. Blein's nursing history?
2. What should be included on Mrs. Blein's nursing care plan regarding observations, measurements, and nursing interventions?
3. Discuss some benefits of an ileostomy over the alternative of continued bouts of severe diarrhea.

Scenario B

Mr. Huang, age 52 years, was found to have occult blood in his stool when he underwent a physical examination for a new insurance policy. Fiberoptic flexible sigmoidoscopy revealed a small lesion in the sigmoid colon; the biopsy result was positive for malignancy. He is scheduled for a hemicolectomy.

1. What are the probable postoperative problem statements/nursing diagnoses that should be on Mr. Huang's care plan?
2. What are the psychosocial concerns that need to be addressed for this patient? What would be appropriate nursing interventions?
3. What further treatment will be necessary for Mr. Huang?

Scenario C

Mr. Frick has a history of diverticulitis. He reports that he has intermittent diarrhea and left lower abdominal discomfort. He is admitted to the hospital for symptoms of nausea, vomiting, and severe abdominal pain and distention. Mr. Frick is diagnosed with peritonitis.

1. What signs or symptoms should you observe for that may signal worsening of his condition?
2. What medical orders do you anticipate from the provider to treat Mr. Frick's peritonitis?
3. Discuss general nursing interventions that would be appropriate for Mr. Frick.

CHAPTER 30

Care of Patients With Disorders of the Gallbladder, Liver, and Pancreas

Objectives

Theory

1. Explain the plan of care for a patient with cholelithiasis.
2. Describe treatment for a patient with cholecystitis.
3. Compare the ways in which the various types of hepatitis can be transmitted.
4. Identify signs and symptoms of the various types of hepatitis.
5. Devise appropriate nursing interventions for a patient with cirrhosis and ascites.
6. Summarize potential causes of liver failure.
7. Differentiate the signs and symptoms of acute and chronic liver failure.
8. Discuss the criteria used for selection of liver transplantation recipients.
9. Devise a nursing care plan for a patient with cancer of the liver.
10. Prepare a plan for adequate pain control for a patient with pancreatitis.
11. Compare the treatment options for cancer of the pancreas.

Clinical Practice

12. Perform preoperative teaching for a patient who is to undergo laparoscopic cholecystectomy.
13. Evaluate a nursing care plan, including psychosocial concerns, for a patient who has hepatitis with jaundice.
14. Implement a discharge teaching plan for a patient who has been in the hospital with a flare-up of chronic pancreatitis.

Disorders of the Gallbladder

Cholelithiasis and Cholecystitis

Etiology

Cholelithiasis is the presence of gallstones within the gallbladder or in the biliary tract. The stones may vary in size, from very small “gravel” to stones as large as golf balls. Tiny stones pass into the bile ducts, where they become lodged and obstruct bile flow (Figure 30-1). When stones lodge in the common bile duct, the patient has **choledocholithiasis**. Cholelithiasis is more likely to occur in people with a sedentary lifestyle, a familial tendency, diabetes mellitus, and obesity. Cholesterol-lowering drugs increase the amount of cholesterol secreted in bile. This cholesterol secretion can increase the risk of gallstones.

Cultural Considerations

Ethnic Predisposition to Gallstones

Native Americans are genetically more prone to develop gallbladder stones than any other group. Hispanic Americans have the next highest propensity to develop gallstones. Teaching dietary changes to decrease the amount of cholesterol and total fat in the diet may be an effective means of decreasing the incidence of gallstones in these populations (National Digestive Diseases Information Clearinghouse, 2013).

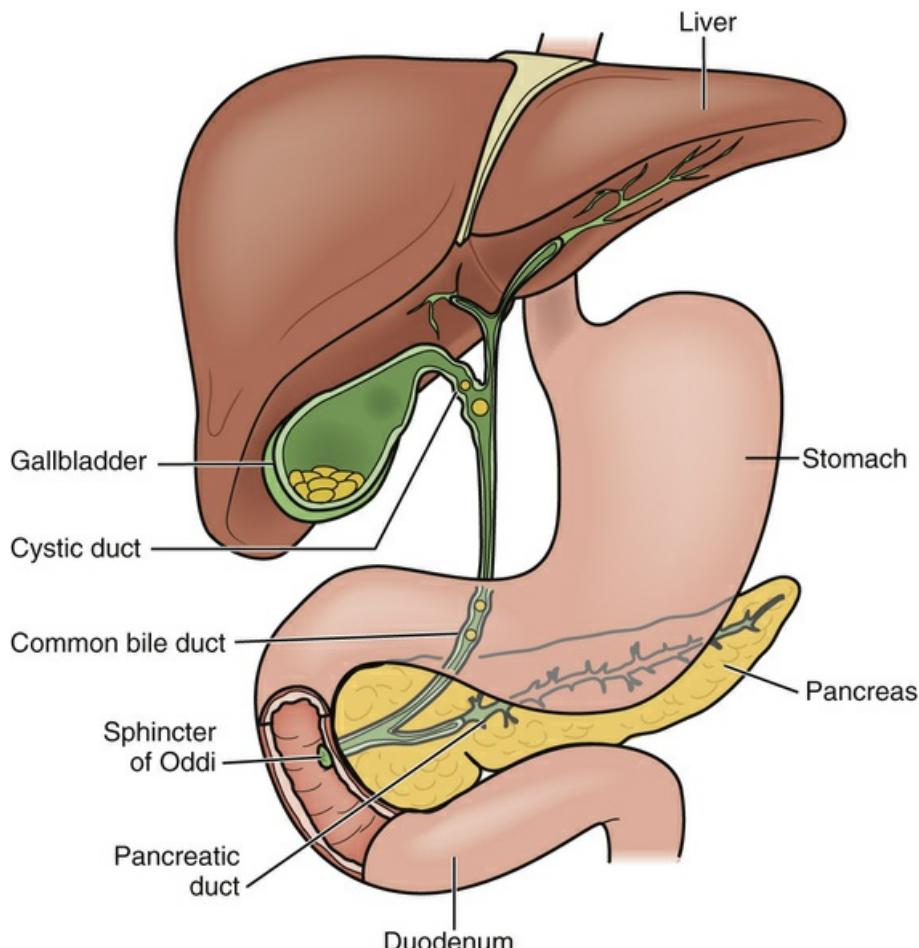

FIGURE 30-1 Gallstones within the gallbladder with obstruction of the common bile and cystic ducts.

Hemolytic disease, extensive resection of the bowel to treat Crohn disease, bariatric surgery, rapid weight loss, multiple pregnancies, and use of oral contraceptives or hormone replacement therapy also increase the risk for gallstones.

Cholecystitis is an inflammation of the gallbladder and is associated with gallstones in 90% to 95% of occurrences. Other causes include obstructive tumors of the biliary tract and severely stressful situations such as cardiac surgery, severe burns, or multiple trauma.

Pathophysiology

Cholelithiasis (gallstones) develops when the balance between cholesterol, bile salts, and calcium in the bile is altered to the point that these substances precipitate. When cholesterol precipitates, the nucleus of a stone can be formed. The stone grows as layers of cholesterol, calcium, or pigment accumulate over the nucleus. Immobility, pregnancy, and obstructive lesions decrease bile flow. Stasis of bile leads to changes in chemical composition and stone formation. The formation of stones within the gallbladder can cause irritation and areas of inflammation in the gallbladder wall (cholecystitis). Infection can occur from organisms such as *Escherichia coli*. The organisms enter the gallbladder through the sphincter of Oddi from adjacent structures.

Signs and Symptoms

Symptoms depend on the degree of obstruction to bile flow and extent of inflammation of the gallbladder. The absence of bile in the intestine results in clay-colored stools that float as a result of undigested fat content. If a duct is obstructed by a stone, obstruction of bile flow by stones in the cystic or common bile duct causes strong muscle contractions that attempt to move the stones along; severe pain may be triggered by a fatty meal. Nausea and vomiting, fever, and leukocytosis occur with cholecystitis. Pain may be referred to the right clavicle, scapula, or shoulder. As bile backs up into the liver and blood, **jaundice** (yellow tint to skin and sclera) occurs. If obstruction is unrelieved, inflammation occurs and can progress to liver damage.

The symptom most often present in an acute flare-up of chronic cholecystitis is unbearable upper right quadrant pain (**biliary colic**). The pain sometimes is referred to the back at the level of the shoulder blades. Attacks can occur as frequently as daily or may only appear once every year or so. Vomiting may accompany acute flare-ups, along with chills and fever. If the inflammation is not corrected or if there is an infection, the gallbladder can become filled with pus and rupture. Rupture spills gallbladder contents into the abdominal cavity and causes peritonitis.

Chronic cholecystitis causes milder symptoms between acute attacks. Symptoms are indigestion after eating fatty foods, flatulence, nausea after eating, and some discomfort in the right upper quadrant. **Table 30-1** compares signs and symptoms of gallbladder disorders.

Think Critically

What questions would you ask when assessing a patient who might have cholecystitis?

Older Adult Care Points

Cholelithiasis should be considered in any older adult with abdominal pain when another cause cannot be found. Symptoms may be atypical, and the presenting symptom of cholecystitis in this age group may be low-grade fever rather than pain.

Table 30-1
Comparison of Gallbladder Disorders

SIGN/SYMPOTM	CHOLELITHIASIS	ACUTE CHOLECYSTITIS	CHRONIC CHOLECYSTITIS
Pain/biliary colic	Sudden onset, acute	Waves of pain lasting 2-6 hr	Intermittent during the year; pain commonly referred to back at shoulder blade
Nausea, vomiting	Often present	Frequent	During acute attack
Indigestion and flatulence	—	—	Common complaint
Low-grade fever	Present	Present, often with chills	Present
Jaundice	If duct is obstructed	May be present	May be present during attack

Diagnosis

Gallstones usually can be diagnosed with ultrasonography or computed tomography (CT) of the

gallbladder and biliary tract. Cholescintigraphy (hepatobiliary iminodiacetic acid [HIDA] scan) diagnoses abnormal contraction of the gallbladder or obstruction. Liver function tests are helpful to diagnose gallbladder and biliary tract disease. Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) will be slightly elevated. If there is common duct obstruction, gamma-glutamyl transpeptidase (GGT) is elevated. In biliary obstruction, both direct bilirubin and alkaline phosphatase levels are elevated.

The diagnosis of cholecystitis is aided by indicators of infection, such as elevated white blood cell count and sedimentation rate.

Treatment

Initially, a low-fat diet, loss of excessive body weight, and restriction of alcohol intake are recommended, and meals are spaced so that no large amounts of food are put into the intestinal tract at any one time. This prevents overstimulation of gallbladder activity. Treatment varies depending on whether or not the patient has symptoms. Medical treatment includes giving oral medications that dissolve the gallstones. If the patient does not respond to this therapy or if bile obstruction occurs, correction of the obstructed biliary tract is indicated. Endoscopic retrograde cholangiopancreatography (ERCP) may be performed to remove stones obstructing the common duct. The procedure combines endoscopy with fluoroscopy to visualize and treat obstructions. Gallbladder removal is indicated for patients with ongoing symptoms or complications. The procedure may be done laparoscopically or as an open abdominal surgery. Antibiotics are usually only given if peritonitis is present or as surgical prophylaxis.

The surgical procedure of choice is **cholecystectomy** (gallbladder removal). Laparoscopic cholecystectomy is the most common surgical procedure used. One to four small incisions are made in the abdomen; abdominal muscles have less trauma from smaller incisions, and the patient experiences less pain and a quicker recovery than with an “open” cholecystectomy. A laparoscope with an attached camera and a dissecting laser are used along with grasping forceps. Carbon dioxide (CO₂) is instilled into the abdominal cavity to aid visualization. The gallbladder is removed through the incision at the umbilicus. The patient will have dressings over the incisions on the abdomen. In the United States 90% of cholecystectomies are performed laparoscopically. Recovery time is shorter for the laparoscopic procedure compared with open procedures.

Monitor the patient closely for internal bleeding and watch for signs of increasing abdominal rigidity and pain and for changes in vital signs. Sometimes the retained CO₂ used during a laparoscopic procedure causes “free air” pain. Early and frequent ambulation helps the CO₂ gas dissipate. The patient is usually discharged after recovering from the anesthesia. Depending on his age and condition, a longer stay may be indicated, and he must have careful discharge teaching about signs of complications.

Patient Teaching

Postoperative Laparoscopic Cholecystectomy

Teach the patient to:

- Remove the bandages from the puncture site(s) the day after surgery and shower, leaving the Steri-Strips intact. They will fall off in 7 to 10 days.
- Report the following signs and symptoms if they occur:
- Redness, swelling, bleeding, or bad smelling drainage from wound site
- No bowel movement or gas for 3 days or watery diarrhea for more than 3 days

- Bile-colored drainage or pus from any surgical site
- Severe abdominal pain that is not relieved by medication or is getting worse
- Nausea, vomiting, chills, or fever greater than 101 °F
- Light-colored stool, dark urine, or yellow tint to the eyes or skin, which may indicate obstruction to the flow of bile
- Resume normal activities gradually.
- Expect that return to work is probable 1 week after surgery.
- Stick to a low-fat diet for several weeks, slowly introducing fattier foods to determine whether they cause unpleasant symptoms.

With an open abdominal cholecystectomy, a 2- to 4-day stay in the hospital is typical, and there is about a 6-week recovery period. Residual stones can lodge in the common duct after cholecystectomy. ERCP is usually used to remove residual stones.

Oral dissolution therapy is available and works best on small cholesterol stones. Ursodiol (Actigall) and chenodiol (Chenix) are prescribed for 6 months to 2 years to dissolve stones. This therapy may be tried in a patient who is a poor surgical risk. Although the medication may dissolve the stones, there is a high incidence of reoccurrence. Lithotripsy, or “shock wave” therapy, is rarely used for gallstones. The procedure involves using sound waves directed through the body to break up the stones. The treatment of choice is gallbladder removal.

Nursing Management

Preoperative care.

Preoperatively, the patient will be kept on nothing-by-mouth (NPO) status. An analgesic may be ordered to decrease pain, and antiemetics are given for nausea. If nausea cannot be controlled with medication, a nasogastric tube may be placed to reduce vomiting.

Clinical Cues

In the recent past, morphine was not used because it was thought to cause spasm of the sphincter of Oddi; however, this is not supported by research ([Bloom, 2014](#)).

Intravenous (IV) fluids are begun to prevent dehydration. Coagulation times are monitored if jaundice is present, and vitamin K, if needed based on international normalized ratio (INR), is administered before surgery to improve clotting ability of the blood. The patient scheduled for gallstone surgery has needs similar to those of any patient having abdominal surgery. Teaching is adapted for the standard procedure or the laparoscopic procedure (see [Chapters 4 and 5](#)).

Postoperative care.

The patient is placed in the semi-Fowler position after he recovers from anesthesia. This position is more comfortable and decreases strain on the sutures. The patient will also be able to take deep breaths and cough more easily in this position.

A patient who has had open gallbladder surgery may have tubes or drains if continuing drainage is expected. In many cases, the surgery was performed to relieve an obstruction to the flow of bile through the bile ducts or to drain purulent material to the outside. The drainage is absorbed by the dressings over the surgical wound. Dressings must be changed often and should be checked frequently for signs of fresh bleeding. Tubes may also exit the surgical wound and drain into a bag,

which needs to be emptied routinely. The drain is left in as long as necessary and is then removed by the surgeon.

When an obstruction of the common bile duct has occurred because of stones or tumors, the surgeon may insert a small T-shaped tube (T-tube) directly into the common bile duct during an open cholecystectomy (Figure 30-2). This tube must be kept patent at all times and is connected to a bedside drainage bag. The length of time the T-tube is left in place varies according to the condition of the patient. Only a small amount of bile will be going to the duodenum. No tension should be put on tubes or drains that have been inserted in the surgical wound. **Dressings must be changed carefully because T-tubes are sutured in place, and if they are accidentally pulled out, the patient must be returned to the operating room and the incision reopened to replace the tube.**

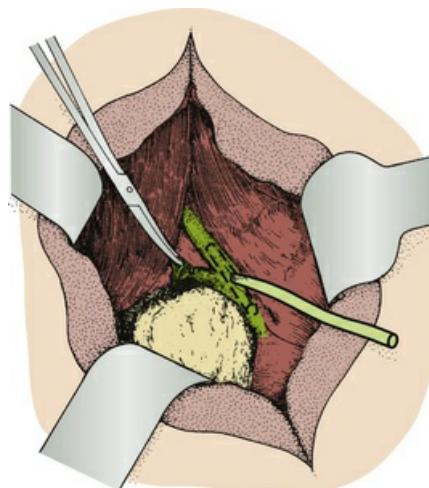

FIGURE 30-2 T-tube inserted into the common bile duct and sutured in place.

The patient should be prepared to expect a greenish yellow discharge (bile) on the dressings. The drainage bag is emptied when the dressing is changed. Patients may go home with the T-tube in place.

Patient Teaching

Caring for a T-Tube

Teach the patient to:

- Wear loose-fitting, older clothes.
- Coil the drainage tubing and secure it to the abdomen with tape.
- Take showers rather than baths.
- Avoid heavy lifting and strenuous activity.
- Carefully change the dressing every day, cleansing the skin around the tube.
- Inspect for signs of infection: redness, swelling, warmth, pain, or pus.
- Take his temperature every day and report to surgeon if it is greater than 100° F (37° C).
- Empty the drainage bag at the same time each day.
- Note the amount, color, and odor of the drainage.
- Report any change in drainage, abdominal pain, nausea, or vomiting to the surgeon.

- Return to the surgeon for the follow-up appointment.

Carefully observe the color of the patient's stools because a return of a normal brown-colored stool is an indication that bile is flowing and entering the small intestine. If the bile duct is obstructed, there will be signs of jaundice and stool will be light in color.

Patients who have had an open cholecystectomy may be reluctant to deep-breathe and cough because of pain in the operative area. Encourage these exercises with the use of an incentive spirometer, and auscultate lung sounds every shift to discover any signs of extra secretions or atelectasis. A patient-controlled analgesia (PCA) pump will help the patient to cooperate with turning, coughing, and ambulating and thus prevent complications.

No specific diet is recommended for patients after gallbladder surgery, although it is wise to avoid excessive amounts of fatty foods.

Think Critically

Can you outline the points to be covered for teaching a patient who is about to undergo a cholecystectomy?

Complications

Constant irritation of the gallbladder from inflammation and infection produce purulent material, and a fistula may form. Necrosis, gangrene, and rupture of the gallbladder causing peritonitis may occur. Choledocholithiasis may cause inflammation of the common duct and obstruct the pancreatic duct. This can lead to pancreatitis.

Disorders of the Liver

The liver becomes inflamed when injured by trauma, toxins, or tumor invasion. Disruption of the normal functions of the liver occurs depending on how much of the liver tissue is affected. Chronic inflammation causes fibrosis of the liver cells and abnormal function.

Hepatitis

Etiology and Pathophysiology

There are five types of viral **hepatitis** (Table 30-2) that cause physical problems. Researchers believed they had discovered a new virus, hepatitis F, but the finding was not confirmed; when a valid discovery was made, hepatitis G emerged. Since its discovery, additional structural information has become known, and the virus has been labeled GBV-C. Liver cells are damaged either by direct action of the virus on hepatocytes or by cell-mediated immune responses to the virus. Hepatitis viruses cause extensive inflammation of the liver tissue. Liver cell damage results in necrosis of hepatic cells. The Kupffer cells proliferate and enlarge. Bile flow may be interrupted because of the inflammation. With severe inflammation, fibrous scar tissue may form in the liver. Scar tissue often obstructs normal blood flow, causing further damage from ischemia.

Table 30-2
Comparison of Hepatitis-Causing Viruses

HEPATITIS A VIRUS (HAV)	HEPATITIS B VIRUS (HBV)	HEPATITIS C VIRUS (HCV)	HEPATITIS D VIRUS (HDV)	HEPATITIS E VIRUS (HEV)
Transmission Mode				
Fecal-to-oral route; poor sanitation and contaminated water and shellfish; often from infected food	Sexual contact; blood and body fluid contact; perinatal from mother to infant	Contact with blood and body fluids; sexual contact with carrier; contact with contaminated surgical, tattooing, and piercing equipment	Blood and body fluid contact; accompanies hepatitis B; close personal contact	Fecal-to-oral route; contaminated water or food
Incubation Period				
15-60 days (average 30 days)	6 wk-6 mo (average 12-14 wk)	6-7 wk	Same as hepatitis B, which precedes it; chronic carriers of hepatitis B are at risk throughout their carrier state	14-60 days (average 40 days)
Infective Period				
Most infectious 2 wk before onset of symptoms; not likely to be infectious after first week following onset of jaundice	Begins before symptoms appear and persists for 4-6 mo after acute illness; persists for lifetime of chronic carriers	Begins 1-2 wk before symptoms appear; continues throughout life for chronic carriers	Blood potentially infectious in active hepatitis B infection; may still be present in blood of chronic hepatitis B carriers even though undetectable	Shedding of virus starts during the incubation period and into the early acute phase of the disease
Signs and Symptoms				
Acute onset Prodromal phase: Malaise, fever, loss of appetite, nausea, fatigue, joint aching, skin rash, and upper abdominal discomfort May develop jaundice; malaise and fatigue	Slow onset May be asymptomatic	Slow onset May be asymptomatic until liver damage has occurred	Slow onset May be asymptomatic	Abdominal pain, anorexia, dark urine, fever, hepatomegaly, jaundice, malaise, nausea and vomiting

Liver cells do have the capacity to regenerate and resume their normal appearance. The cells can function as long as there are no complications or added stressors.

Hepatitis A and hepatitis E viruses are transmitted primarily by the oral-fecal route. They are responsible for the epidemic forms of viral hepatitis. Hepatitis A virus can be transmitted by food handlers to customers or by mollusk shellfish from contaminated waters. Hepatitis E virus infection is primarily seen in less developed countries. It is transmitted through fecal contamination of water.

Hepatitis B, C, and D viruses may cause chronic inflammation and necrosis of liver tissue. A carrier state of hepatitis B, C, or D may occur, and asymptomatic individuals can transmit infection to others. **Hepatitis B and C viruses are transmitted by parenteral routes and sexually; they are present in the semen, vaginal secretions, and saliva of carriers. Sexual partners of patients who are carriers of hepatitis B or C virus are at high risk for contracting the virus.** Hepatitis D virus coexists with hepatitis B or C virus and is transmitted in the same ways.

Intravenous drug use is currently the primary cause of hepatitis C infection; therefore users are a target group for screening and counseling. The virus can also be transmitted by straws used to snort cocaine. Accurate numbers are hard to obtain because many infected individuals are asymptomatic and have not been tested. Since 1992 all blood products have been tested for blood-borne pathogens. Patients who received blood transfusions and clotting factors before that time may have been exposed and may be carriers. Hepatitis B and C viruses can be transmitted from mother to infant. **Hepatitis B and C are the most serious forms of hepatitis, often progressing to chronic hepatitis, cirrhosis, liver cancer, and death.**

Cultural Considerations

Hepatitis B Virus Among Asian Americans

Hepatitis B virus infection is 5 to 12 times more common among Asian Americans than the general U.S. population. It is the leading cause of liver disease and cancer among Asians ([Maxwell et al, 2014](#)). Because of the high number of people who are unaware of their infection, the virus is passed from mother to child and within families.

Older Adult Care Points

Older adults who had several major surgeries and blood transfusions before 1992 are at higher risk for hepatitis B and C. These patients may be carriers of these viruses.

Signs and Symptoms

The clinical signs and symptoms of hepatitis A tend to have an acute onset, whereas in hepatitis B, C, and D the onset is slower and more insidious. There are four phases of hepatitis A. In the first, the **viral replication** phase, individuals will have positive blood tests but display no symptoms. The second is the **prodromal** phase, in which symptoms such as nausea and fatigue and those that would likely be diagnosed as influenza begin (see [Table 30-2](#)).

The third, or **icteric**, phase is characterized by jaundice and lasts 2 to 4 weeks. Urine becomes dark and stools may become light if bile flow is obstructed. Pruritus may occur from the bile pigment deposited in the skin. The liver becomes tender and enlarged.

The fourth phase, the **convalescent** phase, begins when jaundice is disappearing. Convalescence may take 2 to 4 months. Major complaints are malaise and fatigue. Liver enlargement may continue, but if the spleen was enlarged, it returns to normal in this phase.

With chronic hepatitis B and C, patients are likely to be asymptomatic or have symptoms of chronic liver disease. Patients with acute hepatitis B or C could also be asymptomatic. Symptoms include fatigue, nausea, vomiting, poor appetite, right upper quadrant pain, dark urine, and light-colored stools.

Hepatitis D sometimes causes massive destruction of liver cells, liver failure, and death. Hepatitis B and D become chronic in 2% to 10% of infected patients. The patient is then a constant carrier of the virus. There are no currently known signs and symptoms of GBV-C, but many patients also have hepatitis B and/or C virus at the same time. GBV-C is diagnosed by laboratory tests.

Clinical Cues

We often assume that liver disorders are associated with jaundice; however, be aware that viral hepatitis without jaundice (anicteric hepatitis) is two to three times more common than viral hepatitis with jaundice.

Diagnosis

Hepatitis is diagnosed by history, physical examination, and laboratory testing. Serologic assays or enzyme immunoassays (EIAs) detect specific antibodies to the various types of hepatitis. Molecular assays can detect viral nucleic acid. These assays do not measure the severity of disease or indicate prognosis. The genotype assay can be used to predict the response to and duration of therapy. Chronic hepatitis is determined by liver biopsy. Elevations in liver function tests (LFTs) are expected findings ([Table 30-3](#)). Abnormalities in the white blood cell count, platelets, alkaline phosphatase, albumin, and prothrombin time (PT)/international normalized ratio (INR) may also occur depending on the severity of the disease.

Table 30-3
Laboratory Test Findings in Acute Viral Hepatitis

TEST	ABNORMAL FINDINGS
Aspartate aminotransferase (AST)	Elevated in prodromal phase up to 20 times normal; decreases as jaundice subsides
Alanine aminotransferase (ALT)	Elevated in prodromal phase; ALT/AST ratio greater than 1; decreases as jaundice subsides
Gamma-glutamyl transpeptidase (GGT)	Elevated

Bilirubin	Elevated unconjugated (direct) bilirubin
Alkaline phosphatase	Some elevation
Serum albumin	Normal or decreased
Serum bilirubin (total)	Elevated to about 8–15 mg/dL (137–257 μmol/L)
Prothrombin time/international normalized ratio (INR)	Prolonged

Treatment

Hepatitis A is treated by rest and avoidance of any substances, including alcohol, that can cause liver damage. These measures help the liver to regenerate. A well-balanced diet helps liver cells to heal. Four to six small meals a day are tolerated more readily than three larger ones. Sucking on hard candy is recommended and adds to caloric intake. Nausea may be treated with ondansetron (Zofran) or over-the-counter medications. Phenothiazines are not used because of their hepatotoxic effects. Vaccines are available for those at risk for exposure. People who have been exposed to the patient should be notified so they can receive prophylaxis.

For hepatitis B, drug therapy is used to decrease the viral load, thereby decreasing the disease progression ([Table 30-4](#)). Pegylated interferon alpha 2a (Pegasys), entecavir (Baraclude), and tenofovir disoproxil fumarate (Viread) are all available for use in treatment of hepatitis B. Antiviral medications have been used successfully in treatment of acute hepatitis C. Combinations of medications have proved the most effective. Nonpharmaceutical treatment is supportive to enhance the patient's natural defenses and promote healing of the liver. Hydration, sufficient rest, and adequate nutrition are the goals. Medication for nausea may be prescribed to encourage adequate nutrition.

 **Table 30-4**

Drugs Commonly Used to Treat Liver Disorders

CLASSIFICATION	ACTION	NURSING IMPLICATIONS	PATIENT TEACHING
Diuretic			
Potassium-Sparing Diuretics			
Spirostanolactone (Aldactone)	Blocks action of aldosterone in the distal nephron, preventing sodium uptake in exchange for potassium secretion.	It is not necessary to supplement potassium for patients taking this type of diuretic alone.	Avoid foods high in potassium content: bananas, oranges, salt substitutes, dried apricots, and dates.
Amiloride (Midamor)	Potassium is “spared” (not secreted), and sodium is excreted.	Monitor potassium levels.	Alcohol consumption can worsen side effects of the medication.
Eplerenone (Inspra)	Blocks aldosterone.	If administered with ACEIs or ARBs, may increase risk of hyperkalemia.	Can take with or without food. May cause dizziness.
Triamterene (Dyrenium)	Inhibits the reabsorption of sodium in the distal tubule of the kidney.	Sensitive to light. Monitor potassium levels.	Take after a meal with a full glass of water.
Loop Diuretics			
Furosemide (Lasix)	Blocks reabsorption of sodium and chloride in the loop of Henle, promoting water secretion. Promotes powerful diuresis.	Give early in the morning. Monitor potassium levels and supplement potassium as needed. Monitor for hypokalemia, I&O. Weigh patient daily. Assess for hearing loss. Monitor for postural hypotension.	Warn that the drug will cause the need to empty the bladder frequently. Caution regarding dizziness when changing positions.
Bumetanide (Bumex)	Prevents the reabsorption of sodium in the ascending loop of Henle	Monitor potassium. Can produce ototoxicity. Can react with NSAIDs, gentamycin, and digitalis	Do not use if allergic to sulfa medications.
Ethacrynic acid (Edecrin)	Prevents the reabsorption of sodium.	Weigh patient throughout treatment to assess volume loss. Monitor potassium.	Avoid taking within 4 hours of bedtime to avoid getting up to the bathroom during the night.
Torsemide (Demadex)	Increases urinary excretion of sodium, chloride, and water.	Onset of action is within 1 hr and action lasts 6 to 8 hours. Use cautiously in patients with a sulfa allergy.	Report to provider if using aminoglycosides, NSAIDs, or digoxin. Drug interactions may occur.
Laxative: Ammonia Detoxificant			
Lactulose (Cephulac)	Prevents absorption of ammonia in the colon; increases water in the stool.	Assess stool amount and color. Monitor serum ammonia level, electrolytes, and I&O. Assess perineal skin frequently for excoriation from diarrhea.	Advise that this drug is intended to cause bowel evacuation and diarrhea is likely.
Antibiotic			
Neomycin (Mycifradin)	Decreases protein synthesis in bacterial cells, causing bacterial death.	Monitor renal function and hearing.	Explain the purpose of this drug.
Rifaximin (Xifaxan)	Decreases bowel flora. This prevents the breakdown of protein in the GI tract and helps prevent formation of ammonia.	May cause flatulence or headache. Observe for dehydration.	Taken twice per day with food.
Vasoconstrictor			
Vasopressin (Pitressin)	Causes vasoconstriction; stops bleeding of esophageal varices.	Monitor BP and I&O—may cause water retention.	Explain the purpose of the drug.
Vitamins			
Thiamine (vitamin B ₁)	Corrects vitamin B ₁ deficiency that occurs from excessive alcohol use.	Assess thiamine levels.	Explain purpose of the drug.
Vitamin K (AquaMEPHYTON)	Needed for hepatic formation of coagulation factors II, VII, IX, and X.	Monitor prothrombin time and INR.	Explain injection may cause discomfort.
Antiretrovirals			
Lamivudine (Epivir)	Inhibits replication of HBV.	Monitor blood count, viral load, liver functions, amylase, lipase, and triglycerides. Watch for signs of lactic acidosis.	GI complaints and insomnia resolve after 3–4 wk. Drug is not a cure, but will help control symptoms. Notify provider of swollen lymph nodes, fever, malaise, and sore throat. May still pass virus on to others; maintain precautions.
Ribavirin (Rebetol)	Inhibits viral protein synthesis.	Ribavirin is used together with interferon alpha-2a to treat chronic HCV.	Drug may cause fainting or dizziness.
Adefovir dipivoxil (Hepsera)	Prevents DNA replication.	Monitor respiratory status; assess for skin rash.	Report any difficulty breathing or itching, swelling, or redness of the eyes.
Entecavir (Baraclude)	Prevents viral replication.	Monitor renal function.	May cause weakness.
Telbivudine (Tyzeka)	Prevents viral replication.	Monitor renal function and electrolytes.	May cause lactic acidosis and myopathy.

Tenofovir disoproxil fumarate (Viread)	Prevents viral replication.	Monitor renal function and electrolytes.	May cause lactic acidosis and severe hepatomegaly.
Immunomodulator			
Peginterferon alpha-2a (PEG-Intron, Pegasys)	Inhibits viral replication and increases phagocytic action of macrophages, augmenting specific cytotoxicity of lymphocytes.	Perform baseline assessments. Monitor for signs of depression; offer emotional support. Monitor for abdominal pain and bloody diarrhea. Monitor viral load.	Maintain hydration and avoid alcohol. May experience flulike symptoms.
Antimetabolite/Neoplastic Metabolite			
5-Fluorouracil (5-FU) and floxuridine (FUDR)	Antimetabolite that acts during cellular metabolism to prevent cellular division.	Perform baseline assessments with attention to temperature. Monitor blood count.	Avoid crowds and prevent exposure to infection. Promptly report fever, diarrhea, vomiting, bleeding, bruising, or redness and burning of the palms of hands or soles of feet.

BP, Blood pressure; *GI*, gastrointestinal; *HBV*, hepatitis B virus; *HCV*, hepatitis C virus; *I&O*, intake and output; *INR*, international normalized ratio; *NSAID*, nonsteroidal anti-inflammatory drug.

Vaccines are available to provide active immunity against hepatitis A and B. The vaccine for hepatitis A is administered in two doses, 6 months apart. The vaccine for hepatitis B produces immunity in about 95% of vaccinated individuals and is administered in three or four doses for probable lifetime immunity ([Buggs, 2012](#)).

Passive immunity to type A hepatitis can be conferred by the administration of immune globulin (IG). IG is also recommended for those who have been exposed to someone infected with hepatitis B virus who was not immunized against this virus. There is no protective vaccine for hepatitis C virus.

Health Promotion

Healthy People 2020 Goal for Hepatitis B

Hepatitis is an occupational hazard for all people who have direct contact with patients or surgical and diagnostic equipment. Standard Precautions must be observed at all times. All health care personnel should be immunized with the hepatitis B vaccine. These practices will help meet the [Healthy People 2020](#) goal of reducing hepatitis B and the National Patient Safety Goal to reduce the risk of health care-associated infections.

❖Nursing Management

■ Assessment (Data Collection)

Data collection for a patient with hepatitis should include a nursing history of any previous contacts and whether the contacts have been notified and immunized. By law, viral hepatitis must be reported to the state department of public health. **Because the liver detoxifies many chemicals and metabolizes certain drugs, a complete list of recently taken or current medications is essential. It may be necessary to discontinue some drugs that are particularly toxic to the liver** (see [Box 27-1](#)).

Assess for problems related to silent gastrointestinal (GI) bleeding, respiratory distress, and neurologic dysfunction. Mental confusion and coma associated with hepatic encephalopathy occurs from circulating toxins that result from liver failure. **Encephalopathy** is malfunction or disease of the brain.

Focused Assessment

Data Collection for a Patient With a Liver Disorder

Health History

- Have you ever had a parasitic infection?
- Do you have a history of cancer?
- How much alcohol do you drink?
- Do you have a history of hepatitis?
- Have you been exposed to hepatitis?

- What drugs do you take?
- Have you been exposed to pesticides or industrial chemicals? Which ones?
- Has your appetite decreased? Have you had nausea or vomiting?
- Are you more fatigued than usual?
- Have you noticed any fever?
- Have you noticed dark-colored urine?
- Have you had any light or clay-colored stools?
- Have you had excessive gas?
- Have you been bruising easily?
- Has your skin been itchy or made you feel uncomfortable?
- Has your abdomen increased in girth lately?
- Do you have abdominal pain? Where? Can you describe it?
- Have you gained weight recently?
- Do you take dietary supplements?

Physical Assessment

- Inspect the skin for signs of jaundice, scratch marks, and general condition.
- Inspect the sclera and mucous membranes of the mouth for signs of jaundice.
- Gently palpate the abdomen for masses and for liver enlargement.
- Auscultate bowel sounds.
- Measure abdominal girth for a baseline.
- Inspect extremities for signs of edema.
- Check liver function test values and urinalysis for bilirubin presence.

Nursing Diagnosis and Planning

Problem statements specific to hepatitis infection might include:

- Altered nutrition due to anorexia, nausea, and vomiting
- Fatigue due to disease process and malaise
- Pain due to inflamed liver and pruritus
- Insufficient knowledge due to disease process and self-care needed
- Inadequate diversional activity
- Altered body image due to yellow discoloration of skin

Specific NANDA-I diagnoses can be chosen from the NANDA-I list (see inside back cover).

Expected outcomes might be:

- Patient will maintain body weight within normal limits during

illness.

- Patient will verbalize lessened fatigue after rest periods each day.
- Patient will verbalize a decrease in pain after pain medication and comfort measures.
- Patient will verbalize knowledge of disease process and self-care within 2 days.
- Patient will engage in appropriate diversional activities during convalescence.
- Patient will list personal strengths that compensate for altered appearance.

Older Adult Care Points

Older adults are at higher risk for drug-induced hepatitis if they have chronic conditions that require the administration of various drugs that can cause liver damage over a long period of time. With liver inflammation, the liver will not function well, and drug dosages will need to be lowered; otherwise drug toxicity may occur.

Implementation and Evaluation

Nursing interventions include reviewing trends of serum liver enzyme levels and serum bilirubin values. Preventing the spread of infection is a major concern when caring for patients with viral hepatitis. The patient and family will need to be instructed regarding special precautions to prevent the spread of the infection, such as proper handling of body secretions, proper hand hygiene, and limiting contact with others.

Sedatives must be given with caution because a diseased liver cannot detoxify them very well. Alcohol is particularly damaging to the liver and should be avoided for 4 months after recovery from hepatitis.

The convalescence of patients with hepatitis is slow and long. A nutritious diet with supplements is prescribed. A variety of diversional activities that are not physically taxing should be planned, such as a new hobby or learning a new skill, computer games, puzzle books, and movies. Nursing interventions for selected problem statements relevant to patients with hepatitis are found in [Table 30-5](#) and [Table 27-2](#).

Complementary and Alternative Therapies

Promoting Good Liver Function

Several supplements are known to be beneficial to promoting good liver function. *N*-acetylcysteine (NAC), glutathione (GSH), choline, methionine, milk thistle, carnitine, and antioxidants are helpful. NAC promotes detoxification pathways; choline helps prevent deposition of fat in the liver. Carnitine allows fats to be used as energy and alleviates deposition of fat in the liver and elsewhere in the body. The provider should always be consulted before the patient takes supplements.

Table 30-5

Common Problem Statements, Expected Outcomes, and Nursing Interventions for Patients

With Hepatitis

PROBLEM STATEMENT	EXPECTED OUTCOMES	NURSING INTERVENTIONS
Fluid volume deficit due to nausea and vomiting	Patient will cease vomiting within 24 hr. Patient will establish fluid balance within 48 hr as evidenced by moist mucous membranes, good skin turgor, and stable blood pressure.	Administer antiemetics as ordered. Monitor IV infusion site and fluid rate. Encourage clear oral fluids if ordered and tolerated. Monitor electrolyte levels for imbalances. Monitor I&O. Provide mouth care q2h while awake.
Altered nutrition due to nausea, vomiting, and improper diet	Patient will ingest a 1200-calorie diet per day within 7 days after subsidence of acute vomiting. Patient will maintain present weight.	Keep door of room closed to keep odors out. Offer mouth care before meal time. Provide six small meals a day plus small, high-calorie snacks between meals. Weigh daily and record. Keep hard candy at bedside for snacking.
Altered comfort due to jaundice and bile pigments in skin causing itching	Patient will verbalize that itching is decreased.	Assist to bathe with tepid water three times a day. Apply lotion q2h. Provide diversional activities. Teach relaxation techniques.
Insufficient knowledge due to ways in which HBV is transmitted, effects of hepatitis on the body, self-care measures, and measures to prevent transmission to others	Patient will verbalize ways HBV is transmitted, effects on body, self-care measures, and measures to prevent transmission to others before discharge.	Teach ways in which HBV is transmitted: parenteral routes, sexual contact, contact with blood and body fluids. Give explanation in understandable terms of what HBV does to the body. Reinforce teaching regarding self-care measures: hygiene, diet, rest, follow-up. Teach importance of not sharing personal articles (especially razor, toothbrush, etc.) with others. Instruct to inform health care workers of the presence of the virus until tests for it are negative. Inform that sexual partner(s) will need injection of special immune globulin for protection and then immunization.
Disturbed body image due to yellow skin color from jaundice	Patient will demonstrate acceptance of present body image by allowing visitors within 3 days.	Assure that jaundice is not permanent. Allow to ventilate feelings about the illness and present appearance. Encourage verbalization of positive aspects about self. Increase fluid intake to help flush bilirubin from blood during recovery.
Fatigue due to vague flulike symptoms	Patient will verbalize less fatigue before discharge.	Assess current level of energy. Assist with ADLs as needed. Suggest that visitors come when energy level is higher. Cluster care and allow for periods of rest. Help identify activities that require more energy and help patient prioritize accordingly.

ADLs, Activities of daily living; HBV, hepatitis B virus; I&O, intake and output; IV, intravenous.

Prevention

Transmission precautions.

Both feces and blood of patients with hepatitis A contain virus during the **prodromal stage** (infected but asymptomatic) and early symptomatic stage. Consistent use of Standard Precautions will provide protection for health care personnel; the patient and family must use precautions at home.

Hepatitis B and D viruses are rarely transmitted by the fecal-oral route, but it is strongly recommended to be very careful when disposing of a patient's stool. Standard Precautions guidelines must be carefully followed for handling, sterilizing, and disposing of equipment contaminated with blood. Hepatitis viruses are transmitted by sexual contact, so the patient must be educated.

Home Care Considerations

Preventing the Spread of Hepatitis Virus

Hepatitis A

- Notify close contacts so they can obtain immune globulin protection and hepatitis A vaccine.
- Practice extremely good hygiene, washing with warm water and soap (liquid soap is best).
- Wash hands after using the toilet and before eating and after changing diapers.
- Avoid preparing food during the infectious period.
- Use separate bath and hand towels from other members of the family.

- Avoid sharing toothbrushes.
- Use gloves to disinfect the bathroom fixtures with a 10 : 1 bleach solution.
- Refrain from sexual contact until the provider states that the infectious period is over.

Hepatitis B or C

- Avoid sexual contact until there is no chance of transmission of the virus.
- Advise close contacts to obtain hepatitis B vaccine as indicated.
- Avoid sharing razors or toothbrushes because of the chance of blood transmission.

Safety Alert

Hepatitis C

Hepatitis C virus is transmitted by blood and saliva. Standard Precautions and careful handling of all body fluids are recommended. The first line of defense is scrupulous hand hygiene. Wear gloves when handling plasma-containing body fluids and use extreme caution when handling used needles, syringes, and IV tubing. Needle sticks; open wounds; and the mucous membranes of the eyes, nose, and mouth can serve as portals of entry. Dentists, providers, nurses, and other health care workers must be informed of a patient's carrier status.

When a patient with viral hepatitis has been admitted to the hospital, the infection control professional must be notified. It is important to familiarize yourself with the hospital's policies and procedures so that protection for others and follow-up for the infected patient is not overlooked. Infection with hepatitis A in a person who handles food on the job must be reported promptly. The Centers for Disease Control and Prevention (CDC) has published guidelines for the care of patients hospitalized with hepatitis. These same guidelines can be modified for home care to prevent the spread of the infection.

Complications

A small percentage of patients with hepatitis can develop massive necrosis of liver cells that results in acute liver failure. *Acute liver failure* is the preferred term according to the American Association for the Study of Liver Diseases. *Fulminant hepatitis* or *necrosis* and *fulminant hepatic failure* are older terms. The only hope for recovery is a liver transplant; without transplant, death occurs in about 75% of these cases. Symptoms of liver diseases include mental confusion, disorientation, and drowsiness, which indicate hepatic encephalopathy. **Ascites** (abnormal accumulation of serous fluid within the peritoneal cavity) and edema accompany liver failure.

Safety Alert

Subsequent to a CDC warning in 2013, a body building and weight loss supplement marketed as OxyElite Pro was recalled and removed from the market. It was linked to acute liver failure ([FDA, 2013](#)).

Cirrhosis

Etiology

There are approximately 31,000 deaths attributed to chronic liver disease and cirrhosis in the United States annually ([Taylor, 2014](#)). Excessive alcohol ingestion is the leading cause of cirrhosis in the United States, and hepatitis B or C is the second most common cause ([Sood, 2013](#)). **Postnecrotic cirrhosis** is caused by viral hepatitis, toxic substances, parasites, or infection. There are three other types of cirrhosis. **Laënnec cirrhosis**, or **portal cirrhosis**, results from alcoholism. The first change caused by excessive alcohol ingestion is the deposition of fat in the liver cells. This is reversible if

alcohol consumption is halted; otherwise, widespread scar formation occurs. **Biliary cirrhosis** is from chronic biliary obstruction and infection. **Cardiac cirrhosis** results from long-standing, severe right-sided heart failure in patients with cor pulmonale.

Cultural Considerations

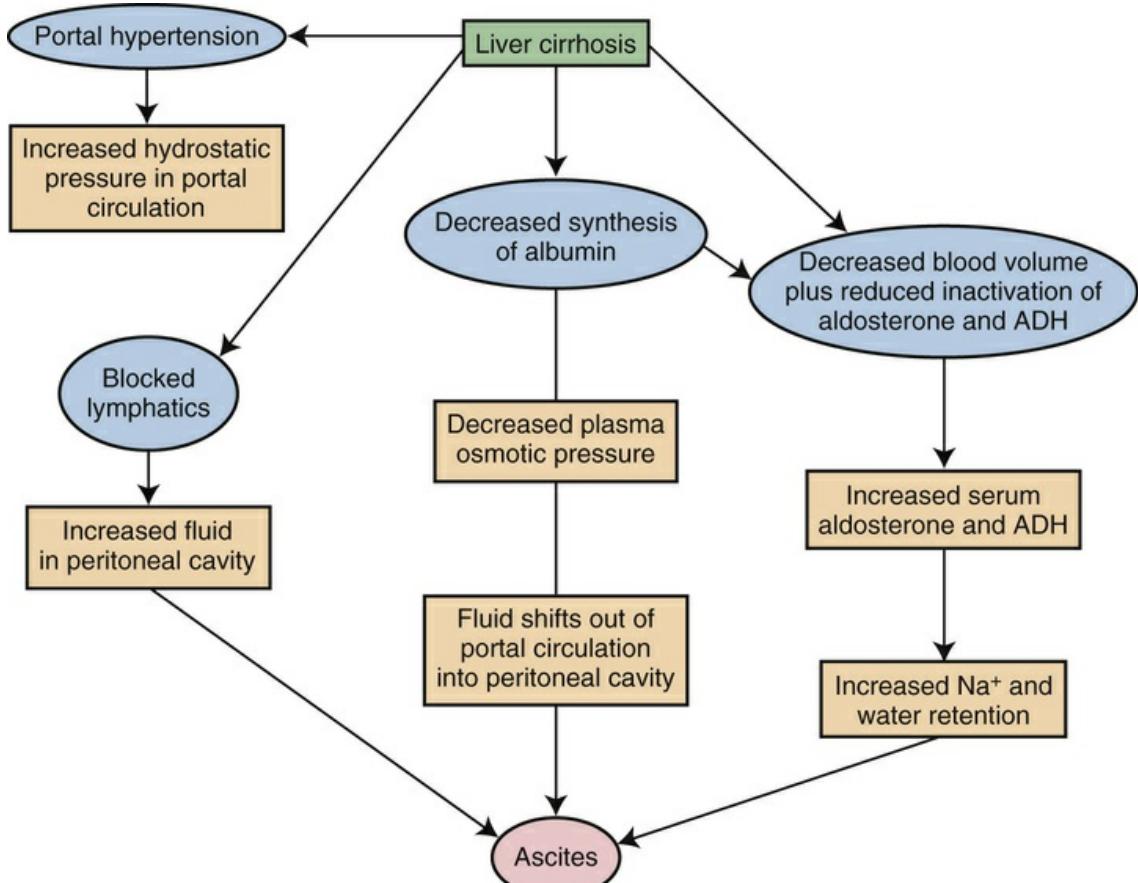

Liver-Related Deaths

Death related to liver disease is not among the top 10 causes of death for the general population; however for the American Indian and Alaska Native population, chronic liver disease and cirrhosis rank fifth as a cause of death, and for the Hispanic population liver disease is the sixth leading cause of death ([Kochanek et al, 2014](#)).

Pathophysiology

Cirrhosis is a progressive, chronic disease of the liver. Normal hepatic structures are destroyed and replaced with necrotic tissue. Fibrous bands of connective tissue develop in the organ, which eventually constrict and partition the liver tissue into irregular nodules. If this process is halted before too much liver tissue is damaged, the liver tissue will regenerate. Late cirrhosis is considered irreversible.

When liver cells begin to degenerate, the blood vessels within the liver also fail to function. This causes an obstruction to the flow of blood through the portal circulatory system, causing portal systemic hypertension. There is altered vessel permeability and fluid leakage into the abdomen, resulting in ascites. As pressure increases in the hepatic veins, there is a shift of protein-rich plasma filtrate into the lymphatic ducts. If the pressure is high enough in the ducts, the excess fluid will ooze from the surface of the liver into the peritoneal cavity. The fluid has a high colloidal pressure because of its high protein content and is not readily reabsorbed. Fluid accumulates in the cavity, causing increased abdominal girth and weight gain. Secondarily, the damaged liver's inability to synthesize albumin and the osmotic pressure within the blood vessels falls, allowing fluid to be pulled out into the tissues. The third mechanism contributing to ascites and edema is excess circulating aldosterone, which is not properly metabolized by the damaged liver. The excess aldosterone causes sodium and water retention ([Concept Map 30-1](#)).

CONCEPT MAP 30-1 Relationship of systemic portal hypertension and ascites in liver cirrhosis. *ADH*, Antidiuretic hormone.

Signs and Symptoms

Cirrhosis usually progresses without symptoms until severe liver damage is present. Subjective symptoms of liver cirrhosis include fatigue, weakness, headache, anorexia, indigestion, abdominal pain, nausea, and vomiting. Fluid retention in the right hemithorax or ascites can limit expansion of the chest and cause dyspnea. Objective symptoms of liver cirrhosis include excessive gas, skin rashes, and fever. Leg and foot edema and **palmar erythema** (redness of the palms that blanches with pressure) occur. Sometimes bluish varicose veins, called **caput medusa**, radiating from the umbilicus (indicating portal hypertension) are seen. Bleeding and bruising because of deficiencies in vitamin K, thrombin, or prothrombin interfere with clot formation. The liver often is enlarged and “knobby” and is palpable below the level of the right rib cage. Abdominal distention is present. The spleen also enlarges. Skin lesions, jaundice, **pruritus** (severe itching of the skin), bleeding disorders, endocrine disorders, and peripheral neuropathy occur in late disease. **Spider angiomas** (abnormal collection of blood vessels under the skin) may appear on the face, neck, upper trunk, and arms.

Urine may become dark and foamy, and stools turn clay colored, which indicates that bile is not reaching the intestine. Jaundice occurs either because the liver cannot metabolize bilirubin or because bile flow is obstructed. Excessively high levels of bile pigment (**bilirubin**) are present in the blood. The pigment is deposited in the skin, mucous membranes, and body fluids, causing a change in color ranging from pale yellow to golden orange. The first signs of jaundice are usually seen in the sclera of the eye (**icterus**), which takes on a yellow tint. Jaundice is not always a sign of liver damage. In **hemolytic jaundice**, there may be an increased level of bilirubin as a result of excessive destruction of red blood cells, with resultant release of the pigment into the bloodstream. Figure 30-3 shows the signs and symptoms of cirrhosis. **Elevations in liver enzymes usually do not occur until 65% of liver function is gone.** The patient is likely to delay seeking medical attention until symptoms are pronounced.

Think Critically

Can you list the ways in which you would collect data when checking a patient for signs of jaundice?

Clinical Cues

In people with dark skin, jaundice is best detected by checking the buccal mucosa, hard palate, palms, soles of the feet, sclera, and conjunctiva.

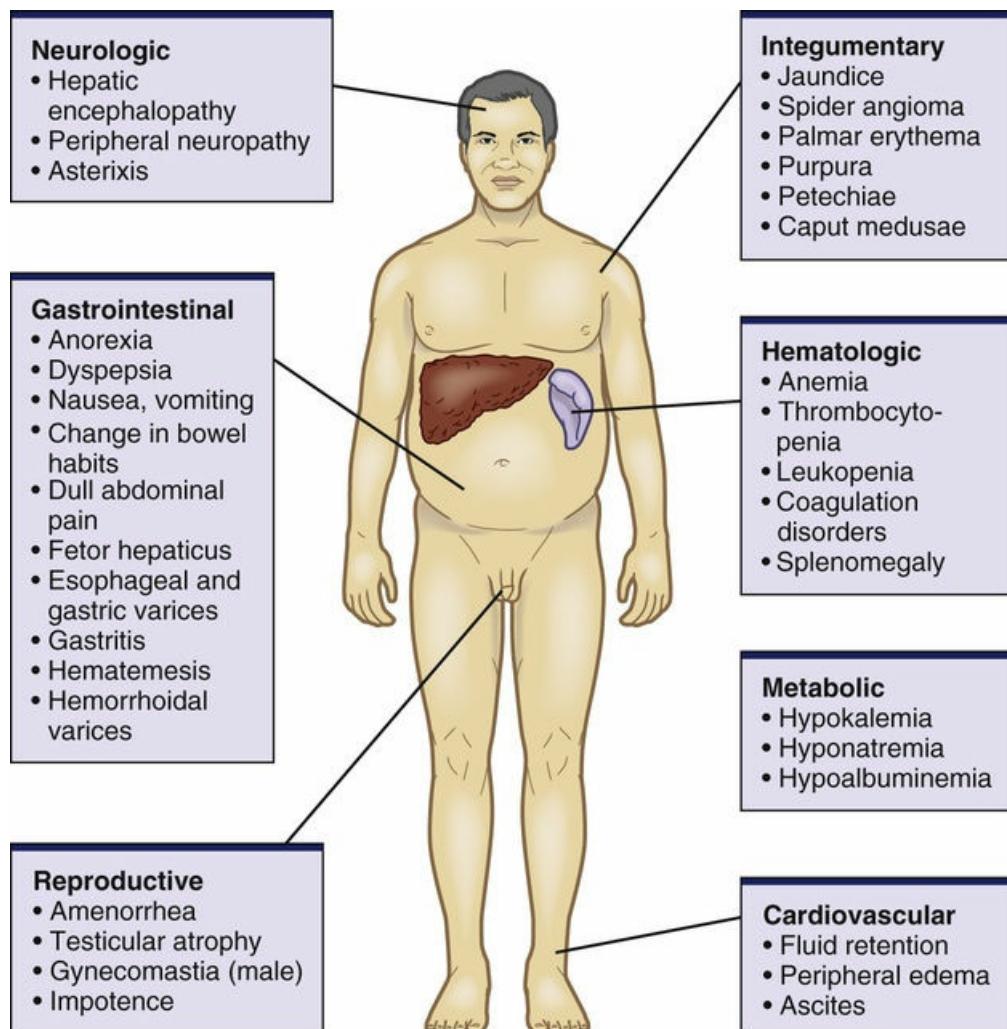

FIGURE 30-3 Signs and symptoms of cirrhosis. (From Lewis SL, Heitkemper MM, Dirksen SR, et al: *Medical-surgical nursing: Assessment and management of clinical problems*, ed. 9, St. Louis, 2014, Mosby.)

Diagnosis

A definitive diagnosis of cirrhosis of the liver is made by liver biopsy. Laboratory testing may show a low albumin level and elevated PT/INR, as well as elevated AST, ALT, ammonia level, and lactate dehydrogenase (LDH) values. CT and liver ultrasound can help determine the size of the liver and presence of any masses and outline the hepatic blood flow and any vascular obstruction. Magnetic resonance cholangiopancreatography—similar to ERCP but without the use of an invasive procedure—may be performed.

Treatment

Treatment is aimed at stopping the liver damage, restoring the liver's functions, and managing the

symptoms. **Medical treatment of ascites includes restriction of fluid and sodium intake and administration of diuretics.** Abdominal **paracentesis** (removal of ascites fluid) can be performed to remove accumulated fluid; however, this is a temporary measure that poses problems of rapid fluid shift, loss of protein, and the potential for introducing infectious organisms into the peritoneum. A transjugular intrahepatic portosystemic shunt (TIPS) may be used to decrease pressure between portal and hepatic veins in the liver and decompress **varices** (abnormally dilated veins). A catheter is inserted into the venous system and threaded to the hepatic vein and then directed to the portal vein. Stents are placed through the liver that extend into both veins, bypassing some of the portal circulation, thereby decreasing pressure. TIPS is performed to decrease risk of bleeding from esophageal varices and reduce accumulation of ascites.

Safety Alert

Liver Inflammation

Patients with liver inflammation or cirrhosis should avoid taking large doses of vitamins and minerals. Vitamin A, iron, and copper can worsen the liver damage.

Traditionally, limitation of dietary protein intake was prescribed; however, this approach is being challenged, and the current recommendation is to manage encephalopathy with medications rather than to restrict protein. Vegetable proteins are preferred because they do not contribute to encephalopathy ([Caruana and Shah, 2011](#)).

Thiamine, zinc, and multiple vitamins are given to counteract vitamin deficiency. Lactulose, an exchange resin, is given orally or by a feeding tube to induce diarrhea and prevent diffusion of ammonia out of the intestinal tract. Ammonia has been believed to be the origin of hepatic encephalopathy; however, many patients with cirrhosis have elevated ammonia levels without symptoms, and patients with significant alteration in level of consciousness have normal ammonia levels. Studies continue ([Wolf, 2013](#)). Kidney failure sometimes accompanies liver failure (hepatorenal syndrome).

Cholesterol-binding medications such as cholestyramine (Questran), colestipol (Colestid), and colesevelam (Welchol) may be given to relieve pruritus from bile pigment deposits in the skin.

Research continues on use of cell-based and non-cell-based liver dialysis therapies to “bridge” patients who are waiting for a liver transplant or to support function while acute failure is resolving. Devices trialed so far have failed to show survival benefit with the therapy. Many patients with acute liver failure have potential for liver regeneration if function can be supported during the healing process ([Maiwall et al, 2014](#)).

Nursing Management

Assessment (Data Collection)

A thorough assessment to identify specific patient care problems related to abnormal liver function is performed (see [Focused Assessment](#)). Assess for safety issues related to change in mental status. The patient may have signs of bleeding. Pay extra attention to ammonia levels, albumin, AST, ALT, and PT/INR results. Increase in ascites is determined by measuring and recording abdominal girth each day. Daily weight checks should also be initiated if fluid retention is observed. If alcoholism is an issue, be vigilant for signs of withdrawal, which may occur 6 to 12 hours after the last drink and can continue for 3 to 5 days (see [Chapter 46](#) for additional information). Be sure to get an order to implement the alcohol withdrawal protocol if indicated.

Nursing Diagnosis, Planning, Implementation, and Evaluation

The intake of alcohol and administration of drugs toxic to the liver must be completely restricted. Sedatives and opiates are either avoided or given with great caution. Rest may be prescribed to aid healing. The degree of rest and activity is dictated by the stage of illness. Nutritional deficiencies are treated with supplements and diet. The patient is at great risk for infection and should be protected from exposure to infectious agents; antibiotics should be given quickly when infection occurs.

Nursing diagnoses, expected outcomes, and interventions for patients with cirrhosis are listed in [Nursing Care Plan 30-1](#) (see also [Table 30-5](#)). Stabilization of fluid balance, normalization of vital

signs, and progress toward baseline mental status and increasing ability to perform activities of daily living (ADLs) independently are indicators that the expected outcomes are being met; if not, new interventions are chosen for the plan.

Think Critically

Can you identify signs and symptoms that you might find when assessing a patient with advanced cirrhosis of the liver?

Nursing Care Plan 30-1

Care of a Patient With Cirrhosis of the Liver

Scenario

A 62-year-old man with a 25-year history of alcoholism is admitted with hepatic encephalopathy caused by progressive alcoholic cirrhosis. His complaints include thirst, extreme fatigue, a swollen abdomen, edema of the feet and ankles, jaundice, itching, shortness of breath, nausea and indigestion, drowsiness, and confusion. Esophageal varices are present. All his liver function test results and his ammonia level show elevation, and his PT and INR are prolonged. His hematocrit, hemoglobin, and serum albumin levels are low.

Problem Statement/Nursing Diagnosis

Actual (or potential for) altered breathing pattern/*Altered gas exchange due to fluid accumulation in the chest (hydrothorax) or abdomen (ascites).*

Supporting Assessment Data

Subjective: "I feel like I can't get my breath."

Objective: Shallow rapid breathing, RR 28-32/min; pauses to catch breath after slight exertion of moving in bed. Pulse oximetry 88% on room air.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will maintain adequate oxygenation as evidenced by respiratory rate of 12-24/min and oxygen saturation of greater than 92%.	Assess rate, rhythm, and quality of respirations and pulse oximeter readings at baseline and after interventions. Place in semi-Fowler position and observe for relief. Auscultate lung fields at the beginning of the shift and as required (PRN) for worsening breath sounds.	Changes in respiratory pattern or pulse oximeter suggest worsening, stabilization, or improvement. Raising head of bed (HOB) usually alleviates dyspnea, but ascites or hydrothorax may restrict chest expansion. Compare findings to your initial assessment to discover changes.	Breathing is shallow and rapid if lying in supine position. If assisted to a sitting position, experiences temporary subjective relief. Pulse oximeter 93% when coached to inhale deeply. Relief obtained with HOB at 30 degrees. Diminished in the bases bilaterally, with fine crackles.
	Administer oxygen as ordered.	Oxygen is generally ordered if saturation falls below 92% (provider may set the parameter higher).	Currently, pulse oximeter shows 93% when awake; however, level drops to 90% when asleep.
	Encourage use of incentive spirometer and teach deep breathing and coughing.	Chest expansion may be limited; therefore patient must be encouraged to make an extra effort to prevent pneumonia and atelectasis.	Willing to try spirometer, but needs continuous reminding. Family members able to help by encouraging him.

Problem Statement/Nursing Diagnosis

Potential for bleeding due to esophageal varices and decreased clotting factors/*Risk for bleeding related to esophageal varices and decreased clotting factors.*

Supporting Assessment Data

Subjective: "Thirsty."

Objective: Elevated liver function test results; cirrhosis, spider angiomas, jaundice, ascites, and prolonged PT/INR.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will not experience life-threatening hemorrhage while hospitalized. Any bleeding will be promptly recognized and reported.	Monitor stool and emesis for blood and other bleeding signs. Feed only soft foods. Give vitamin K as ordered. Monitor vital signs q2-4h as ordered.	Alerts to bleeding. Prevents mechanical irritation of esophagus. Vitamin K is needed for synthesis of clotting factors. Vital sign changes, restlessness, and confusion may indicate bleeding.	No signs of bleeding. Eating soft foods; favors puddings and cooked cereals. Vitamin K administered. BP 120/80, pulse 87/min, RR 24/min; is anxious.

	Observe for increasing restlessness and confusion.	Indicators of hypoxia secondary to bleeding.	Alert and oriented to person and place.
	Monitor PT and INR.	Prolonged clotting times contributes to rapid blood loss.	Laboratory test results pending. Continue plan.

Problem Statement/Nursing Diagnosis

Acute confusion/*Acute confusion due to increased ammonia level caused by liver failure.*

Supporting Assessment Data

Subjective: Confused as to month.

Objective: Elevated serum ammonia and drowsiness.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Serum ammonia levels will not increase further during hospitalization.	Administer oral antibiotics as ordered.	Antibiotics kill intestinal bacteria that help digest protein and produce ammonia.	Administered medication.
Serum ammonia levels will return to normal within 2 mo.	Administer lactulose as ordered.	Lactulose decreases absorption of ammonia.	Lactulose administered; diarrhea occurring. A&D ointment applied to anal area after bowel movements.
	Monitor serum ammonia levels.	Assists in determining likelihood of coma.	Laboratory work to be drawn in A.M. Continue plan.

Problem Statement/Nursing Diagnosis

Potential for injury/*Risk for injury due to confusion, drowsiness, and weakness.*

Supporting Assessment Data

Subjective: "This room looks strange. I can't find the toilet."

Objective: Elevated serum ammonia and slight confusion.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will not experience injury while hospitalized.	Monitor mental status every 2h.	Determines worsening of disorientation.	Oriented to person and place, can recall month with repeated coaching.
	Place call bell within reach and bed at lowest level. Activate bed alarm.	Prevents injury from accidental fall from bed.	Bed down, call bell within reach, alarm activated.
	Offer frequent assistance with toileting and other needs (i.e., hygiene, fluids).	Decreases incidents of wandering or falls if trying to meet own needs.	Offered toileting and mouth care q2-3h. No injury sustained. Continue plan.

Problem Statement/Nursing Diagnosis

Inability to perform self-care due to fatigue, drowsiness and ascites/*Deficient self-care due to fatigue, drowsiness, and ascites.*

Supporting Assessment Data

Subjective: "I'm so sleepy and weak."

Objective: Cannot perform ADLs; very drowsy, ascites present.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will be able to assist with ADLs within 2 wk.	Have patient brush own teeth and wash face. Add in other self-care activities as energy level increases. Allow rest periods between activities.	Gradual increase in activity level allows for patient to participate and build strength.	Patient able to brush teeth, wash face, and wash perineal area.
Patient will be able to perform ADLs independently within 1 mo.	Offer mouth care q2h.	Mouth care improves appetite. Improved nutrition increases energy level.	Mouth care given q2h.
	Assist with meal trays, gradually decreasing assist.	May lack fine motor coordination to open packages.	Set up meal tray. Patient able to unwrap eating utensils and take lids off of liquids.
	Assist with toileting. Gradually decrease assist.	Prevents falls and aids with elimination.	Assisted with toileting. Needed to be steaded upon standing, able to ambulate without assist. Continue plan.

Problem Statement/Nursing Diagnosis

Fluid retention/*Excess fluid volume excess due to ascites and peripheral edema from portal hypertension.*

Supporting Assessment Data

Objective: Ascites, edema of feet and ankles, 6-lb weight gain in 2 days.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will have no further increase in ascites this week.	Measure abdominal girth every shift.	Determines whether ascites is increasing or decreasing.	Abdominal girth down inch.
Patient will return to normal fluid balance within 2 wk.	Administer diuretics as ordered and monitor I&O.	Diuretics remove excess fluid from the body. I&O tracks fluid removal.	Diuretic administered. Intake 400 mL; output 670 mL.
	Weigh daily and record.	Daily weight indicates whether diuretic therapy is effective.	Weight down 1.5 lb.
	Turn at least q1-2h. Provide good skin care.	Turning and skin care prevent pressure sores.	Turned q2h; skin care provided; no reddened or excoriated areas over pressure points. Continue plan.

Critical Thinking Questions

1. Can you describe the correct way to measure abdominal girth?
2. Why is good skin care even more important when a patient has edema and ascites?
3. How high would a PT or INR level have to climb before you would report it to the provider immediately?
4. Why would it be important to monitor this patient for symptoms of alcohol withdrawal?

ADLs, Activities of daily living; *BP*, blood pressure; *I&O*, intake and output; *INR*, international normalized ratio; *PT*, prothrombin time; *RR*, respiration rate.

Complications

Esophageal varices.

Bleeding from **esophageal varices** (dilated, distorted, engorged veins) is a major complication of cirrhosis. They are the result of portal congestion and hypertension. In advanced cirrhosis, blood that normally flows from the intestines to the portal vein and on through the liver is shunted to other veins, including the veins of the upper stomach and lower esophagus. The added load of blood causes congestion of these veins. When the vein walls rupture, massive bleeding occurs. Another factor in hemorrhage is that the liver is no longer able to make vitamin K, which is an essential component of clotting factors. Varices may rupture and produce **hematemesis** (vomiting of bright red blood) from increased blood pressure, coughing, vomiting, or mechanical irritation from poorly chewed food. More than 20% of patients with cirrhosis who have bleeding esophageal varices die within 6 weeks of the first bleed ([Carale, 2014](#)).

Treatment options are administration of parenteral vasopressors such as vasopressin (Pitressin) to lower portal pressure, injection sclerotherapy, or ligation of the bleeding vessels ([Figure 30-4](#)). Surgical intervention is only used when endoscopic treatment or medications have failed to control the bleeding. Vasoconstrictors such as somatostatin (Zecnil) and octreotide (Sandostatin) are used to reduce portal blood flow. A beta blocker may be given to lower blood pressure. The patient is given vitamin K to help rectify clotting factor deficiencies. The treatment of hemorrhage of the upper GI tract is discussed in [Chapter 28](#).

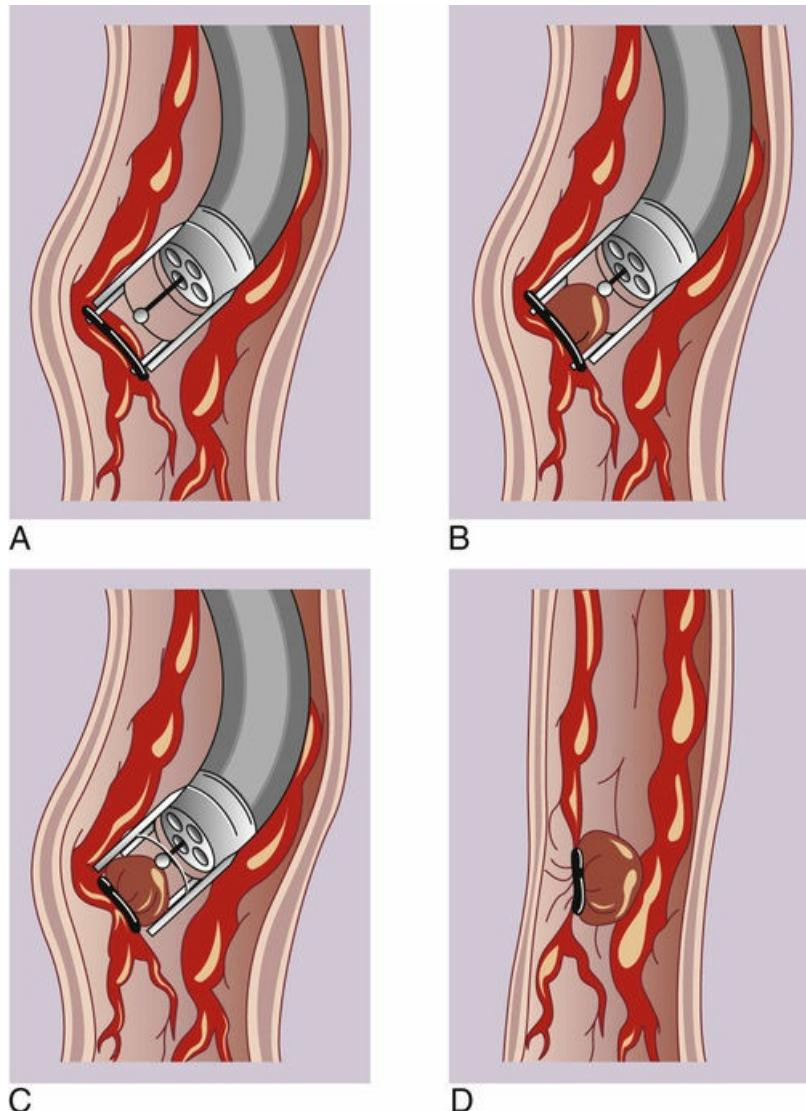

FIGURE 30-4 Treatment for esophageal varices. **A**, Endoscope positioned over varix. **B**, Suction is applied to draw varix toward the endoscope. **C**, Ligation band is deployed around varix. **D**, Band in place.

Encephalopathy.

Portal systemic encephalopathy or hepatic encephalopathy is another dangerous complication of cirrhosis. Encephalopathy in this instance is directly related to liver failure and is believed to be caused by the buildup of ammonia and gamma-aminobutyric acid. Symptoms such as delirium, convulsions, **asterixis** (flapping tremors), and coma occur. Asterixis is identified by having the patient hold out the arms and hands and observing for rapid flexing and extension movements of the hands. There may be rhythmic movements of the legs with dorsiflexion of the foot and rhythmic movements in the face with strong eyelid closure. **Fetor hepaticus** (breath with a sweet, fecal odor) occurs as liver failure progresses.

Liver Transplantation

Liver transplantation is considered for patients with progressive and advanced liver disease that does not respond to treatment. It is most commonly done for nonalcoholic cirrhosis, chronic active hepatitis, sclerosing cholangitis, metabolic disorders, and biliary atresia in children. Some recovered alcoholics with cirrhosis are candidates. Between 70% and 80% of liver transplant recipients survive at least 3 years with good quality of life. Survival rates are 67% at 10 years after transplant (UNOS, 2012). Organ transplantation, tissue matching, and measures to prevent organ rejection are discussed in Chapter 11. If the patient has encephalopathy preoperatively, an intracranial pressure

monitor is placed to assess intracranial pressure (ICP). Every attempt is made to keep ICP within normal limits because increased ICP levels are correlated with decreased survival rates after transplantation.

Nursing Management

After surgery a T-tube and Jackson-Pratt drains will usually be in place. The patient must take cyclosporine for life to prevent rejection of the new liver. Other immunosuppressants such as azathioprine (Imuran), corticosteroids, tacrolimus (Prograf), monoclonal antibody OKT3, and interleukin-2 receptor antagonists such as basiliximab (Simulect) and daclizumab (Zenapax) may also be added. Strict infection control and prevention is necessary, and the patient is monitored closely for signs of hemorrhage or hypovolemia. Measures are instituted to prevent pneumonia, atelectasis, and pleural effusions. Liver function, serum potassium, serum glucose, and coagulation factors are monitored closely. Right quadrant or flank pain, increasing jaundice, fever, and changes in stool and urine color may indicate organ rejection. Close medical supervision is necessary after discharge.

Cancer of the Liver

Etiology

Primary cancer of the liver is rare in the United States but is a common malignancy in Africa and Asia, where it is caused by a parasite called the *liver fluke*. Liver cancer may be triggered by aflatoxin, a mold that grows on spoiled peanuts, corn, and grains. Metastatic liver cancer is much more prevalent than primary liver cancer, but the end result is the same. Cirrhosis and hepatitis B or C increase the risk. Because of an increase in hepatitis C, there has been an increase in hepatocellular carcinoma. Three times as many men as women develop liver cancer.

Pathophysiology

There are two types of primary liver cancer: (1) hepatoma, which arises from the hepatocytes, and (2) cholangiocarcinoma, or bile duct cancer. Benign tumors also occur in the liver. Hepatoma usually develops in people who have cirrhosis. A rare disorder called *hemochromatosis*, which causes deposits of iron in the body, predisposes to the development of hepatoma. The cause of cholangiocarcinoma is unknown, but it occurs more often in people with inflammation of the bowel, such as ulcerative colitis.

Pathophysiologically, there is irritation and inflammation with disruption of the structure of normal liver cells. The cancer spreads throughout the organ and invades the portal vein and lymphatics. It may metastasize to the lungs, brain, kidneys, and spleen.

Signs, Symptoms, and Diagnosis

Symptoms may include right upper quadrant pain, fatigue, anorexia, weight loss, weakness, or fever plus signs of poor liver function. Pain may radiate to the back. Because symptoms often are vague, diagnosis of liver cancer occurs late, and death may occur within 6 to 18 months.

Diagnostic tests are used to determine the presence of tumor and the stage of the cancer and to find areas of metastasis. Fine-needle biopsy or brush biopsy during ERCP gives a definitive diagnosis for bile duct cancer.

Treatment and Nursing Management

If no distant spread is found and there is no lymph node involvement, surgical resection may be attempted. If the tumor is primary and has not metastasized, liver transplantation is an option. Treatment is combined radiation and chemotherapy that is infused intravenously or directly into the hepatic circulation. Commonly used agents are 5-fluorouracil (5-FU), floxuridine (FUDR), doxorubicin, and methotrexate. In chemoembolization, an interventional radiologist cannulates the main artery feeding the tumor and injects chemotherapy agents. The treatment may induce toxic hepatitis, which subsides after the end of therapy. A newer drug, sorafenib (Nexavar), has improved the survival of patients with advanced cancer. Other drugs that inhibit tumor growth by interfering with the blood supply that feeds the tumor are being tested in combination with sorafenib and include bevacizumab (Avastin), erlotinib (Tarceva), and sunitinib (Sutent) ([Axelrod](#),

2012).

Tumor ablation is used for tumors less than 5 cm in diameter. Ethanol or acetic acid is injected through the skin into the tumor. The liquid destroys the cancer cells. The procedure is carried out in the radiology department with the use of ultrasound.

Laser or radiofrequency ablation that uses heat to destroy cancer cells is performed with a local anesthetic. This procedure is used for cholangiocarcinoma. Cryotherapy may be used during surgery; a probe deposits liquid nitrogen to the tumor site. Cancer cells are destroyed by freezing.

Nursing care includes assessing for signs and symptoms of liver failure and blockage in the common bile duct. Additional care is directed at the associated problems, such as ascites and encephalopathy. Surgical care is provided as for other abdominal surgery patients (see [Chapter 5](#)). Care of patients undergoing chemotherapy and radiation for cancer is discussed in [Chapter 8](#).

Disorders of the Pancreas

Acute Pancreatitis

Pancreatitis is an inflammation of the pancreas. It may be acute or chronic. Pancreatitis frequently accompanies obstruction of the pancreatic duct from gallstones or from the backflow of bile into the pancreatic duct.

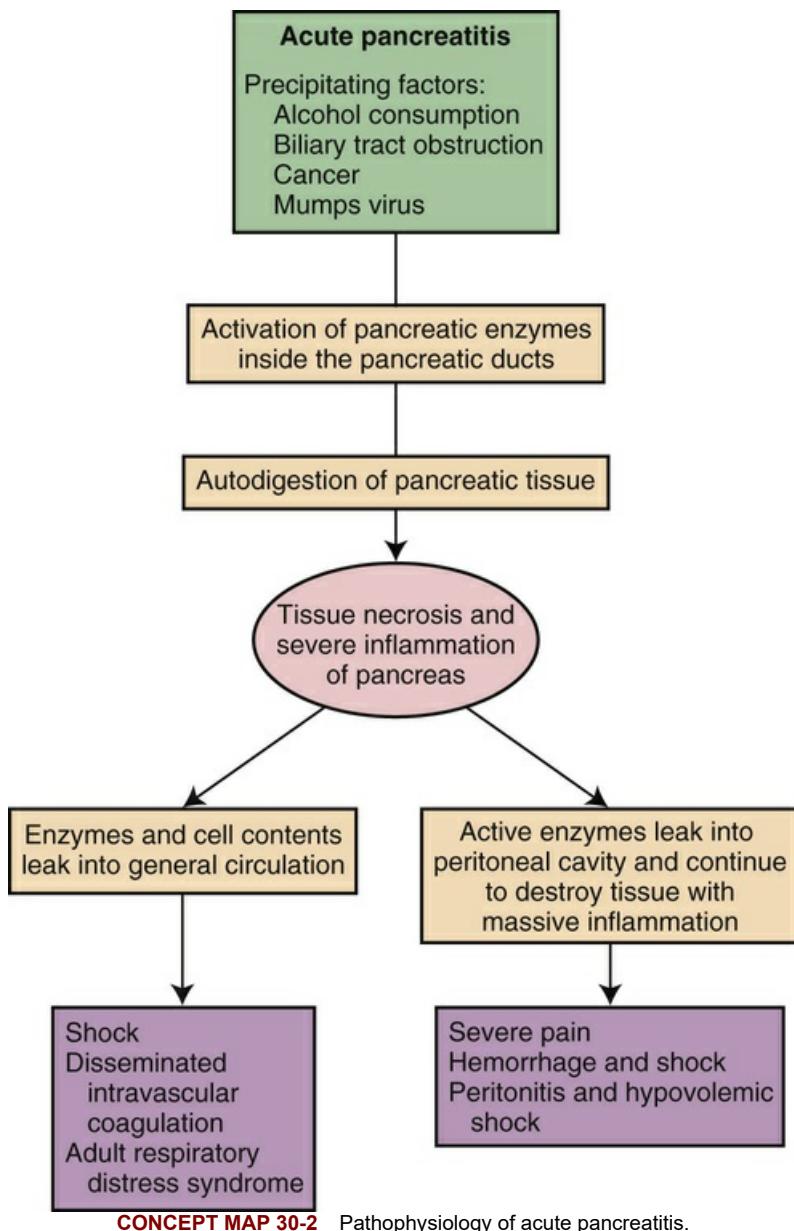

Etiology

Many cases of pancreatitis are related to alcoholism, although it can be caused by biliary disease. Viral infections, trauma, ERCP, penetrating ulcers, drug toxicities, metabolic disorders, scorpion stings, and a variety of other factors can cause pancreatitis. Men tend to develop pancreatitis related to alcohol. In women, it is more commonly associated with gallstones.

Pathophysiology

In some types of pancreatitis, the severe inflammation and damage are caused by escape of pancreatic digestive enzymes. The enzymes act directly on the tissue, causing hemorrhage, autodigestion, and necrosis. It is unclear how the autodigestion is activated. Reflux of bile and duodenal contents into the pancreatic duct is a possible mechanism. A gallstone stuck in the ampulla of Vater can cause edema of the sphincter of Oddi, which might permit reflux of duodenal contents. Alcohol can cause spasm of the sphincter of Oddi, blocking secretion through the pancreatic ducts. This may lead to activation of the pancreatic enzymes within the pancreas.

Pancreatic abscess or pseudocysts may develop. An abscess may form from the purulent liquefaction of the necrotic pancreatic tissue. A **pseudocyst** is a saclike structure that forms on or around the pancreas. It may contain several liters of enzymatic pancreatic exudates. If a pseudocyst ruptures, it may cause hemorrhage. Shock may occur, as may other life-threatening complications ([Concept Map 30-2](#)).

Signs and Symptoms

Pancreatitis causes abdominal pain that is usually acute, but this can vary among individuals. The pain is steady and is localized to the epigastrium or left upper quadrant. As it progresses, it spreads and radiates to the back and flank. Sitting and leaning forward may ease the pain. The severity of the pain may slowly decrease after 24 hours. **Eating makes the pain worse.** Nausea, vomiting, sweating, jaundice, and weakness often accompany pain.

Clinical Cues

A patient with acute pancreatitis may curl up in a tight fetal position (knee-chest) because this opens up the retroperitoneal space and decreases pain. Assuming a supine position for a procedure or assessment is likely to increase the pain; therefore acknowledge the patient's discomfort and help him to resume the position of greatest comfort when the procedure is over.

Examination of the abdomen will reveal tenderness and guarding. If peritonitis is present, there will be distention and rigidity. Bowel sounds may be reduced or absent. A pseudocyst can be palpated as an epigastric mass in about 50% of cases. If retroperitoneal bleeding is present, there

may be bruising in the flanks or a bluish discoloration around the umbilicus. There may be signs and symptoms of respiratory distress (secondary to atelectasis, pleural effusion, or respiratory distress syndrome) or shock, tachycardia, leukocytosis, and fever. Serum amylase may be two times normal and will remain elevated for 72 hours. Serum lipase remains elevated for several days. If biliary obstruction is involved, mild jaundice may be present. Laboratory values will indicate hypoglycemia, hypocalcemia, and hypokalemia.

Diagnosis

Diagnosis is based on the symptoms, risk factors, and results of tests performed to rule out other disorders. An abdominal ultrasound, CT scan, and serum and urine amylase studies are usually ordered.

Treatment and Nursing Management

Pain evaluation and control are primary nursing responsibilities. Vital signs are taken frequently, urinary output is monitored, and the patient is monitored for signs of shock. Observe for signs of restlessness, use of accessory muscles for breathing, irritability, confusion, or dyspnea, which indicate respiratory distress, and administer oxygen as ordered. Monitor laboratory values and note changes. Monitor administration of fluids and observe for electrolyte imbalances. The patient is kept NPO during the acute phase to prevent stimulation of digestive enzymes from the pancreas and further aggravation of the inflammation. Nasogastric intubation with suction may be employed to empty the stomach and duodenum. IV fluids are given until the edema of the pancreas and the pancreatic duct has subsided. If the patient is receiving total parenteral nutrition (TPN), blood glucose needs to be checked regularly, and insulin may be necessary. As soon as pain and nausea are managed, oral feeding with a low-fat solid diet may be provided. Nutritional support is important to healing. Most patients with acute pancreatitis recover after receiving this type of treatment.

Assess for tolerance of the diet as the patient resumes foods. If abscess or pseudocyst are present, they will be surgically drained. Intravenous meperidine or morphine via PCA pump may be needed to control pain. Histamine (H_2)-receptor antagonists or a proton pump inhibitor may be given to decrease the hydrochloric acid secretion that stimulates pancreatic activity. Administration of antispasmodics such as dicyclomine (Bentyl) or propantheline bromide (Pro-Banthine) is helpful.

Clinical Cues

When a powdered form of pancreatic enzymes must be taken, it should be mixed in nonprotein food, such as applesauce. Care must be taken not to let any of the medication remain on the lips or skin because it will cause irritation. Supplementation of pancreatic enzymes is used for chronic pancreatitis.

Think Critically

Your patient with acute pancreatitis has a nasogastric tube in place. The patient says, "I want this tube taken out, and I want to eat." What will you say to the patient?

Chronic Pancreatitis

Etiology and Pathophysiology

Chronic pancreatitis is most commonly seen in men who have been drinking alcohol for many years. Repeated bouts of inflammation cause progressive fibrosis of the gland, stricture of the ducts, and eventual calcification.

Signs and Symptoms

Abdominal pain is the major symptom. There may be periods of acute pain, but chronic pain at intervals of months or years is more common. Other symptoms are related to pancreatic insufficiency as less and less pancreatic tissue is functional. Malabsorption with weight loss and steatorrhea, constipation, mild jaundice with dark urine, and diabetes mellitus develop.

Diagnosis

Determination of bicarbonate, protease, amylase, and lipase concentration and output in the duodenum after stimulation with secretin is a helpful test for chronic pancreatitis. This test is done in conjunction with ERCP. Ultrasound may be utilized via the endoscope. Other helpful diagnostic tests are fecal fat determination, fasting blood glucose, arteriography, and radiographic examinations of the pancreas. Pancreatic cancer or a liver disorder can produce the same results on these tests. The differential diagnosis is difficult. Serum amylase and lipase may be elevated slightly or not at all. There may be increases in serum bilirubin and alkaline phosphatase. Leukocytosis and an elevated sedimentation rate are present. Advanced disease is best identified by CT scan.

Treatment and Nursing Management

Treatment during an acute episode of chronic pancreatitis is the same as for acute pancreatitis. Help your patient by reinforcing information about the disease process and the therapeutic regimen, which will include prescribed pancreatic enzymes to be taken with low-fat meals. Long-term pain control presents problems. The patient is switched to nonnarcotic pain medications to try to prevent addiction, but these are often insufficient for pain control. Complications such as diabetes mellitus must be addressed, and diet requirements and medications should be reviewed with the patient. Chronic pancreatitis interferes with the patient's usual lifestyle and often is accompanied by depression, so your patient should be periodically assessed for signs of depression, and appropriate referrals should be made. A **major nursing action is to be supportive of efforts to abstain from alcohol.** Table 30-6 presents problem statements and specific interventions appropriate for patients with pancreatitis.

Table 30-6

Common Problem Statements, Expected Outcomes, and Nursing Interventions for Patients With Pancreatic Disorders

PROBLEM STATEMENT	EXPECTED OUTCOMES	NURSING INTERVENTIONS
Acute pain due to pancreatic inflammation	Patient's pain level will decrease as measured on the pain scale within 1 hr of instituting nursing measures. Patient will state that pain is controlled within 8 hr.	Medicate with analgesic as ordered. Instruct in use of PCA pump if ordered. Encourage relaxation techniques to decrease discomfort. Assess q2h for adequate pain relief. Administer adjunctive medications as ordered. Assist into knee-chest position for comfort. Maintain NPO status and NG tube for decompression as ordered and explain how these two therapies decrease the pain.
Potential for altered breathing pattern due to irritation or to diaphragm pressure from ascites or pancreatic abscess/pseudocyst	Patient will maintain adequate oxygen levels as evidenced by oxygen saturation within normal limits.	Observe for signs of respiratory distress. Auscultate lungs for crackles or abnormal lung sounds. Monitor oxygen saturation with pulse oximeter. Administer supplemental oxygen as ordered. Encourage use of incentive spirometer as ordered. Place in semi-Fowler's position as tolerated to promote better lung expansion.
Potential for bleeding due to potential autodigestion or rupture of abscess resulting in circulatory collapse	Patient will not experience shock symptoms while hospitalized.	Monitor laboratory values for liver enzymes, ammonia, albumin, sodium, potassium, calcium, and magnesium daily. Observe for subtle changes in mental status. Monitor vital signs closely. Observe stool for signs of bleeding. Monitor urine output. Report frank bleeding promptly.
Insufficient knowledge about pancreatitis and its treatment and prevention of recurrence	Patient will verbalize understanding of disease process within 2 wk.	Instruct in patient-specific causes (i.e., alcohol, ulcer, gallstones) and disease process (i.e., eating triggers digestive enzymes which act directly on the tissues).
	Patient will verbalize understanding of treatment regimen within 1 wk.	Explain all aspects of treatment (e.g., NPO and NG decompression decrease the release of enzymes, and therefore pain is decreased) and reason for each medication (e.g., dicyclomine decreases GI tract spasms).
	Patient will verbalize ways to prevent recurrence of pancreatitis before discharge.	Teach ways to prevent recurrence of pancreatitis (i.e., abstain from alcohol).
Fear due to possibility of disability or death	Patient will verbalize that fear has decreased before discharge.	Establish trusting relationship by attentive, caring attitude. Encourage verbalization of fears; actively listen. Encourage contact with minister, hospital chaplain, or spiritual advisor. Point out any encouraging signs of improvement.

GI, Gastrointestinal; NG, nasogastric; NPO, nothing by mouth; PCA, patient-controlled analgesia.

Cancer of the Pancreas

Etiology

The cause of pancreatic cancer is unknown. It is estimated that 48,960 new cases of cancer of the pancreas and 40,560 deaths will occur in the United States in 2015 (American Cancer Society, 2015). It is more common in men than in women and occurs more often in people older than 55 years. Diets high in red meats and fats may increase the risk. Cancer of the pancreas is often fatal within 1 year. It is usually in an advanced state when discovered because it is asymptomatic in the early stages.

Cultural Considerations

Pancreatic Cancer Deaths

More African American men die of pancreatic cancer than do men from any other ethnic group ([American Cancer Society, 2015a](#)). Alcohol use and abuse is a major factor. Working with community leaders to discourage the immoderate use of alcohol might decrease the problem.

Pathophysiology

Cigarette smoking is the major risk factor for pancreatic cancer; 2 to 3 of every 10 cases are linked to tobacco use. Obesity and dietary factors also contribute to pancreatic cancer. Other risk factors include diabetes and chronic pancreatitis. Adenocarcinoma arising from the epithelial cells in the ducts is the most common form of pancreatic neoplasm. Tumor in the head of the pancreas obstructs biliary and pancreatic flow. Cancer in the body and tail of the pancreas usually remains asymptomatic until it is well advanced and invades the liver, stomach, lymph nodes, or posterior abdominal wall and nerves. Metastasis occurs early. Biliary obstruction usually causes liver failure.

Health Promotion

Smoking Cessation

Most people are aware of the relationship between smoking and lung cancer; however, it is also necessary to teach patients the effects on other vital organs, such as the pancreas. Provide referral to community resources for smoking cessation and written materials with options on how to quit.

Signs and Symptoms

Epigastric pain and weight loss are the main symptoms of pancreatic cancer. Anorexia and vomiting may occur, and the patient may develop a dislike for red meat. When the disease is advanced, jaundice appears along with dark urine and clay-colored stools. There is glucose intolerance. There is a high incidence of clot formation with pancreatic cancer.

Safety Alert

Deep Vein Thrombosis

Because of the increased risk of clot formation in patients with pancreatic cancer, it is important to assess for signs and symptoms of deep vein thrombosis (DVT): pain, heat, or swelling in the calves. One leg may be swollen; measure the calf and ankle and compare to the other leg. Check for signs of pulmonary embolus as well: restlessness, apprehension, chest pain, decreased oxygen saturation, and shortness of breath. Should these signs and symptoms occur, report them to the provider immediately. The Joint Commission's National Quality Core Measures require rigorous prevention of DVT for all patients.

Diagnosis

Diagnosis is made by ultrasonography, imaging techniques, and fine-needle biopsy. Elevated carcinoembryonic antigen levels occur 80% to 90% of the time when pancreatic cancer is present. However, serum beta-human chorionic gonadotropin and carbohydrate antigen (CA) 72-4 are the strongest indicators of pancreatic cancer. The tumor markers CA 19-9 and CA 242 are used to monitor for potential spread or recurrence.

Treatment

High doses of opioid analgesics are usually required to keep the patient comfortable. Drug dependency should not be a concern. Treating or preventing malnutrition is a major goal. Enteral feedings may need to be given into the jejunum (**jejunostomy**). TPN may be needed to provide

adequate nutrition (see [Chapters 3 and 28](#)).

Surgical treatment is appropriate for resectable tumor in about 15% to 20% of patients but has not been highly successful in curing the disease. It provides a 5-year survival rate of less than 5%. Surgery is used mainly to relieve symptoms of obstructive jaundice, severe pain, or other complications. A Whipple procedure, or radical pancreaticoduodenectomy, may be done for cancer of the head of the pancreas. The head of the pancreas, the gallbladder, the duodenum, part of the jejunum, and all or part of the stomach are removed. The spleen may also be removed. The remaining structures are anastomosed to the jejunum. Another option is total pancreatectomy. The patient will usually go to the surgical critical care unit after surgery. Nursing care is the same as for any abdominal surgery, but there are many complications that can occur; vigilance is essential. The patient will need enteral feedings, perhaps for life. A stent may be placed in the pancreatic duct to promote exit of pancreatic secretions and enzymes.

Other treatments include radiofrequency ablation and microwave therapy, which use heat to destroy tissue, and cryosurgery, which uses cold. Embolization therapy can be used to cut off the blood supply to the tumor. Cyberknife treatment—an image-guided radiosurgery that helps target pancreatic tumor without disrupting other tissue—is an option. Intensive external beam radiation therapy may offer pain relief, alleviate duct obstruction, and improve food absorption. Radioactive iodine (^{125}I) seeds may be implanted in combination with systemic or intra-arterial administration of floxuridine.

Gemcitabine (Gemzar) and 5-FU are common for treatment of nonresectable or metastatic tumors ([American Cancer Society, 2015](#)). Outcomes for advanced cases are better when erlotinib is added. A combination of drugs has proven most effective, and other commonly used drugs include irinotecan (Camptosar), docetaxel (Taxotere), capecitabine (Xeloda), oxaliplatin (Eloxatin), and cisplatin (Platinol). Other drugs that may be used include the targeted-therapy drug sunitinib, which blocks the growth signal, and octreotide and lanreotide, which suppress the hormone release from the tumor. Ongoing trials are showing promise in new treatment options.

Nursing Management

Nursing care is geared toward managing the severe pain and managing the side effects of treatment. Postoperatively, observe for hyperglycemia, hemorrhage, bowel obstruction or paralytic ileus, wound infection, and intra-abdominal abscess. Monitor the NG tube for clear, colorless, bile-tinged drainage or frank blood with an increase in output because this may indicate leakage at an anastomosis site. Postoperative care is similar to that for any patient who has had abdominal surgery (see [Chapter 5](#)). [Chapter 8](#) discusses care of patients undergoing chemotherapy or radiation for cancer.

Community Care

Nurses in the community should promote immunization against hepatitis B virus in all persons at risk. Teenagers and adults should be counseled about the possibility of transmission of hepatitis B virus by sexual contact and advised of measures for protection. The hepatitis A vaccine should be recommended for those traveling in areas where this disorder is prevalent and for those at risk of liver problems. Nurses should be aware of policies and procedures for reporting new cases of hepatitis to local health departments. All health care workers should be tested for the presence of hepatitis C virus.

Nurses in extended care facilities should be alert to signs of jaundice in patients. Dark-colored urine is a common early sign of a problem. Cancer and gallstones are both more prevalent in older adults, and when abdominal pain occurs these disorders must be considered. Home care nurses must be particularly alert to the possibility of liver or pancreatic problems caused by medications the patient is taking. Encourage regular laboratory work as recommended when the patient is taking a drug known to be potentially damaging to the liver.

Get Ready for the NCLEX® Examination!

Key Points

- Factors that are associated with cholelithiasis and cholecystitis include hemolytic disease, surgical treatment of Crohn disease, rapid-weight-loss diets or starvation, multiple pregnancies or hormonal replacement therapy, major trauma, burns, and cardiac surgery.
- Signs and symptoms of acute cholecystitis include acute pain, fever, anorexia, nausea and vomiting, dehydration, and mild jaundice.
- Typical symptoms of chronic cholecystitis are indigestion, flatulence, nausea after eating fatty foods, and intermittent pain referred to the back.
- There are five main types of hepatitis: A, B, C, D, and E (see [Table 30-2](#)). Hepatitis is treated by rest, a nutritious low-fat diet, and avoidance of substances that are harmful to the liver (see [Box 27-1](#)).
- Signs and symptoms of liver disorders are fatigue, weakness, anorexia, abdominal pain, nausea and vomiting, skin rashes, itching, fever, dark urine, light-colored stools, peripheral edema, bruising, and jaundice.
- Chronic inflammation causes fibrosis and cirrhosis of the liver cells. Diagnosis of cirrhosis includes liver biopsy, liver function tests, prothrombin time, and albumin levels.
- Bleeding esophageal varices and hepatic encephalopathy are complications of cirrhosis.
- Chemotherapy, radiation, and ablation therapies are used for treatment of liver cancer.
- In acute pancreatitis, inflammation and damage are caused by escape of pancreatic digestive enzymes, causing hemorrhage, autodigestion, and necrosis. Symptoms include acute, steady pain in the epigastrium or left upper quadrant. Serum lipase and amylase are elevated. Treatment consists of pain control, reduction of pancreatic secretions, restoration of fluid and electrolyte balance, and treatment for complications such as shock or diabetes.
- Chronic pancreatitis is related to alcoholism. Long-term pain control is an issue.
- Signs and symptoms of pancreatic cancer are weight loss, anorexia, vomiting, and signs of pancreatic dysfunction. Not smoking reduces the risk of pancreatic cancer by 50%.
- Treatment of pancreatic cancer includes pain management and chemotherapy and radiation, which may improve food absorption, relieve pain, and alleviate duct obstruction.

Review Questions for the NCLEX® Examination

1. Before being discharged to home, a patient with gallbladder disease is given instructions regarding the care of the drain and the T-tube. Which patient statements indicate successful teaching? (*Select all that apply.*)

1. “I must empty the bag at the same time each day.”
2. “Loose-fitting clothes must be worn.”
3. “I will have yellowish skin discoloration the rest of my life.”

4. "Passing brown stools indicates return to normal function."

NCLEX Client Need: Reduction of Risk Potential

2. If the patient has a history of chronic cholecystitis, which comment is cause for greatest concern?

1. "I have back pain at the level of the shoulder blade."

2. "I had nausea after eating a hamburger and fries."

3. "I have generalized abdominal pain and fever."

4. "I have discomfort in the right upper part of my abdomen."

NCLEX Client Need: Physiological Adaptation

3. A nurse is caring for a 57-year-old patient with ascites resulting from liver disease. The nurse anticipates that the provider will use which therapeutic regimen to reduce portal hypertension?

1. Vascular shunting of the portal venous systems

2. Repeated abdominal paracentesis

3. Diet restrictions and nutrient supplementation

4. Fluid replacement therapy

NCLEX Client Need: Reduction of Risk Potential

4. A patient with high levels of serum ammonia asks, "Why do I have to continue taking lactulose?" What is the best response?

1. "It destroys ammonia-producing bacteria in the intestines."

2. "It reduces intestinal absorption of ammonia."

3. "It corrects vitamin B₁ deficiency."

4. "It is used in preparation for a diagnostic test."

NCLEX Client Need: Pharmacological Therapies

5. A nurse is caring for a patient who underwent a recent liver transplantation. The nurse reinforces the teaching related to self-care. Which teaching topics are most important to address before discharge?

1. Reporting of any kind of pain associated with fever and changes in stool color
2. Location and meeting time of local support groups
3. Use of strict hand hygiene in changing dressings
4. The life-long need to take antirejection medications

NCLEX Client Need: Reduction of Risk Potential

6. A nurse is caring for a patient who underwent radical pancreaticoduodenectomy. Which postoperative complication would be the most likely to occur and cause the greatest concern?

1. Hypoglycemia
2. Adhesions
3. Hemorrhage
4. Anorexia

NCLEX Client Need: Reduction of Risk Potential

7. Which instructions should be given to a patient regarding preventing the spread of hepatitis A? (Select all that apply.)

1. Bleach solutions must be used to clean the bathroom.
2. Somebody else should be doing the cooking right now.
3. No vaccination is available for hepatitis A.
4. Good hand hygiene prevents the likelihood of passing the virus.

NCLEX Client Need: Safety and Infection Control

8. A patient has cirrhosis of the liver and ascites. The nurse should question which order?

1. Bed rest with bathroom privileges
2. Discontinue furosemide (Lasix) 80 mg
3. Give 2-g sodium diet

4. Fluid restriction 1500 mL/24 hr

NCLEX Client Need: Pharmacological Therapies

9. A patient with acute pancreatitis has a bluish discoloration around the umbilicus. What actions should the nurse take? (*Place in priority order.*)

1. Place head flat and feet elevated.
2. Notify provider.
3. Assess vital signs.
4. Verify patency of IV line.

NCLEX Client Need: Physiological Adaptation

10. One goal of nursing care for a patient during the acute phase of pancreatitis is reduction of pain. Which nursing interventions help alleviate pain? (*Select all that apply.*)

1. Reinforce use of the PCA pump.
2. Maintain IV fluids as ordered.
3. Provide a bland diet with additional fluids.
4. Administer dicyclomine (Bentyl).
5. Give pancreatic enzymes.
6. Place the patient in a supine position.

NCLEX Client Need: Physiological Adaptation

Critical Thinking Questions

Scenario A

Mr. Moser is admitted to the hospital with a diagnosis of cirrhosis of the liver. He is 59 years old and has been hospitalized several times for his condition. He has shortness of breath as a result of a swollen and enlarged abdomen, is anemic because of minimal but constant esophageal bleeding, and appears jaundiced. He has severe abrasions on his arms, legs, and abdomen from repeated scratching to relieve his pruritus. Mr. Moser is very depressed and will not converse with you when you enter his room with his breakfast tray the first morning you are assigned to his care. He refuses to eat and indicates his attitude by pushing the tray away and turning on his side to face the wall.

1. What nursing measures might help relieve some of Mr. Moser's problems?
2. Why do you think he is mentally depressed?

3. How would you go about helping him emotionally?
4. What special observations must you make while caring for Mr. Moser?
5. How would you explain a paracentesis to Mr. Moser if one were ordered for him?

Scenario B

Mrs. Lincoln, age 46 years, is admitted to the hospital for a laparoscopic cholecystectomy. She is extremely obese and enjoys eating rich, fatty foods, even though she knows this will add to her obesity and precipitate attacks of cholecystitis. You are assigned to care for Mrs. Lincoln when she returns from surgery.

1. How will you position this patient?
2. What would you need to assess to determine whether complications are occurring?
3. What would you need to teach the patient and family before discharge?
4. What problems might occur after discharge? What should be the diet for Mrs. Lincoln?
5. How soon will Mrs. Lincoln probably be able to resume most of her usual activities?

Scenario C

You are working in an employee health clinic and taking a health history from Mr. Austin, who is 52 years old. He reports that he has chronic pancreatitis.

1. What physical signs and symptoms should you ask about?
2. What questions should you ask about diet and lifestyle?

UNIT X

Musculoskeletal System

OUTLINE

Chapter 31 The Musculoskeletal System

Chapter 32 Care of Patients With Musculoskeletal and Connective Tissue Disorders

CHAPTER 31

The Musculoskeletal System

Objectives

Theory

1. Describe the normal anatomy of the musculoskeletal system.
2. Show how the musculoskeletal system provides the function of movement.
3. Discuss how the musculoskeletal system provides protection for the body.
4. Illustrate causes of disorders of the musculoskeletal system and ways to prevent them.
5. Compare the procedure and nursing care for the following diagnostic tests: bone scan, arthroscopy, electromyography.
6. Distinguish ways in which older adults can increase musculoskeletal strength and protect bones.

Clinical Practice

7. Perform an assessment on a patient with a musculoskeletal disorder.
8. Assist in the development of a nursing care plan for a patient with a musculoskeletal disorder.
9. Use measures to reduce the chance of contracture for patients with musculoskeletal injuries.
10. Assist patients with musculoskeletal injuries with active or passive range of motion.
11. Provide care for a patient who has undergone magnetic resonance imaging (MRI) with contrast.
12. Teach a patient to properly use an assistive device.

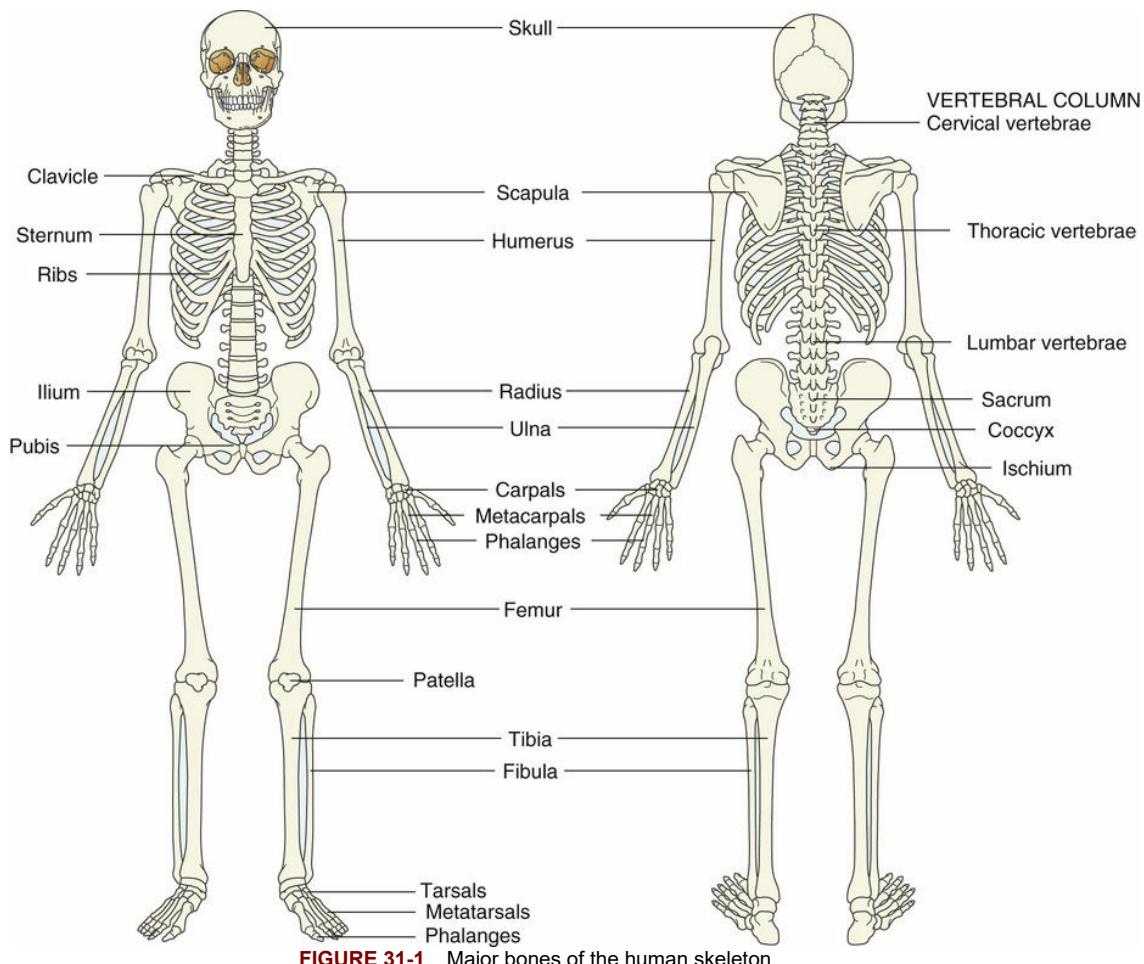

KEY TERMS

- ankylosis** (ăng-kĭ-LŌ-sĭs, p. 732)
- cartilage** (KĂR-tĭ-lăzh, p. 719)
- contractures** (kōn-TRĀK-chûrz, p. 732)
- crepitation** (KRĒP-ĕ-tā-shŭn, p. 721)
- isometric exercises** (ī-sō-MĒT-riks, p. 729)
- kyphosis** (kī-PHŌ-sĭs, p. 726)
- ligaments** (LĬG-ă-mĕnts, p. 719)
- orthopedic** (ör-thō-PĒ-dik, p. 721)
- ossification** (ös-ĕ-fi-KĀ-shŭn, p. 721)
- tendons** (TĚN-dōnz, p. 719)

Anatomy and Physiology of the Musculoskeletal System

Structures of the Musculoskeletal System

- The musculoskeletal system consists of the bones, joints, cartilage, ligaments, tendons, and muscles.
- There are two distinct groups of bone cells; those that are transformed into mature cells and those bone cells that form cartilage first, and then are gradually replaced by mature bone cells as the person grows older.
- A total of 206 bones make up the human skeleton ([Figure 31-1](#)).

- Bone is either compact or spongy. Spongy bone contains red bone marrow ([Figure 31-2](#)).

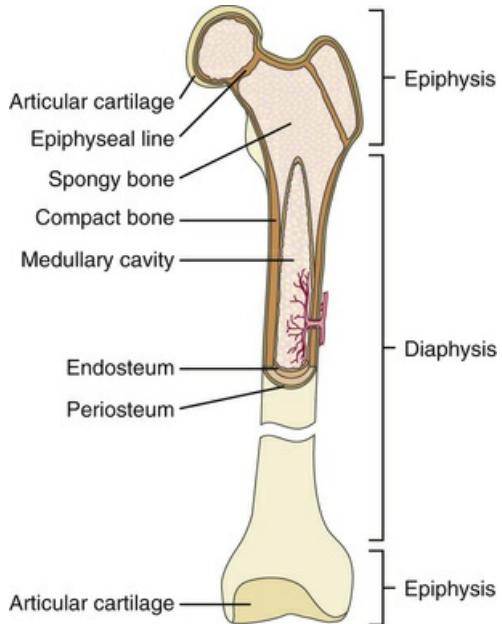

FIGURE 31-2 General features of long bones. (From Black JM, Hawks JH: *Medical-surgical nursing: Clinical management for positive outcomes*, ed. 8, Philadelphia, 2009, Saunders.)

- Bones are classified as long, short, flat, or irregular.
- Each bone has markings on its surface that make it unique (see Table on Evolve[®]).
- The haversian system is a canal system that runs through the bone and contains the blood and lymph vessels.
- A joint is the articulation point between two or more bones of the skeleton. There are immovable, slightly movable, and freely movable joints ([Table 31-1](#)).

Table 31-1
Types of Moveable Joints and Examples

TYPE OF JOINT	EXAMPLE	MOVEMENT
Hinge	Elbow	Bidirectional to flex and extend
Pivot	Head of radius around ulna	Rotational to supinate and pronate
Saddle	Thumb	Circular clockwise and counterclockwise
Ball and socket	Shoulder and hip joints	Ball rotates within socket and moves up and down
Condyloid	Head to neck joint	Up and down and side to side
Gliding	Articulating surfaces of vertebrae	Lateral and up and down

- **Ligaments** join the bones of a joint together.
- **Tendons** are connective tissues that provide joint movement.
- **Cartilage** is a type of connective tissue in which fibers and cells are embedded in a semisolid gel material. Cartilage acts as a cushion. The meniscus in the knee joint is a type of cartilage.
- A bursa is a fluid-filled sac that provides cushioning at friction points in a freely movable joint.
- Skeletal muscle is made up of hundreds of muscle fibers bundled together and surrounded by a connective tissue sheath.
- Fascia is a connective tissue that surrounds and separates the muscles.
- The muscle coverings contain blood vessels and nerves.
- Muscle has properties that allow it to be electrically excited; cause it to contract, extend, or stretch; and provide elasticity.
- Skeletal muscles are attached to bones by tendons.

Functions of the Bones

- Bones provide shape to the body.
- The skeleton provides a rigid framework that supports the internal organs and the skin.

- The skeleton protects the internal organs of the body.
- The skeleton provides attachments for tendons and ligaments and contributes to movement of the body.
- The red bone marrow in the spongy bones forms red blood cells, white blood cells, and platelets.
- The bones store and release minerals, such as calcium and phosphorus.
- The blood and lymph vessels in the canals transport nutrients to the bone cells and remove wastes.
- Bone is maintained by remodeling: existing bone is resorbed into the body and new bone is built by osteoblasts to replace it.

Functions of the Muscles

- Contraction of skeletal muscles is produced by synchronized contraction of many muscle fibers.
- Skeletal muscles contract, thereby providing movement and joint stability, maintaining posture, and producing body heat.
- By shortening and stretching, opposing muscle groups provide movement of the joints.

Aging-Related Changes in the Musculoskeletal System

- **Ossification**, or replacement of cartilage by more solid bony tissue, is not completed throughout the body until age 20 to 25 years.
- Bone density decreases in older adults because of the resorption of minerals.
- The loss of bone mass, or osteoporosis, occurs with aging and is more severe in women.
- The bones of older adults are brittle and less compact; thus they break easily.
- The bones of older adults do not heal readily after a fracture because the physiologic exchange of minerals decreases with advancing age, making the process of repair much slower.
- Thinning of the intervertebral cartilage and collapse of the vertebra result in kyphosis (dowager's hump). This is partially responsible for the decrease in height in older adults.
- Joint cartilage thins and erodes from years of use and results in stiffness and **crepitus** (a grating sound) of the joints.
- Joint motion may decrease, limiting mobility; swelling may occur.
- Ligaments become calcified and lose their elasticity.
- Older adults have a decrease in muscle mass; cells decrease in number and the muscles atrophy. Consequently, older adults have less strength and endurance than younger people.
- Tendons shrink and become sclerotic, slowing muscle movement.
- Muscle cramping, especially at night, increases because of impaired circulation and accumulation of metabolic wastes.

Musculoskeletal Disorders

Causes

Disease, trauma, malnutrition, and aging all contribute to musculoskeletal problems. Trauma may cause bruising, strain, sprain, or fracture. Poor nutrition may deprive the body of sufficient calcium and phosphorus to build strong bones. Inadequate protein intake can cause muscle wasting. Malignant tumors place a large nutritional demand on the body, and nutritional imbalances may occur that cause muscle wasting. Tumor may invade bone as either a primary or metastatic cancer. The decrease in estrogen production after menopause in women is believed to be a contributing factor to the occurrence of osteoporosis.

Prevention

Preservation of motion and mobility are important to prevent long-term **orthopedic** (refers to the function and structure of the musculoskeletal system) disability. Weight-bearing exercise throughout life is needed to maintain bone mass and can decrease the incidence of osteoporosis and increase muscle strength, mass, agility, balance, and coordination, thereby preventing falls and consequent fractures. A *Healthy People 2020* objective is to reduce hospitalizations related to osteoporosis-related hip fractures.

Complementary and Alternative Therapies

Benefits of Tai Chi

Research in older community-dwelling adults has shown that tai chi has beneficial effects for increasing mobility, strength, balance, and flexibility ([Malone, 2013](#)).

Lifting and moving objects correctly using large muscle groups helps prevent muscle strain and sprains. Seat belt use in an automobile reduces the incidence of trauma to bone and muscle during accidents. Wearing bicycle, motorcycle, and other sports helmets reduces the incidence of skull fractures. Consuming recommended amounts of calcium throughout the life span, obtaining sufficient vitamin D from sunshine or supplements, and maintaining adequate protein intake all help build healthy bone and muscle ([Dugdale, 2012](#)). Refraining from using steroids on a long-term basis helps prevent osteoporosis and fractures.

Nutrition Considerations

Nutrition for Bone Growth and Density

Adequate amounts of calcium and phosphorus are essential for bone growth and density. Although green vegetables are a source of calcium, that calcium is not readily absorbed. Dairy products such as cheese, yogurt, and milk are better choices. Nondairy sources of calcium include canned sardines, salmon, tofu, figs, and dried apricots. Magnesium and vitamin K are required for healthy bones as well. These are provided by a healthy diet containing meat and green vegetables, such as spinach.

Health Promotion

Smoking and Musculoskeletal Health

Smoking has a significant effect on the bones and joints; smoking:

- Increases the risk of developing osteoporosis

- Increases the risk of a hip fracture with advancing age
- Increases the risk of developing exercise-related injuries
- Has a detrimental effect on fracture and wound healing
- Has a detrimental effect on athletic performance
- Is associated with low back pain and rheumatoid arthritis

Data from American Association of Orthopedic Surgeons, 2015.

Think Critically

What could you do now to promote healthy bones during your later years?

Diagnostic Tests and Procedures

Laboratory blood tests are performed on the minerals needed for bone growth (calcium and phosphorus), to detect bone disorders such as bone metastasis (alkaline phosphatase), detect muscle damage (creatine phosphokinase [CPK]), detect gout (uric acid), or to diagnose rheumatoid arthritis or other connective tissue diseases (Table 31-2). Specific diagnostic tests of the musculoskeletal system are listed in Table 31-3.

Clinical Cues

Diagnostic tests for musculoskeletal disorders (and other disorders) often use contrast media or radiation. Before diagnostic testing, all patients should be assessed for allergies, and women of childbearing age may need a pregnancy test.

Table 31-2
Laboratory Blood Tests for Musculoskeletal Disorders

TEST	NORMAL VALUE	ABNORMAL SIGNIFICANCE
Calcium	8.4-10.6 mg/dL 2.0-2.65 mmol/L	Elevated in extended immobilization and metastatic bone disease.
Phosphate (phosphorus)	3.0-4.5 mg/dL 1.0-1.5 mmol/L	Elevated when calcium level is high.
Alkaline phosphatase (ALP)	35-150 U/L	Elevation may indicate Paget disease or bone metastasis.
Creatine kinase (CK)	Male: 55-170 U/L Female: 30-135 U/L Isoenzymes ≤5% of total CK activity	Elevated levels of CPK isoenzymes may indicate muscle damage.
Myoglobin	<90 mcg/L	Elevation indicates muscle damage such as from trauma.
Uric acid	Male: 4.0-8.5 mg/dL 0.24-0.51 mmol/L Female: 2.7-7.3 mg/dL 0.16-0.43 mmol/L	Elevation indicates presence of gout.
Rheumatoid factor (RF)	<1 : 120 titer	>1 : 160 titer may indicate rheumatoid arthritis.
Antinuclear antibodies (ANA)	<1 : 40 dilution	Elevation may indicate rheumatoid arthritis or other autoimmune disease.

Table 31-3
Diagnostic Tests and Procedures for Musculoskeletal Disorders

TEST	PURPOSE	DESCRIPTION	NURSING IMPLICATIONS
X-ray films of the bones or joints	To detect fracture, avulsion, joint damage	Part to be x-rayed is positioned by technician, and x-ray films are taken.	Assess for pregnancy before testing.
Computed tomography (CT)	To detect musculoskeletal problems, especially of the spine and skull	The patient is placed on a hard table and the part to be studied is positioned inside the machine; the procedure takes 30-60 min. Contrast material may be used. There is a clicking sound as the machine rotates to take the next view. A computer enhances the radiographic findings.	Patient must lie very still. Assess for allergies to contrast media.
Magnetic resonance imaging (MRI)	To diagnose musculoskeletal disorders	Magnetic fields and radio waves are used to visualize tissue densities by the density of hydrogen ions. Computer enhancement depicts normal and abnormal tissue.	There must be no metal on the body and no metal implants because of the strong magnetic fields used. The patient must lie still for 15-60 min.
Dual energy x-ray absorptiometry (DEXA)	To measure bone density of spine, hip, femur, or forearm To monitor changes in bone density and to diagnose metabolic bone disease	Uses minimal radiation exposure. Patient will lie supine on the imaging table with the legs supported. The scintillator camera is passed over the patient and projected onto a computer screen.	Height is measured. All metallic objects must be removed. Test takes about 30 min.
Bone scan	To detect tumor, metastatic growths, bone injury, or degenerative bone disease	An IV injection or oral dose of a radioisotope is given, and after a specified time for the substance to be taken up by the bone, the area is scanned by scintillation camera.	Check for allergies and pregnancy. Patient will be asked to lie quietly for 30-60 min during the scanning. All metal must be removed from the area to be scanned. Ensure patient that she will not be "radioactive."

Gallium/thallium scans	To detect bone problems, especially tumor invasion	The radioisotope gallium citrate (GA-70) or thallium-201 is administered 1-2 days before the scan.	The isotope is eliminated from the body in 6-24 hr. The procedure takes 30-60 min, during which lying still is required; sedation may be given.
Arthrography (arthrogram)	To provide radiographic pictures of a joint showing the outline of the joint cavity and soft tissue structures not visible on routine x-ray films	Fluid may be aspirated from the joint space. A contrast agent, air, or both are aseptically injected into the joint after the area is anesthetized. The joint is manipulated to disperse the contrast agent. X-ray films are taken with the joint held in various positions.	Informed consent is often required. There will be feelings of pressure and some discomfort. Administer an analgesic after the procedure, if needed. Observe for swelling; apply ice as ordered. Advise patient that crackling sounds may be heard or felt in the joint after the test and usually disappear in a day or two. Instruct patient to report any increasing pain or swelling to the provider.
Arthroscopy	To inspect the interior aspect of a joint, usually a knee, with a fiberoptic endoscope to diagnose problems of the patella, meniscus, and synovium; also used to evaluate the progress of arthritis or effectiveness of treatment	After injection of local anesthesia, an incision is made and the arthroscope is introduced into the interior of the joint; instruments for tissue biopsy or surgical procedure may be passed through the arthroscope.	A sedative may be administered. Ambulation is encouraged when patient recovers from sedation, but without overuse or strain of the joint for a few days. Observe for bleeding or swelling; ice packs may be used in the immediate postprocedure period. Assess for swelling, circulation, and sensation periodically to detect any complications.
Arthrocentesis	To extract synovial fluid for analysis or to reduce swelling	A needle is inserted into the joint space and synovial fluid is aspirated. Corticosteroid may be injected after aspiration of fluid. The joint may be immobilized afterward. Ice packs are applied to relieve pain and reduce swelling.	The elastic bandage, if present, should be worn for 2-3 days. Patient should avoid overuse of the joint until pain and swelling have subsided. Administer ordered analgesics PRN.
Culture of synovial fluid	To determine organism responsible for infection	Synovial fluid is aspirated and sent for culture and sensitivity to determine appropriate antibiotic for therapy. Results take 48-72 hr to determine.	Have specimen of fluid transported to laboratory immediately.
Biopsy	Bone: to detect tumor cells Muscle: to obtain tissue for cellular analysis	Under local anesthesia, a piece of bone or muscle is excised and sent for pathologic analysis.	Offer emotional support during the procedures. Afterward, medicate for discomfort as needed, apply ice packs to decrease swelling, observe for bleeding; perform circulation and sensation checks distal to the area biopsied.
Electromyelography (EMG)	To detect abnormal nerve transmission to the muscle and abnormal muscle function; helps determine rehabilitation progress	Needle electrodes are inserted in affected muscles, and, as the muscles are stimulated, the electrical impulses generated by the muscle contractions are amplified and displayed on an oscilloscope; tracings also are made on graph paper. The test usually takes about an hour.	Obtain a signed consent form. Caffeine-containing drinks and smoking are restricted 3 hr before the test. Withdraw muscle relaxants, anticholinergics, and cholinergic drugs before the test as ordered. There may be slight discomfort when the electrodes are inserted; explain that she will be asked to relax and contract her muscles.

CPK-MM, Creatinine phosphokinase isoenzyme; IM, intramuscular; IV, intravenous; PRN, as needed.

Range-of-motion (ROM) testing involves both active and passive maneuvers. In active testing, the part being measured must be moved by the patient. In passive testing, the evaluator moves the body part while the patient is relaxed.

The measurement of ROM in a joint is called *goniometry* (Figure 31-3). One system of measurement commonly used is based on a full circle of 360 degrees. Each joint is evaluated in terms of the number of degrees it can be moved from the 0-degree position.

FIGURE 31-3 Measurement of joint motion with a goniometer. (From Mourad LA: *Orthopedic disorders*, St. Louis, 1991, Mosby.)

Muscle strength is measured on the basis of the ability of a muscle to move the part to which it is attached, working against the force of gravity. A grading system is used, ranging from grade 5 (normal strength) to grade 0 (complete paralysis).

Other techniques used to evaluate musculoskeletal function include inspection, palpation, and tests for stability of a joint under stress.

Think Critically

How would you explain the difference between a bone scan and a dual energy x-ray absorptiometry (DEXA) scan to a patient considering the purpose of each test and the difference in the procedures?

❖Nursing Management

Data Collection

History Taking

When reviewing the patient's past history, keep in mind the significance of disorders that primarily affect other systems but secondarily affect the bones and muscles. For example, sickle cell disease and hemophilia can cause bleeding into the joints and muscles, and psoriasis is sometimes the first sign of psoriatic arthritis, which is an inflammatory condition that affects the spine and the peripheral joints. Nutritional deficiencies can affect the mineral composition of bone and muscle, making them more susceptible to trauma and loss of function.

Family history may be significant because some bone and muscle disorders are either inherited or have a familial tendency. For example, about 30% of those who have psoriatic arthritis have a family history of psoriasis ([National Psoriasis Foundation, 2014](#)).

Focused Assessment

Data Collection for the Musculoskeletal System

- What do you see as your current problem?
- When is the pain the worst? What seems to bring it on? What relieves it?
- Do you have any pain in your wrists, elbows, knees, hips, or feet?
- Have you noticed any changes of sensation in your hands, feet, or elsewhere?
- Do you have any joints that are stiff, swollen, or painful?
- Do you have any restriction of movement in any joint?
- Do you have trouble sleeping because of muscle or joint pain?
- Do you have any joint deformity? Bunion? Hammer toe? Deformed knuckle?
- Have you ever had an injury to a bone?
- Have you ever experienced a severe muscle strain or muscle problem?
- Is there a history of osteoporosis or arthritis in your family?
- Do you have diabetes, sickle cell disease, psoriasis, systemic lupus erythematosus, or any other chronic metabolic disease?
- Are you taking any steroid medications regularly?
- Do you find that your fatigue level has increased?
- Do you have any problems with bathing, dressing, grooming, toileting, eating, ambulation, or going on social outings?
- Can you easily arise from a seated position?

- Do you have difficulty opening containers?
- What do you eat or drink that contains calcium? How much of it do you eat or drink?
- What is your daily (weekly) sunshine exposure? Do you take a vitamin D supplement?
- Do you use any alternative therapies or any other type of self-care measures? Are those self-care measures helping?
- Tell me about your work; do you lift, pull, or push? Are you sitting for prolonged periods or doing repetitive motions?
- Does your home have stairs or other features that are causing problems for you?
- Are you able to independently do home maintenance tasks (e.g., mow the lawn)?
- What type of physical activities or exercise do you routinely do (e.g., sports, gardening)? How often do you participate in these activities?

Physical Assessment

Observe the patient for signs of joint pain, such as limping, poor posture, awkward gait, difficulty in arising or walking, and wincing on movement. Watch the patient during performance of activities of daily living (ADLs), noting problems of movement, and changes in facial expression to pick up signs of problems. If the patient is admitted with a fracture, obtain a history of the precipitating event so that an assessment can be made of other areas that may have been injured. Sometimes it is necessary to consult family members or someone who lives with the patient about the patient's true ability to perform the ADLs. A **self-care deficit** is one of the primary issues for patients who have a problem with mobility.

Focused Assessment

Physical Assessment of the Musculoskeletal System

Note the following points:

- *Posture:* Is there evidence of **kyphosis**, such as a rounded upper back, also called a *dowager's hump*? Are the knuckles swollen or deformed, indicating arthritis?
- *Gait:* Is it steady and even? Awkward?
- *Balance:* Is the patient able to sit, stand, and walk with a good center of balance?
- *Mobility:* Is any supportive device being used, such as a cane, brace, splint, or elastic bandage?
- *Range of motion:* Is the patient able to move the neck, shoulders, arms, legs with full range of motion?
- *Strength:* Are grips in hands and push-pull in arms equal bilaterally? Is straight-leg raising against resistance equal bilaterally?
- *Spine:* Any tenderness of the vertebrae on palpation?
- *Appearance of joints:* Is there any redness, deformity, or loss of motion in elbows, hands, knees, ankles, and feet?
- *Skeletal muscle appearance in arms and legs:* Is there any degree of atrophy?
- *Ability to perform ADLs:* Is the patient independent or need assistance to dress, bathe, toilet, eat?

Older Adult Care Points

Approximately 30% to 40% of inpatient safety incidents are related to falls, and older adults are particularly vulnerable because of changes related to aging, such as decreased strength, unsteady balance, loss of endurance, slow reflexes, gait disturbances and increased postural sway, and chronic diseases such as arthritis. Conduct a fall risk assessment (see [Box 9-4](#)) and initiate fall precautions ([Centers for Disease Control, 2014](#)).

Nutrition Considerations

Vitamin D Associated With Decreased Risk for Falls

In a Cochrane review of 41 trials that included 25,422 subjects, higher vitamin D level was associated with a lowered risk for falls among older adult nursing home residents ([Cameron et al, 2010](#)).

Think Critically

After a hip replacement, can you trust a statement of “I can shop, cook, clean, and do everything I need to do by myself”? If you cannot trust the statement, why not? How would you gather data about an older adult patient’s ability to perform self-care activities at home before she is discharged?

Nursing Diagnosis and Planning

Caring for immobile patients requires careful planning. Making beds for bed-confined orthopedic patients is best done by two people. Bathing and grooming are more time consuming when the patient has an immobilized limb or has some other orthopedic device. **Planning for toileting needs at regular intervals is important for the well-being of a patient who is unable to get out of bed unassisted.** Neglecting such needs may cause incontinence and the time-consuming task of changing the bed and cleaning up the patient; incontinence is also demoralizing for the patient and increases the risk of tissue breakdown from the moisture and irritation of urine or feces.

Repositioning the patient at 2-hour intervals is included in the daily work plan to prevent pressure ulcers.

Common problem statements and example outcomes and interventions for patients with musculoskeletal problems are presented in [Table 31-4](#). Several other secondary problem statements may be appropriate for patients who are immobile. Constipation, altered tissue integrity, social isolation, potential for injury, and other problems caused by immobility may occur ([Box 31-1](#); see also [Chapter 9](#)).

Table 31-4

Common Problem Statements, Expected Outcomes, and Interventions for Patients With Musculoskeletal System Disorders

PATIENT PROBLEM	GOALS/EXPECTED OUTCOMES	NURSING INTERVENTIONS
Altered physical mobility due to immobilization, loss of limb, stiffness, pain, weakness, or inability to bear weight.	ROM of unaffected joints will be maintained. No signs of joint contractures will be present at discharge.	Active ROM at least tid for all unaffected joints while on bed rest. Passive ROM on affected joints as ordered. Ensure that joints are in correct alignment when at rest and after turning. Maintain body in proper alignment. Assess immobilizer for correct fit and positioning every shift; assess for signs of complications related to pressure or pins. Supervise exercise to prepare muscles for ambulation. Instruct in use of ambulatory devices appropriate; supervise practice; assess for proper “fit” of device. Encourage use of prosthesis for ambulation; assist with practice. Assess for signs of complications in stump and assess that prosthesis is attached correctly. Maintain abduction pillow between legs if one is ordered.
Limited activity intolerance due to stiffness, pain, limited mobility, fatigue.	Patient will space activities and rest to conserve energy. Patient will use assistive devices to conserve energy.	Determine factors that increase fatigue. Space activities with rest periods throughout the day. Assist to set goals for slow, steady increase in exercise and activity during periods of remission of arthritis symptoms. Perform exercises after heat treatments to decrease discomfort; apply in safe manner. Apply cold as needed after exercise for discomfort. Administer medications to decrease inflammation and pain, allowing greater level of activity. Advise of assistive devices that might make ADLs easier and help conserve energy. Assist in obtaining needed devices.

Pain due to injury, surgery, or joint disorder.	Pain will be controlled as evidenced by patient verbalization. Pain will be decreased with medication.	Supervise practice with assistive device. Assess for factors contributing to pain level, such as increased pressure, infection, positioning, or swelling. Assess pain in systematic, objective manner and track course of pain and effectiveness of pain control (see Chapter 7). Instruct in relaxation, distraction, and imagery techniques to decrease pain. Instruct in use of various heat and cold treatments to decrease pain. Administer analgesic, anti-inflammatory, and steroid medications, as ordered, to decrease pain. Instruct in use and side effects of each drug. Assist to an anatomically correct position to enhance circulation and alignment. Advise of alternative methods of pain control, such as transcutaneous electrical nerve stimulation (TENS). Monitor patient-controlled analgesia (PCA) use for effectiveness of pain control.
Potential for infection due to trauma or surgical incision.	No signs of infection will be present, as evidenced by normal white blood cell (WBC) count and normal temperature; wounds will be kept clean and dry.	Follow Standard Precautions and strict Contact Precautions when performing patient care, and use strict aseptic technique for wound or pin care. Assess for signs of infection every shift; assess wound for redness, swelling, and tenderness. Administer prophylactic antibiotics as prescribed. Assess temperature trends and trend of WBC values for signs of infection. Assess patient for subjective signs of malaise. Sniff around cast for signs of foul odor indicating infection.
Altered tissue perfusion due to swelling and pressure.	Patient will have no evidence of seriously decreased circulation distal to site of trauma. No evidence of nerve compression from swelling will be present.	Perform neurovascular assessment hourly for 8 hr, then q2h for 48 hr. Question patient regarding sensation distal to site of trauma or surgery. Apply cold to area of injury or surgery, as ordered, to reduce swelling; elevate extremity to slightly above heart level. Immediately report signs of compartment syndrome (i.e., severe, unrelenting pain; numbness) to provider and obtain order for measures to relieve pressure.
Altered self-care ability due to immobilization.	Patient will receive assistance for all ADLs, as needed.	Assess degree of inability to perform various self-care activities. Formulate plan to assist patient with ADLs. Answer calls for assistance with toileting promptly; do not leave on bedpan longer than necessary. Open food containers and cut food as needed for self-feeding with one hand. Do not serve extremely hot liquids to patients who have difficulty with coordination or with holding drinking containers or to immobilized patients. Provide assistive devices and help patient to be as self-sufficient as possible without incurring undue fatigue when performing ADLs. Caution patients about change in body's center of gravity when a limb is casted or amputated.
Altered body image due to change in appearance and/or loss of mobility or function.	Patient will begin adaptation to change in appearance or loss as evidenced by verbalization of feelings of self-worth; maintenance of relationships with significant others; active interest in personal appearance; willingness to resume usual roles and participate in social activities; and making plans to adapt lifestyle to meet restrictions imposed by loss.	Assess degree of body image disturbance, noting verbal or nonverbal clues to negative response to changes. Assist to verbalize feelings about effect of loss on usual roles and lifestyle. Be present and supportive during initial dressing changes on stump after amputation. Assist patient to identify strengths and abilities and positive coping mechanisms. Clarify misconceptions about limitations on mobility and activity. Promote activities that require patient to confront the body changes that have occurred, such as bathing, ADLs, or dressing changes. Demonstrate acceptance of patient and encourage significant others to do the same with touch and affection. Encourage as much independence as possible; allow to do things for self. Assist patient to explore viable options for changes in lifestyle and career. Refer for vocational retraining if needed. Encourage maximum participation in planning of care and self-care to provide a sense of control over life. Encourage participation in social activities and in a support group. Refer for psychological counseling if adaptation does not occur within 6 mo and patient is depressed or in denial.
Decreased ability for home maintenance due to immobility or limited self-care ability.	Patient will obtain needed assistance with home maintenance.	Assess degree of self-sufficiency and ability to perform ADLs before discharge. Contact social worker for coordination of home care if needed. Obtain bathing and homemaker assistance as needed. Assess continued need for in-home services weekly. Instruct in home adaptations that could aid in efforts at self-care, such as grab bars in bathroom, alterations in counter spaces for food preparation, transportation options for grocery shopping and appointments, or assistive devices for self-feeding and grooming. Assess degree of assistance family members can provide for patient in home environment. Determine safety of home environment for patient.
Potential for disuse syndrome due to immobility or trauma.	Patient will not suffer permanent joint deformity or muscle atrophy.	Position joints as ordered; keep rest of body in correct alignment. Begin exercise of affected joint as soon as provider orders. Encourage active exercise of unaffected joints tid. Perform passive ROM as ordered tid. Assist with use of CPM machine, as ordered. Medicate regularly for pain while CPM machine is in use. Use heat and cold treatments before and after exercising stiff or deformed joints. Assess joints for contractures and muscles for atrophy q24h. Encourage participation in ADLs to exercise joints.

ADLs, Activities of daily living; CPM, continuous passive motion; ROM, range of motion; tid, three times a day.

Box 31-1

Physiologic Consequences of Immobility

- **Cardiovascular system:** Decreased cardiac output with reduced force of cardiac contraction results from a lack of physical activity. Immobility causing decreased use of leg muscles leads to venous stasis and potential formation of blood clots.
- **Respiratory system:** Reduced lung expansion and consequent reduced gas exchange with potential

for atelectasis and pooling of secretions occurs with immobility. Reduced cough effort along with pooled secretions predisposes to stasis pneumonia.

- *Musculoskeletal system:* Prolonged immobility leads to reduced muscle mass and atrophy. Demineralization of bones occurs with lack of weight bearing; osteoporosis may occur.
- *Integumentary system:* Skin breakdown may occur from a reduced flow of oxygenated blood from pressure on the skin resulting from immobility. Combined with lack of appetite from immobility and poor nutritional status, pressure ulcers may develop.
- *Gastrointestinal system:* Slowing of peristalsis and decreased muscle strength occur with decreased physical activity. Decreased appetite and an inability to assume an upright position for defecation also contribute to the constipation that can occur with immobility.
- *Urinary system:* Calcium from bone increases in the blood from immobility, bladder tone decreases, and more time in a supine position from immobility leads to urinary stasis. Infection, renal calculi, and urinary tract infection may occur.
- *Psychological effects:* Feelings of helplessness or hopelessness, boredom, depression, and disturbed body image may be accompanied by anger or anxiety and loss of self-esteem during extended periods of immobility. Social isolation may also occur.

Interventions and outcomes are designed in collaboration with the patient and other members of the health care team. **The physical therapist and occupational therapist are especially important and act as resources for the patient and the nurse.**

■ Implementation

Positioning

Patients with musculoskeletal problems must change their body position frequently and get up in a chair to prevent pressure ulcers, circulatory stasis, and respiratory and urinary complications. **It also is necessary to change joint positions to prevent joint deformity.**

When repositioning the patient, watch for early signs of muscle tightness and resistance to joint motion. Observe during routine ROM exercises; if any tightness or resistance to joint motion is noticed, position the joint extended so that muscles are stretched to normal limit to prevent the development of contractures.

Patients with flaccid paralysis are not necessarily positioned in the same way as those with spastic paralysis. For example, a footboard is appropriate for proper positioning of the feet to prevent footdrop in a patient with flaccid paralysis. In contrast, putting the soles of the feet of a patient with spastic paralysis in contact with a footboard could trigger muscle contraction and aggravate the spasticity. Use a bed cradle to relieve pressure of the bedclothes to help prevent footdrop in these patients.

Preventing ankylosis. Ankylosis is the result of injury or disease in which the tissues of the joint are replaced by a bony overgrowth that completely obliterates the joint. Proper positioning and movement of the joint passively can help prevent this. Sometimes it is extremely difficult to prevent this process (as, for example, in some types of arthritis). In these cases, the joint may be braced in the position that will be most useful to the patient, even though there is no motion in the joint.

Lifting and turning the patient. When working with orthopedic patients, all movements must be *gentle and firm*. When moving or turning the patient, obtain sufficient help from adequately trained personnel. Each person involved, including the patient, should understand exactly what is to happen and how the move will be accomplished. If the patient can help without damaging the diseased joint or limb, encourage her to do so. If she is unable to help, explain the procedure and instruct her to relax completely. Many times the patient is afraid that moving and turning will cause pain. Explaining the long-term benefits, such as preserving skin integrity and decreasing respiratory problems, will increase cooperation.

Exercise

ROM exercises, both passive and active, are planned and carried out as soon as feasible after

decreased mobility occurs as a result of disease, injury, or surgery. The exercises are done to maintain connective tissue within the joint and thereby ensure that every joint retains its function and mobility. **ROM exercises should be done three or four times a day.** Other kinds of exercises are planned according to each patient's needs and the amount of motion allowed by the provider. **Isometric exercises** involve generating tension between two opposing sets of muscles, for example, trying to flex the lower arm while using the opposite hand to try to extend it.

Safety Alert

Caution With Isometric Exercises

Isometric exercise may be contraindicated in patients with hypertension, increased intracranial pressure, or congestive heart failure because isometric exercise causes a significant increase in blood pressure and heart rate.

Gradual mobilization. Progressive mobilization involves assessing the patient's ability to move her limbs, turn herself in bed, transfer herself from bed to chair and back again, and stand and walk. These measurable signs of independent movement represent various stages to which the patient can gradually progress. According to The Joint Commission's National Patient Safety Goals, it is a nursing responsibility to recognize that these patients are at risk for falls while they are learning to regain mobility.

Clinical Cues

The provider's orders should include level of activity (i.e., bed rest, out of bed to chair, physical therapy); however, if this order is not included—or if your assessment finds that the patient either cannot accomplish the orders or has already surpassed the ordered level of activity—notify the provider so that a reevaluation of the patient's abilities and new orders occur.

Setting goals for progressive mobilization must take into account the pathologic condition causing immobility, any contraindications to movement of a body part, and the ability of the patient to understand and take part in carrying out the rehabilitation activities. In some cases, passive exercises and positioning may be necessary until the patient is able to carry out exercises and positioning on her own. If the patient is to be cared for by family members once back at home, it is essential that they be included in planning and setting goals of intervention to prevent disability and promote mobilization.

Health Promotion

Gentle Stretch for Upper Back

Patients who are kyphotic (or those who hunch over their books while studying!) can develop discomfort and tension in the upper midback. Encourage periodic and conscientious attempts to sit upright with the shoulders pulled back. Another exercise is to stand in a corner, place palms on the opposing walls or use an open door frame and gently lean into the corner or the opening. This may feel uncomfortable at first, so encourage the patient to go slow.

Patients suffering from intense joint pain as a result of rheumatoid arthritis will need proper timing of exercises to follow administration of analgesic and anti-inflammatory drugs. If possible, the schedule for drug administration should be adjusted so that the patient receives her first dose of medication in the morning 30 to 60 minutes **before** beginning exercises.

Sometimes after joint surgery, especially after a total knee replacement, the surgeon will order attachment of an apparatus to the affected limb that provides continuous passive motion (CPM) of the joint within set limits. The apparatus is driven by a motor and requires no effort on the part of the patient or nurse to move the limb ([Figure 31-4](#)). It usually is left on all day and is discontinued at night while the patient sleeps. When this type of apparatus is used, the nursing care plan should

include specific instructions regarding its proper application and setting and regular assessment of adequacy of pain relief.

FIGURE 31-4 A continuous passive motion machine encourages joint mobility.

Exercises to recondition muscles for ambulation after injury or immobilization include quadriceps setting and gluteal setting.

Patient Teaching

Quadriceps and Gluteal Muscle Exercises

Quadriceps Setting

- Instruct the patient to straighten the leg out while lying down and to tense the leg muscles and straighten the knee, while raising the heel slightly.
- The contraction is held for a count of five and released for a count of five.
- The exercise is done on each leg 10 to 15 times hourly while the patient is awake.
- Commercial breaks on television are a good reminder to do this.

Gluteal Setting

- Instruct the patient to contract the buttocks and pinch them together for a count of four, then relax for a count of five.
- Repeat 10 to 15 times hourly.

Think Critically

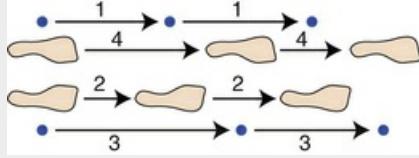

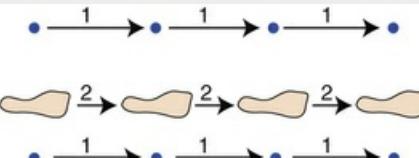

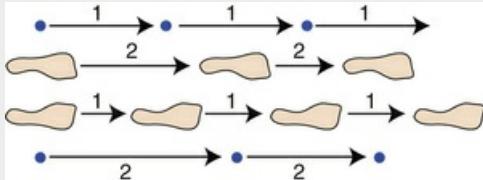

You are working in a long-term care facility. Your patient is in a coma because of a head injury that occurred 3 months ago, but her husband visits every day. How could the husband participate to prevent contractures?

Teaching Ambulation With Assistive Devices

For convalescent patients or those who may always need support while walking, crutches can mean the difference between freedom to move about and confinement to one location. Before attempting to walk with crutches, the patient should be instructed in their use and manipulation to ambulate safely and effectively.

Patient Teaching

Crutch Gaits

GAIT	SEQUENCE	PATTERN
Four-point gait	Advance left crutch. Advance right foot. Advance right crutch. Advance left foot. Advantages: most stable crutch gait. Requirements: partial weight bearing on both legs.	
Three-point gait	Advance both crutches forward with the affected leg and shift weight to crutches. Advance unaffected leg and shift weight onto it. Advantages: allows the affected leg to be partially or completely free of weight bearing. Requirements: full weight bearing on one leg, balance, and upper body strength.	
Two-point gait	Advance left crutch and right foot. Advance right crutch and left foot. Advantages: faster version of the four-point gait, more normal walking pattern (arms and legs moving in opposition). Requirements: partial weight bearing on both legs, balance.	

The type of crutch to be used will depend on the extent of disability or paralysis and the patient's ability to bear weight and maintain balance. If the crutches are too short or too long, patients will have problems with moving and shifting their weight. When walking, the patient should straighten the elbow and the wrist during weight bearing. The muscles of the arms, shoulders, back, and chest are all used in the manipulation of crutches. Therefore many physical therapists start the patient on special exercises to strengthen these muscles several weeks before the patient begins to use the crutches.

Safety Alert

Crutch Safety

Height is considered when fitting crutches to the patient. When in the standing position with axillary crutches, the axillary bar should be two finger breadths below the axilla. The elbow should be flexed at a 30-degree angle when the palms of the hands rest on the handgrip. It is important that the patient not rest her body at the axilla on the top of the crutch; body weight should be borne by the arms on the hand rests of the crutches. If crutches are too long, pressure on the axilla will occur and can cause nerve damage.

To measure for crutches, the patient stands wearing shoes and positions the crutch tips at a point 4 to 6 inches (10 to 15 cm) to the side and 4 to 6 inches in front of the feet. Although the physical therapist supervises the preparation and instruction of patients before they start to use crutches and then evaluates their ability to use them correctly, nurses are sometimes responsible for assisting a patient with crutch walking while she is in the hospital.

Patient Teaching

Special Maneuvers on Crutches

MANEUVER	SEQUENCE
Walking up stairs	Stand at the foot of the stairs with weight on the good leg and crutches. Put weight on the crutch handles and then lift the good leg up onto the first step of the stairs. Put weight on the good leg and lift the injured leg and crutches up to that step. Repeat for each step.
Walking down stairs	Stand at the top of the stairs with weight on the good leg and crutches. Shift weight completely onto the good leg and put the crutches down on the next step. Put weight on the crutch handles and transfer the injured leg down on the step with the crutches. Bring the good leg down to that step. Repeat for each stair step.
Sitting down	Crutch-walk to the chair. Turn around slowly so that the back is to the chair and the backs of the legs touch the seat of the chair. Transfer both crutches to the side with the injured leg and grasp both handgrips with that one hand. As weight is supported on the crutches and the good leg, reach back with the free hand and grasp the arm of the chair. Lower slowly onto the chair seat, using the support of both the crutches and chair. Sit back in the chair and elevate the leg. Keep the knee slightly flexed when elevated because too much extension can decrease the circulation. To get up, bring both crutches along the side of the injured leg and grasp the handgrip firmly. Make sure the crutch tips are firmly on the floor. Place the other hand on the arm of the chair and push up. After becoming upright, transfer one crutch to the other hand for walking.

When teaching a patient to ambulate with a cane, be certain that the cane has an intact rubber tip. The cane is the right length if the handgrip is at hip level and the elbow is bent at a 30-degree angle when weight is placed on the cane. **It should be used on the good side unless the provider orders otherwise.** The tip of the cane should be placed 6 to 10 inches (15 to 25 cm) to the side and 6 inches (15 cm) in front of the near foot when walking. The patient should look straight ahead, rather than down, when ambulating. **The cane is advanced at the same time as the affected leg.** “Go up the stairs with your stronger leg first, then your weaker leg, then the cane. If you are going down the stairs, start with your cane, then your weaker leg, then your strong leg” (www.nlm.nih.gov/medlineplus/ency/patientinstructions/000343.htm).

Walker height is correct when the person's elbow is bent at a 15- to 30-degree angle while standing upright and grasping the handgrips. The walker is lifted or rolled on its wheels slightly in front of the patient while leaning the body slightly forward. A step or two is taken into the walker, and then it is lifted and placed in front of the person again.

▣ Older Adult Care Points

Many older adults are hospitalized with injuries they sustain from inability to maneuver crutches, a cane, or a walker. It is essential that older adults be taught proper methods of using assistive devices and that they receive supervised practice before they are discharged.

Psychosocial Care

Unfortunately, many orthopedic conditions require prolonged periods of confinement to bed or, at best, immobilization of a part of the body and restricted physical activities. This leads to frustration and a feeling of hopelessness and despair on the part of the patient. When the patient is young and unaccustomed to depending on others for personal care, a reaction of anger and bitterness may occur. If the patient is a wage earner or a member of the family on whom others are dependent, there is the additional burden of financial and role problems (see Chapter 9). If there has been an amputation or extensive scarring from an injury, the patient's self-image may suffer.

■ Evaluation

Determining the effectiveness of interventions to treat pain is based mainly on subjective information given by the patient, but also be alert to nuances of body language. Observation of the patient's ability to accomplish ADLs gives clues to improvement in mobility and activity tolerance.

Diagnostic test data from radiographs and laboratory reports are used to determine the effectiveness of treatments. For example, radiographs show whether fractures are healing, whereas laboratory reports help to determine how well rheumatoid arthritis is controlled.

Common Problems Related to the Musculoskeletal System

Common problems specific to musculoskeletal disorders are those related to immobility, pain, and self-care deficit.

Immobility. There are many systemic responses and problems that result from extended immobility (see Box 30-1). These problems are more common with neurologic injuries or disease that cause long-term immobility. For shorter periods of immobility that occur with sprains and strains, joint injury and replacement, fractures, back pain, or arthritis, the goals are for quick ambulation and rehabilitation with a return to an active lifestyle. Many interventions can prevent

disability during the period of immobility.

Preventing Disability

The formation of **contractures** (shortening of skeletal muscle tissue causing deformity), loss of muscle tone, and fixation of joints can be prevented in most cases by consistent nursing intervention. The major components of the intervention are gradual mobilization, an exercise program, proper positioning, and instruction of the patient and family. **Within a matter of a few days, the structures of immobilized muscles and joints begin to undergo changes.** If no effort is made to prevent these changes, the patient will become permanently disabled. The pathologic changes most commonly associated with lack of motion include:

- Contractures
- Loss of muscle tone
- **Ankylosis** (permanent fixation of a joint)

Preventing contractures. Joint motion is the result of a shortening and stretching of opposing muscles. For example, when the flexor muscles of the leg contract and shorten, the opposing extensor muscles relax and lengthen. When skeletal muscles are not regularly stretched and contracted to their normal limits, they attempt to adapt themselves to this limited use by becoming shorter and less elastic. An “adaptive shortening,” or **contracture**, begins to form within 3 to 7 days after immobilization of a body part, and the process usually is complete in 6 to 8 weeks. This means that planning and implementing nursing measures must begin immediately to prevent permanent and crippling disability. The most common contractures that occur in patients immobilized for long periods are footdrop, knee and hip flexion contractures, wrist drop, and contractures of the fingers and arms ([Figure 31-5](#)).

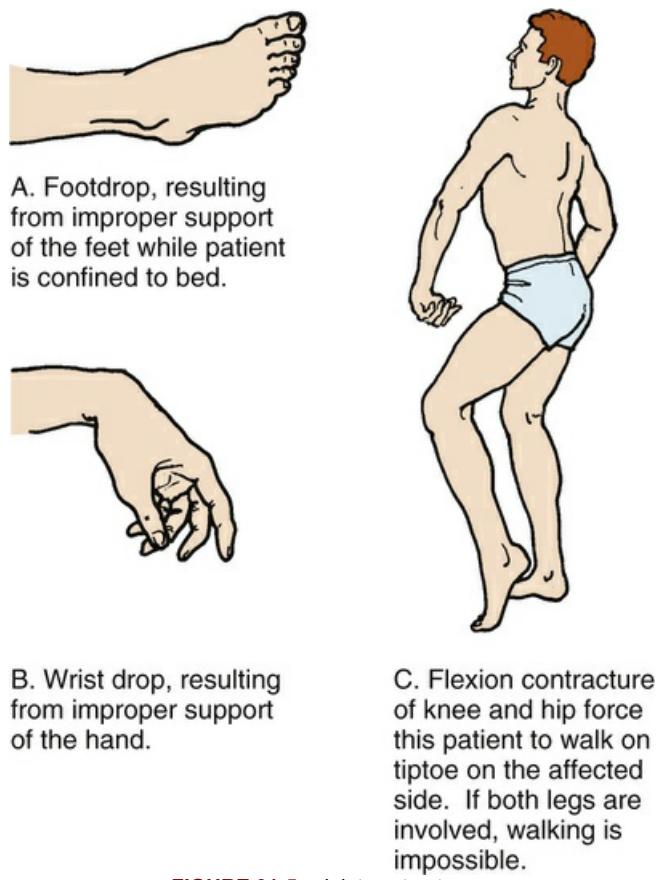

FIGURE 31-5 Joint contractures.

Preventing loss of muscle tone. *Muscle tone* is defined as the readiness of the muscle to go to work—to contract and relax as needed. If a muscle is not regularly stimulated to action or if it is

stretched beyond its normal limits for an extended time, it will lose its ability to contract and relax. For example, in footdrop, the calf muscles are shortened while the opposing flexor muscles are stretched. The result is loss of muscle tone and inability to produce motion. Performing ROM exercises helps prevent this.

Pain. Pain occurs with most musculoskeletal disorders. Immobilization with slings, splints, and braces helps to decrease pain by limiting movement of joints or muscles. Analgesics, muscle relaxants, heat, cold, topical pain-relieving substances, electrical stimulation, acupuncture, acupressure, massage, or chiropractic manipulation also are used to treat pain.

Clinical Cues

Alteration in Self-Care Ability

A patient with a musculoskeletal problem may need a little or a lot of help with activities of daily living. For those with a fracture, bathing help is typically needed. If an arm is immobilized, help with a meal tray and possibly with feeding will be required. Assistance may be needed for repositioning or transferring when the patient is in a leg cast, immobilizer, or external fixation device. A functional assessment should be performed to determine what assistance is necessary.

Common Therapeutic Measures

Special beds. Most hospital beds now have a built-in pressure-relieving mattress to help prevent skin breakdown. Another type of bed for patients who are on bed rest many hours each day has areas that inflate and deflate to deflect pressure from sequential areas of the body. An air fluidized bed is used for various types of immobility and is very helpful in preventing pressure sores because it conforms to the body's weight, and the air shifts as the body's weight is redistributed ([Figure 31-6](#)).

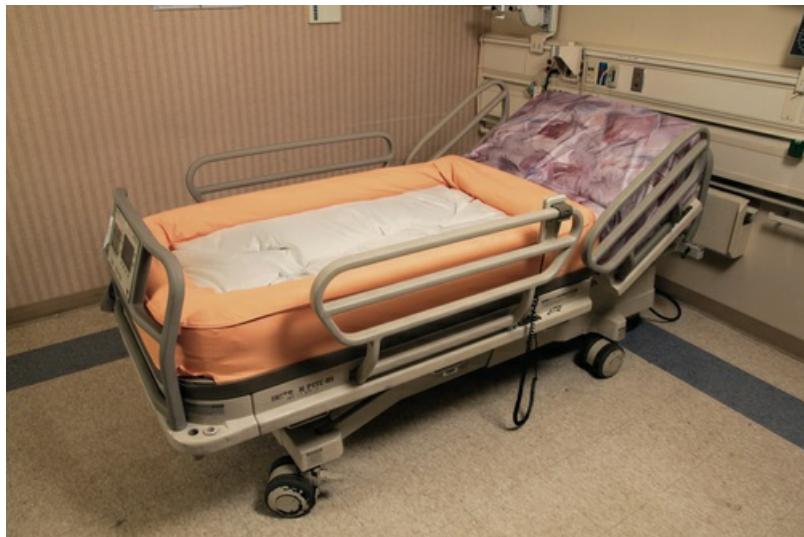

FIGURE 31-6 Clintron Rite Hite air fluidized therapy bed.

A type of bed that often is used for patients in cervical traction is the Roto-Rest bed (see Figure 23-12). This bed very slowly turns the patient about 300 times each day. It provides passive exercise and stimulates peristalsis without risk of injury to the patient. The bed has many other advantages, including several hatches that provide access to all of the common pressure points on the patient. There is a hatch for bowel and bladder care so that a bedpan can be placed without moving the patient. The back side of the patient can be bathed through the various hatches also. Once you are familiar with the bed, it greatly simplifies care of immobilized patients.

Use of slings, splints, and braces. A sling used to support the wrist or elbow should support both joints of the arm. The sling should be positioned so that the fastening at the neck area does not

rub the neck or press on a neck vessel. When a splint is applied to an extremity, it should support the joint that is to be immobilized, fit properly without impeding circulation or slipping out of place, and not cause increased pain ([Figure 31-7](#)). If in doubt about how a particular splint is to be applied, seek help from an experienced nurse or the physical therapist.

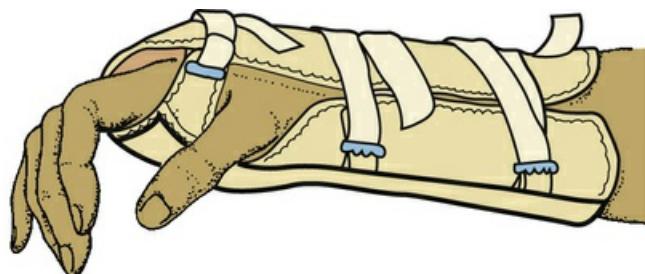

FIGURE 31-7 Wrist splint.

A splint may be used on an extremity to limit motion while healing takes place in the bone, joint, tendon, or muscle. Be certain to check the instructions for application of the splint. Inspect the skin under the splint each shift. Assess circulation after application of the splint.

A brace or immobilizer may be used on a leg during healing of an ankle injury or during the healing phase of a fracture. The device must be applied correctly, and the skin beneath it must be assessed for friction or injury each shift.

Physical therapy. Physical therapy sessions are often prescribed by the provider to assist the patient to regain mobility, increase strength after immobility, decrease pain, and prevent injury. Specific exercises, ultrasound, electrical stimulation of muscles, massage, kinetic taping, and heat and/or cold may be used. The patient is to perform the exercises regularly at home between sessions and after a course of therapy is over. The proper way to use crutches, a cane, or a walker are taught and supervised until the patient is deemed “safe” to use the equipment.

Occupational therapy. The occupational therapist assists patients to perform activities of daily living using adaptive equipment or alternate movements. Learning new ways of getting out of a sitting position, getting in and out of a vehicle, moving in bed, cooking, eating, dressing, and other activities helps the patient regain or maintain independence.

Get Ready for the NCLEX® Examination!

Key Points

- The main functions of the musculoskeletal system are motion, support, and protection.
- Disease, trauma, disuse, malnutrition, and aging all contribute to musculoskeletal problems.
- Exercise and weight training throughout life can decrease musculoskeletal problems late in life.
- Using safety equipment for sports, during exercise, when driving, and while at work is very important in preventing trauma to the musculoskeletal system.
- Nurses teach patients about diagnostic tests and procedures for the musculoskeletal system.
- Self-care deficit, impaired physical mobility, and pain are primary problems for patients with musculoskeletal injuries or disorders.
- Nurses use many interventions to prevent disability during periods of immobility.
- Contractures can permanently impair a patient's ability to perform ADLs. Positioning must be performed correctly, and ROM exercises should be performed three or four times a day to promote function and preserve movement.
- Nurses assist with supervising and teaching ambulation with assistive devices.
- Physical and occupational therapists are part of the collaborative team for musculoskeletal care and rehabilitation.

Review Questions for the NCLEX® Examination

1. When explaining the structure of the knee to a patient who has knee swelling, the nurse states:
(Select all that apply.)

1. "Ligaments provide movement of the joint."
2. "The meniscus in the joint acts as a cushion."
3. "The tendons are needed for movement and can be injured."
4. "The fascia may have deteriorated."
5. "Muscles attach to the bones to help provide movement."

NCLEX Client Need: Physiological Integrity

2. The purpose of the skeleton is to provide a rigid framework that _____ and the skin. *(Fill in the blank.)*

NCLEX Client Need: Physiologic Integrity

3. What action should the nurse perform for the postprocedural care of a patient who just had an

arthroscopy?

1. Follow up on the results of the serum enzymes that were drawn before the test.
2. Prepare an ice pack and obtain an elastic bandage.
3. Check vital signs and pulse every 15 minutes for the first hour.
4. Encourage the patient to take fluids to decrease the swelling.

NCLEX Client Need: Physiologic Integrity

4. When a 76-year-old female patient has a complaint of pain and soreness in the back, a first step in the assessment specific to this patient should include:

1. family or personal history of osteoporosis or arthritis.
2. physical examination of muscle strength of the extremities.
3. history of fracture during the patient's lifetime.
4. appearance of joints in the extremities.

NCLEX Client Need: Physiologic Integrity

5. A nurse is teaching an older adult patient how to increase musculoskeletal and bone strength. Which interventions would be helpful? (*Select all that apply.*)

1. Walk at least 30 minutes a day 5 to 7 days a week.
2. Eat more protein and vitamin C to build muscle.
3. Walk up stairs as often as possible.
4. Perform strength training exercises at least three times a week.
5. Use 10-lb weights for various exercises at least three times a week.

NCLEX Client Need: Safe and Effective Care Environment

6. A nurse is working on a busy orthopedic floor. Which task(s) can be assigned to the UAP? (*Select all that apply.*)

1. Assist an older adult who has an arm sling to perform ADLs.

2. Report the presence of contractures on a bedridden patient.
3. Supervise a patient who is beginning to use crutches.
4. Escort a patient in a wheelchair to the radiology department.
5. Perform passive ROM on a patient who needs a bed bath.
6. Instruct a patient to reapply a prescribed wrist splint to prevent contracture.

NCLEX Client Need: Safe and Effective Care Environment

7. A nurse evaluates a patient's ability to use a cane. Which action indicates proper use of the cane?
1. The cane is advanced at the same time as the good leg.
 2. The handgrip is at the hip level.
 3. The cane is used on the affected side.
 4. The patient looks down while ambulating.

NCLEX Client Need: Safe and Effective Care Environment

8. A 56-year-old man complains to the nurse of joint pains, difficulty rising, and limping. He demonstrates poor posture and uncoordinated gait. The nurse sees the priority problem on his care plan as:
1. Limited ability for self-care.
 2. Altered physical mobility.
 3. Limited coping ability.
 4. Altered activity tolerance.

NCLEX Client Need: Safe and Effective Care Environment

9. The nurse recruits the assistance of adequately trained personnel to turn an immobile patient. To prevent injury to the patient and the nursing staff, which measure should be taken before repositioning the patient?
1. Encourage movement of all joints.

2. Explain the details of the move.
3. Discourage patient participation.
4. Medicate the patient for anxiety.

NCLEX Client Need: Safe and Effective Care Environment

10. To manage joint discomfort associated with movement for a patient with severe rheumatoid arthritis, the nurse should:

1. encourage deep-breathing exercises.
2. administer pain medications immediately after exercise.
3. schedule pain medication administration before exercise.
4. provide a continuous infusion of pain medications.

NCLEX Client Need: Physiologic Integrity

11. A nurse assesses the condition of a patient with a splint applied to the right arm. Which clinical finding is cause for the greatest concern?

1. Warm skin under the splint
2. Redness of skin under the splint
3. Itching under the splint
4. Palpable distal pulses

NCLEX Client Need: Safety and Infection Control

Critical Thinking Questions

Scenario A

Ms. Johnson has had trouble with her left knee for several years. She is scheduled for an arthroscopy and asks you about the procedure.

1. How would you describe the procedure to her?
2. What care is necessary after this procedure?
3. How long is she likely to be immobile after the procedure?

Scenario B

Mrs. Hamid has been experiencing muscle weakness in her right leg for a few weeks. Her health

care provider has scheduled her for an electromyogram (EMG). She asks you about this procedure.

1. Is an informed consent needed for an EMG?
2. How would you describe the test to Mrs. Hamid?
3. What care is needed after the procedure?

Scenario C

Mrs. Green, age 67 years, sustained a fracture of the right humerus when she fell this morning. A cast has been applied.

1. What would you tell her she needs to do at home to keep her joints mobile?
2. What should she do to protect the muscle mass?
3. What nutritional teaching would you provide?

Scenario D

You are caring for Mr. Morgan, a 40-year-old self-employed carpenter. He is a large man with a heavy full-leg cast. He is having a lot of pain and expresses fear that moving will increase the pain.

1. Discuss some important considerations in turning, moving, bathing, and toileting for Mr. Morgan.
2. What is the psychosocial care for a patient such as Mr. Morgan who is immobile?

CHAPTER 32

Care of Patients With Musculoskeletal and Connective Tissue Disorders

Objectives

Theory

1. Compare the assessment findings of a connective tissue injury with those of a fracture.
2. Determine the rationale for the “dos and don’ts” of cast care.
3. Outline the potential complications related to fractures.
4. Discuss the pathophysiology and implications of the six *Ps*.
5. Contrast the preoperative and postoperative care of a patient with a total knee replacement with that of a patient with a total hip replacement.
6. Relate the special problems of patients with arthritis with specific nursing interventions that can be helpful.
7. Illustrate the process by which osteoporosis occurs, ways to slow the process, and how the disorder is treated.
8. Determine important postoperative observations and nursing interventions in the care of a patient who has undergone an amputation.

Clinical Practice

9. Gather data on a patient who has a connective tissue injury.
10. Provide pin care for a patient with external fixation of a fracture.
11. Instruct a patient going home with a cast about proper care of the cast and extremity.
12. Observe a physical therapist teaching quadriceps exercise and then assist the patient to practice.
13. Assess the skin of a patient who has a prosthetic device on an amputated limb.

sprain (SPRĀN, p. 736)
subluxation (süb-lük-SĀ-shūn, p. 737)

Connective Tissue Disorders

Sprain

Etiology and Pathophysiology

A **sprain** is a partial or complete tearing of the ligaments that hold various bones together to form a joint. A sprain occurs during trauma when a joint is forced or twisted past its normal range of motion (ROM). The ankle, knee, and wrist are most the commonly sprained joints.

Signs, Symptoms, and Diagnosis

- *Grade I* (mild): Tenderness at site; minimal swelling and loss of function; no abnormal motion.
- *Grade II* (moderate): More severe pain, especially with weight bearing; swelling and bleeding into joint; some loss of function.
- *Grade III* (severe, complete tearing of fibers): Pain may be less severe, but swelling, loss of function, and bleeding into joint are more marked.

Diagnosis is by physical and radiographic examination to rule out a fracture or other pathology.

Treatment and Nursing Management

RICE is the acronym used for treatment of sprains: **rest**, **ice**, **compression**, and **elevation**. Apply ice immediately after injury and for the next 24 to 72 hours. Apply the ice bag for 10 to 20 minutes every 1 to 2 hours during the day. Wrap the injured part snugly with an elastic bandage, being careful not to cut off circulation, and elevate. These measures can help minimize swelling and pain and stabilize the joint in proper alignment. The goal of treatment is to protect the ligament until it heals by scarring. Ligaments do not “grow” back together. Air casts, braces, or supports are used only until a joint has been strengthened. If a joint is immobilized too long and muscles are not exercised, muscle atrophy—which begins in a matter of days—can cause permanent disability. In some cases, surgical repair may be necessary. Grade III sprains often require a cast. Patients with grade II or grade III sprains need to rest the joint; crutches are needed for a lower extremity sprain. Nonsteroidal anti-inflammatory drugs (NSAIDs) should be prescribed on an around-the-clock basis for the first couple of days to decrease swelling.

Strain

Etiology and Pathophysiology

A strain is a pulling or tearing of a muscle, a tendon, or both. A strain occurs by trauma, overuse, or overextension of a joint. The most commonly strained muscles are the back muscles. (See [Chapter 22](#) for a discussion of the neurologic aspect of back problems.) Muscle strains also occur in other skeletal muscles. The most common sites are the hamstrings, quadriceps, and calf muscles.

Complementary and Alternative Therapies

Soothing Sore Muscles

Arnica applied topically is reported to soothe sore, tired muscles after extended hard work. Valerian or kava brewed as a tea is also believed to relax muscles. A little honey or apple juice will make the teas more palatable (Edelberg, 2014).

Signs, Symptoms, and Diagnosis

A history of overexertion or the presence of soft-tissue swelling and pain may indicate a strain has occurred. Bleeding (ecchymosis, hemorrhagic area) will be present if a muscle is torn.

Treatment and Nursing Management

Ice and compression should be immediately applied, and the body part should be elevated and

rested. The patient is taught to use ice for only 20 minutes each hour. When compression is used, the distal parts of the extremity must be checked for sensation and adequate circulation. Heat can be applied after 48 hours. Anti-inflammatory medications are used for discomfort; when spasm is present, a muscle relaxant may be prescribed. Time is the greatest healer. The patient is cautioned against reinjury and is taught proper ways to lift and move. Surgical repair may be necessary.

Think Critically

How would you assess for a circulation problem or nerve injury after an ankle sprain or strain?

Dislocation

Etiology and Pathophysiology

A **dislocation** is the stretching and tearing of ligaments around a joint with complete displacement of a bone. **Subluxation** is a partial dislocation. This occurs from trauma. The most common sites are the shoulder, knee, hip, ankle, and temporomandibular joint.

Signs, Symptoms, and Diagnosis

Dislocation often includes a history of an outside force pushing from a certain direction, severe pain aggravated by motion of the joint, muscle spasm, or abnormal appearance of a joint. A radiograph will reveal displacement of bone.

Treatment and Nursing Management

Reduction of displacement under anesthesia is used for most dislocations; sometimes manual reduction is used for the shoulder. Reduction can be very painful. Sometimes spontaneous reduction can be achieved. The goal is to stabilize the joint after reduction and then to rehabilitate to minimize muscular atrophy and strengthen the joint. Assess for adequate perfusion and movement of the affected part and distal to it, determine whether swelling is present, and assess the degree of pain. Nursing management is aimed mainly at pain control and encouraging rest of the affected part. Heat or cold applications may be ordered.

Rotator Cuff Tear

Rotator cuff injury usually results from repetitive activity, such as throwing or making overhead motions with the arm. Falls and trauma also may cause the injury. The rotator cuff is composed of four muscles. If the rotator cuff is torn, there is pain and the patient cannot perform abduction and external rotation of the injured shoulder. Treatment consists of rest, sling support for the shoulder, and NSAIDs for the discomfort. Some providers treat with injections of steroids or an anti-inflammatory drug. When the acute episode is over, gentle, progressive exercise is prescribed. Heat is recommended before exercising the joint. If the tear will not heal, surgical repair is indicated.

Anterior Cruciate Ligament Injury

Most anterior cruciate ligament (ACL) injuries of the knee occur from athletic activities, but falls and motor vehicle accidents also may cause such injury. Hyperextension, internal rotation, extremes of external rotation, and deceleration are involved. The ligament may be torn from the femur or tibia. Often a loud “pop” can be heard at the time of injury. There is swelling in the hours after the injury, and the knee feels unstable and can “give way.” Full extension of the leg is difficult.

Diagnosis is by physical examination, radiography, or magnetic resonance imaging (MRI).

Arthroscopy is performed, at which time repair may be done. Sometimes a tendon transplant is needed for the repair.

After injury, the knee is immobilized and measures are instituted to reduce swelling and pain. After repair, continuous passive motion (CPM) may be ordered to promote full mobility. A long leg brace with fixed knee flexion may be used as well. Isometric exercises are prescribed in the recovery period, including quadriceps setting (see [Patient Teaching: Quadriceps and Gluteal Muscle Exercises](#) in Chapter 31), bent-knee leg exercises, and foot exercises.

Meniscal Injury

The meniscus is the shock absorber of the knee and it lies on top of the tibia between the tibia and the femur. A meniscus tear may accompany an ACL injury. This type of injury often results from fixed-foot rotation in weight bearing with the knee flexed during sports activities, such as football, soccer, basketball, or skiing. After the injury, mild swelling occurs and there is joint pain. Popping, slipping, catching, or buckling of the knee can occur. Diagnosis is by physical examination to elicit a "click" and localized pain with particular movements of the joint. MRI is the most specific diagnostic test for a meniscal injury. Surgery for repair is done arthroscopically. Postoperatively, pain management is a priority. An exercise program is prescribed for muscle strengthening during recovery.

Achilles Tendon Rupture

The Achilles tendon attaches the soleus, plantaris, and gastrocnemius muscles to the calcaneus (heel bone). When overstretched, it can rupture. Sports injuries or a fall from a height are the usual mechanisms of injury. Arthritis, diabetes, and taking some antibiotics and other medications can predispose to Achilles tendon rupture. Injury most often occurs with bursts of jumping, pivoting, and running, such as occur in tennis, basketball, handball, and badminton. Symptoms include sudden pain at the back of the ankle or calf. There may be a loud "pop" or "snap" sound. A depression can be felt or seen 2 inches above the calcaneus. Pain, swelling, and stiffness, and then bruising and weakness, follow. There will be an inability to point the toes or stand on tiptoe. Diagnosis is by examination and squeezing the calf muscles while the patient is lying prone. The toes should point downward; if they do not, there is most likely an Achilles tendon injury.

Treatment may be by splinting, casting, or a combination of splinting or casting with surgery. Recovery takes 6 to 8 weeks, followed by physical therapy.

Bursitis

Bursitis is an inflammation of the bursae, the saclike structures that line freely movable joints. It occurs from injury or overuse and often appears when a person has engaged in an unaccustomed activity, such as shoulder bursitis after digging up the garden plot in the spring. Bursitis may occur in any heavily used joint, but it most commonly occurs in the elbow, shoulder, hip, or knee.

Symptoms are localized tenderness and mild to moderate aching pain that is localized to the joint and is exacerbated by activity of the joint. Swelling may be present. Diagnosis is by history of injury and physical examination. Treatment is to rest the joint by altering aggravating activity and using anti-inflammatory agents, ice, massage, and a compression wrap if there is soft-tissue swelling. If these measures—plus time—do not relieve the symptoms, an injection of cortisone into the bursa may be administered.

Bunion (Hallux Valgus)

A bunion, the most common foot problem, is a painful swelling of the bursa that occurs when the great toe deviates laterally at the metatarsophalangeal joint. It may be hereditary, or it may occur from ill-fitting shoes. Bunions are more common in women than in men. Wearing open-toed shoes of soft leather or athletic shoes that are wider in the toe area helps reduce pain. Metatarsal pads can relieve some of the pressure. Corticosteroid injections are given in the joint if active bursitis is present. Analgesics are used for discomfort. Bone realignment of the big toe with removal of bony overgrowth is performed when walking becomes too painful. Hammertoes are often fixed at the same time.

Carpal Tunnel Syndrome

Etiology, Pathophysiology, Signs, and Symptoms

Carpal tunnel syndrome is a nerve problem that occurs when the median nerve is compressed as it passes through the carpal tunnel in the wrist. It produces pain, numbness, and tingling of the hand, particularly at night. Repetitive movements of the hands and wrists, particularly with constant flexion of the wrist, are contributing causes. Such movement occurs in certain types of factory work

and in computer keyboarding. Sometimes there is no known cause.

Diagnosis, Treatment, and Nursing Management

Diagnosis is by physical examination, a compression test, and possibly electromyography to rule out other causes of symptoms. Treatment by rest, splinting, changing the angle of the wrist during repetitive movements, or steroid injection may solve the problem. If the symptoms are of long duration, muscle atrophy occurs; if sensory loss in the fingers and hands is progressive, surgery is indicated. Surgical decompression of the median nerve by transection of the carpal ligament is performed, usually as an outpatient procedure.

Postoperatively, blood flow must be assessed hourly by checking color, warmth of the fingertips, and capillary refill. After anesthesia has worn off, sensation of the fingers is assessed. The wrist is immobilized in a splint and the arm is elevated on pillows to reduce edema. The patient is warned to avoid heavy gripping and pinching for up to 6 weeks.

Fractures

Etiology and Pathophysiology

A **fracture** is a break or interruption in the continuity of a bone. Fractures occur mostly from trauma but result from a pathologic process in which bone has degenerated, such as in **osteoporosis** (metabolic bone disorder that causes a decrease in bone mass) or another metabolic problem. The **mechanism of injury**, or how the injury occurred, can provide clues about the type of fracture. For example, if a patient punches a wall or another solid surface, the fifth metacarpal commonly breaks and the patient sustains a “boxer’s fracture.” Mechanism of injury is also important to help predict injury to the neighboring tissues (see Chapter 43). Damage varies according to the type of fracture, but there is always some degree of tissue destruction, interference with the blood supply, and disturbance of muscle activity at the site of injury.

Safety Alert

Proton Pump Inhibitors and Fracture Risk

In May 2010, the Food and Drug Administration (FDA) issued a warning that proton pump inhibitors (PPIs), including over-the-counter types, increase the risk for fracture of the hip, wrist, and spine. In epidemiologic studies, the risk was highest for people older than 50 years who had used PPIs for more than a year (Ault, 2010). Calcium and vitamin D supplements should be taken when a patient is taking a PPI long term.

Signs, Symptoms, and Diagnosis

A fracture may cause minimal to severe pain depending on the type of fracture, the bone(s) involved, and the amount of displacement. Swelling usually occurs, and there may be bleeding into the tissues. Other symptoms of a fracture include pain, tenderness, deformity of the bone, ecchymoses, crepitus with any movement, and loss of function. **Box 32-1** presents the most common types of fractures. **Figure 32-1** illustrates the characteristics of a variety of fractures. Diagnosis is by physical and radiographic examination.

Older Adult Care Points

Older adults are more at risk of sustaining a fracture because of decreased reaction time, failing vision, reduced agility, alterations in balance, and decreased muscle tone, all of which predispose to falls. Nurses should assess for fall risk and initiate fall precautions as needed. Balance exercises can be very helpful in preventing fractures, as can the use of assistive devices.

Box 32-1

Types of Fractures

- **Complete fracture** is when a bone breaks into two parts that are completely separated.
- An **incomplete fracture** is when a bone breaks into two parts that are not completely separated.
- A **comminuted fracture** is one in which the bone is broken and shattered into more than two fragments.
- A **closed (simple) fracture** is one in which there is no break in the skin.
- An **open (compound) fracture** is one in which there is a break in the skin through which the fragments of broken bone protrude.
- A **greenstick fracture**, common in children, is one in which the bone is partially bent and partially broken.

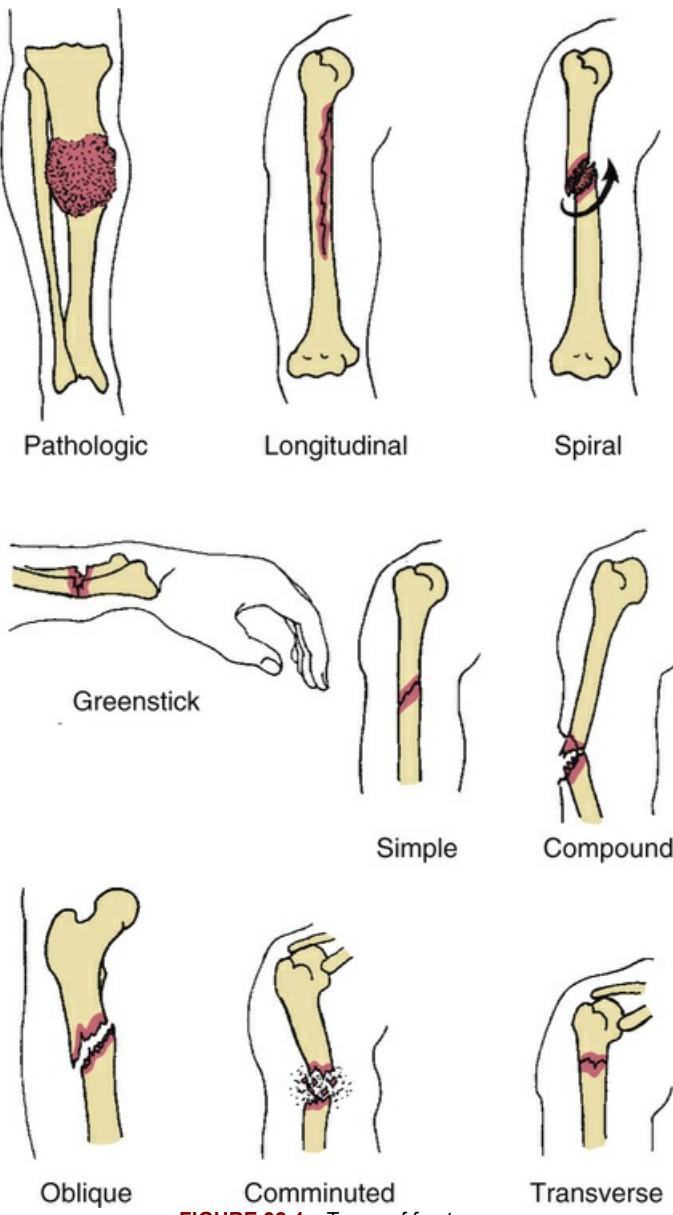

FIGURE 32-1 Types of fractures.

Treatment

The emergency treatment and nursing care of fractures consists of preventing shock and hemorrhage and the immediate immobilization of the part to prevent unnecessary damage to the soft tissue adjacent to the fracture. An inexperienced person should never attempt to straighten or set a broken bone. The injured part should be immobilized in the position in which it is found at the time of injury: "splint it as it lies." The limb should be supported firmly so that it will not be jarred when the patient is being moved. If available, ice in a plastic bag can be applied to the fracture area to help minimize swelling.

In the emergency department or clinic, the patient will be examined by a health care provider, and a radiograph will be ordered if fracture is suspected. After a radiograph of the injured part has been made and the type of fracture and extent of damage have been established, a decision is made as to which method to use in reducing the fracture and providing immobilization. Surgery may be necessary to realign the bones and to reduce the fracture. If the skin was broken when the fracture occurred, tetanus immunization is given unless immunization is current. Prophylactic antibiotics are usually administered when a compound (open) fracture has occurred.

The primary goal in the treatment of fractures is to establish a sturdy union between the broken ends so that the bone can be restored to continuity. The healing and repair of a fracture begin immediately after the bone is broken and proceed through five stages:

1. Blood oozes from the torn blood vessels in the area of the fracture; the blood clots and begins to form a hematoma between the two broken ends of bone (1 to 3 days).
2. Other tissue cells enter the clot, and granulation tissue is formed. This tissue is interlaced with capillaries, and it gradually becomes firm and forms a bridge between the two ends of broken bone (3 days to 2 weeks).
3. Young bone cells enter the area and form a tissue called *callus*. At this stage, the ends of the broken bone are beginning to "knit" together (2 to 6 weeks).
4. The immature bone cells are gradually replaced by mature bone cells (ossification), and the tissue takes on the characteristics of typical bone structure (3 weeks to 6 months).
5. Bone is resorbed and deposited, depending on the lines of stress. The medullary canal is reconstructed during consolidation and remodeling (6 weeks to 1 year).

To facilitate the process of repair and ensure proper healing of the bone without deformity or loss of function, the surgeon must bring the two broken ends together in proper alignment and then immobilize the affected part until healing is complete. The procedure for bringing the two fragments of bone into proper alignment is called *reduction of the fracture*.

Reduction, surgery, and stabilization.

There are two methods to reduce a fracture: closed reduction and open reduction. In **closed reduction**, the bone is manipulated into alignment; no surgical incision is made. A general anesthetic may be given before the fracture is reduced. An **open reduction** is performed after a surgical incision is made through the skin and down to the bone at the site of the fracture. In cases of open (compound) fractures and comminuted fractures, an open reduction is necessary so that the area can be adequately cleansed and bone fragments removed.

There are four methods of stabilizing a fracture after it has been reduced:

1. Internal fixation
2. External fixation
3. Casts, splints, or braces
4. Traction

Internal fixation.

When a fracture cannot be completely reduced by either open or closed reduction and it is impossible to guarantee adequate union of the bone fragments, the surgeon must perform **internal**

fixation of the bone. This means that pins, nails, screws, rods, or metal plates must be used to stabilize the position of the two broken ends. Internal fixation is particularly necessary to treat fractures in older adults whose bones are brittle and may not heal properly (Figure 32-2).

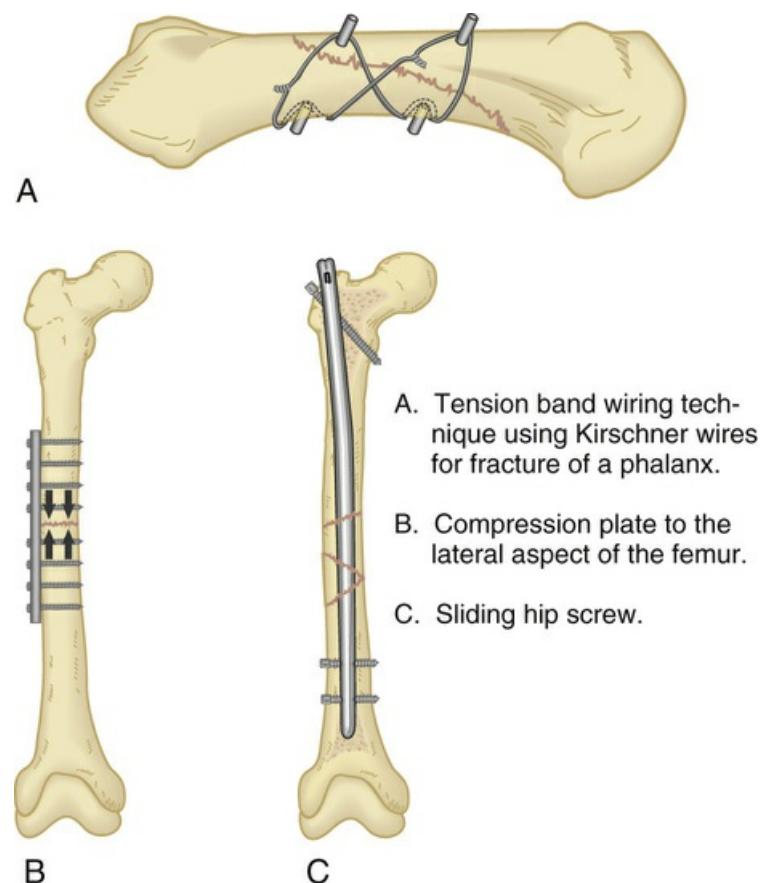

FIGURE 32-2 Examples of internal fixation. **A**, Tension band wiring technique using Kirschner wires for fracture of a phalanx. **B**, Compression plate to the lateral aspect of the femur. **C**, Sliding hip screw. (From Black JM, Hawks JH: *Medical-surgical nursing: Clinical management for positive outcomes*, ed. 8, Philadelphia, 2009, Saunders.)

One of the most common internal fixation procedures is performed on a fractured hip: open reduction and internal fixation (ORIF). An incision is made, the fracture is realigned, and the bone is secured with pins, screws, nails, or plates. A drain will be in place until there is scant drainage (i.e., less than 30 mL in 8 hours). If a prosthesis is implanted, there will be more blood loss and the patient may receive autotransfusion of salvaged blood after surgery. Administration of intravenous (IV) antibiotics to reduce the risk of infection is standard. Care includes maintaining good alignment of the affected leg, preventing complications of immobility, and keeping the patient comfortable with pain control measures.

External fixation.

External fixation of fractures involves the use of a device composed of a sturdy external frame to which are attached pins that have been placed into the bone fragments. Figure 32-3 shows a fixator that is applied by inserting heavy pins on either side of the fracture and then reducing the fracture by tightening nuts attached to the connecting rods.

FIGURE 32-3 External fixation.

External fixation is commonly used for fractures of an extremity or of the pelvis. Indications include:

- Massive open fractures with extensive soft-tissue damage
- Infected fractures that do not heal properly
- Multiple trauma with one or more fractures and other injuries, such as burns, chest injury, or head injury

External fixation has the advantage of allowing more freedom of movement than traction and usually is more comfortable. With good stability the patient may be able to get out of bed, although he must be assisted and advised not to bear weight on the affected limb. Physical therapy exercises will help the patient prevent many of the problems of immobility, and an occupational therapist can suggest ways to cope with activities of daily living (ADLs). Particularly if the fixator must remain in place for months or years, the patient is likely to have problems with self-image and may feel embarrassed or frustrated about being out in public with an apparatus that is large and bulky.

Casts.

Casts are used for stabilizing a fracture after a closed reduction. A cast is rigid and immobilizes the injured body part. The newer fiberglass and polyester-cotton knit casts are lightweight, dry quickly, and can bear weight within 30 minutes of application ([Figure 32-4](#)). They are less bulky, do not crumble easily, and are less likely to be damaged by wetting. However, synthetic casts cost three to seven times more than plaster casts. They are less easily molded to a body part than are plaster casts, and synthetic casts are not suitable for immobilizing the fragments of severely displaced bones or for stabilizing serious fractures. Their rough exterior surfaces can damage the skin and tend to snag clothing and other soft materials. Synthetic casts are used mostly for upper-extremity fractures. Some providers still use plaster of Paris casts for lower extremities because plaster casts can bear more weight and last longer with weight bearing. A newly applied plaster cast usually is not dry for about 48 hours. A dry plaster cast is white, has a shiny surface, and will resound when tapped. A wet plaster cast is grayish and dull in appearance and will give a dull thud when tapped. The edges of plaster casts tend to crumble, with bits of plaster dropping down inside the cast and causing the patient discomfort and skin irritation. This can be prevented by covering the rims of the cast with stockinette or applying tape in a “petal” fashion.

FIGURE 32-4 Synthetic limb cast.

There are **long-leg** and **short-leg** casts, classified by how much leg they cover. A walking **cast shoe** is a canvas sandal with a thick sole that fits over the bottom of the leg cast; this shoe can be used once the patient is allowed to bear weight. When an arm cast is applied, a sling is often used to support the arm and provide extremity elevation. A **spica** cast covers the trunk of the body and one or two extremities. There are long-leg and short-leg spicas that cover one or both legs and shoulder spicas that include the trunk and one arm.

When a surgical repair has occurred, casting is delayed for 1 to 2 weeks until the patient is seen in the office. Casts must be kept dry to prevent infection of the surgical wound. A wet cast must be changed as soon as possible.

Braces and splints.

Braces provide support for fractures that have been reduced. The advantage of a brace is that it can be easily removed for assessment and care of the skin, and then reapplied. Examples include a commercial fracture boot to support the distal tibia, ankle, and foot (Figure 32-5). A hinged brace is used for the elbow and knee, which allows for early motion of the joint. An adjustable dial allows for variations in flexion and extension during recovery. A knee immobilizer prevents motion and provides compression to reduce pain and swelling. Plaster of Paris can be used to create a “backslab” or splint (a slab of plaster that provides support, but does not completely surround the injury). The slab is useful in the early phase because of the swelling that occurs after the injury (Chow et al, 2013).

Clinical Cues

Before cast application (especially plaster of Paris), advise the patient that he will feel warmth as the cast sets and dries. Never put a fresh cast over plastic; the heat generated may burn the skin because it cannot dissipate. A fresh plaster cast should never be covered; air circulation speeds drying.

FIGURE 32-5 Walking boot. (From Roberts JR, Hedges JR: *Clinical procedures in emergency medicine*, ed. 5, Philadelphia, 2009, Saunders.)

Traction.

Traction was used more commonly in the past. Current applications of traction for adults are primarily Buck traction for a hip fracture when there is a delay in going to surgery for repair. Skeletal traction is simple, takes minutes to apply, is inexpensive, and involves no need for anesthesia. It is a good temporary measure unless the patient is undergoing anesthesia for other reasons (Scannell, 2010).

Traction is the application of a mechanical pull to a part of the body for the purpose of extending and holding that part in a certain position during immobilization. The two general types of traction are **skeletal traction** and **skin traction**. In skeletal traction, the surgeon inserts pins, wires, or tongs directly through the bone at a point distal to the fracture so that the force of pull from the weights is exerted directly on the bone. Skeletal traction uses 10 lb or more of weight, and the body acts as the countertraction. With skin traction, a bandage (such as moleskin) or a foam traction boot is applied to the limb below the site of fracture, and pull is exerted on the limb. No more than 7 to 10 lb of weight is used for skin traction. Traction may be continuous (as in the alignment and resultant immobility of fractured bones), or it may be intermittent (as in traction on the spinal column to relieve the symptoms of a slipped disk or muscle spasms).

Figure 32-6 illustrates some of the common types of traction:

- **Buck extension** is a simple skin traction that is used to treat muscle spasms from fractures of the hip or femur, preoperatively, and for dislocation of the hip.
- **Cervical traction** can be provided through the use of tongs inserted into the skull, the use of a halo device (see Chapter 22), or a head halter.
- **Balanced suspension with the Thomas splint and Pearson attachment** is used to treat fractures of the femur and pelvis. The Thomas splint supports the thigh and knee and provides countertraction. The Pearson attachment supports the lower leg, although it has generally been replaced with the use of external fixation.

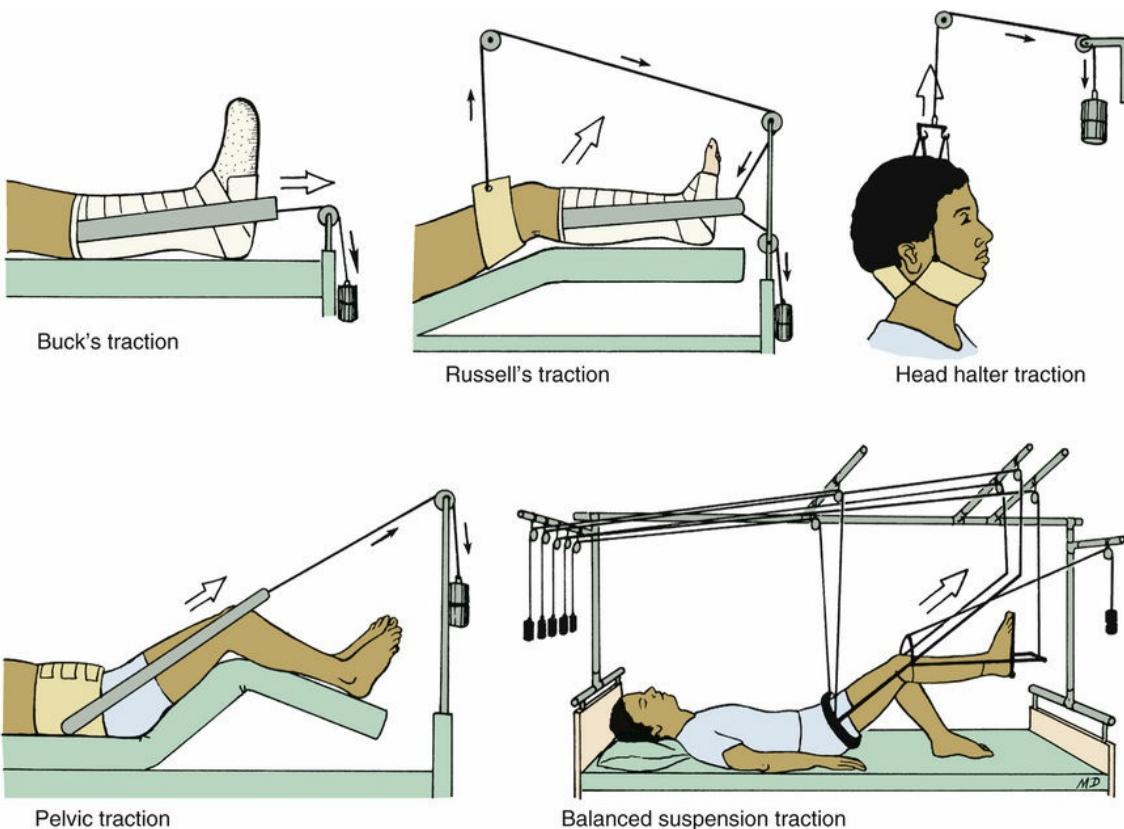

FIGURE 32-6 Common types of traction.

Pelvic traction, Russel's traction and head halter traction are only rarely used now. Skin must be checked regularly under skin traction because breakdown from pressure may occur.

Complications of Fractures

The sooner a fracture is fixed, the less likely the chance for complications. Healing of a fracture can be impeded by improper alignment and inadequate immobilization. Continued twisting, shearing, and abnormal stresses prohibit a strong, bony union. Inadequate levels of serum calcium and phosphorus, vitamin deficiency, and generalized atherosclerosis—which deprives the healing site of adequate blood supply—also can complicate a fracture by delaying healing.

Infection.

Infection of the tissue at the fracture site is probably the most serious impediment to healing. Open comminuted fractures should be surgically addressed within 6 hours to decrease the chance of infection. Prevention of infection after surgery is a 2013 National Patient Safety Goal. Typically cefazolin (Ancef) is administered within 1 hour of incision, and two doses are given postoperatively. If the wound is grossly contaminated, additional antibiotics will be prescribed. It is important to monitor the patient's temperature and white blood cell (WBC) count for elevations and assess the appearance of the area carefully for redness, swelling, heat, or purulent drainage.

Osteomyelitis.

Osteomyelitis is a bacterial infection of the bone. It is common in diabetic ulcers left untreated or that won't heal. The causative organism is most often *Staphylococcus aureus*, which enters the bloodstream from a distant focus of infection, such as a boil or furuncle, or from an open wound, as in an open (compound) fracture. It is usually found in the tibia or fibula, in vertebrae, or at the site of a joint prosthesis. Osteomyelitis has a sudden onset with severe pain and marked tenderness at the site, high fever with chills, swelling of adjacent soft parts, headache, and malaise. Diagnosis of osteomyelitis is made on the basis of:

- Laboratory findings indicating an acute infection, such as high sedimentation rate and WBC count
- Radiographs, which may show bone destruction 7 to 10 days after onset of the disease

- History of injury to the part, open fracture, boils, furuncles, or other infections
- Biopsy, in which the bone sample exhibits signs of necrosis

The earlier osteomyelitis is diagnosed and treated, the better the prognosis. Intravenous antibiotics are often needed, and antibiotics are prescribed for 4 to 6 weeks; the abscess is incised and drained. Dead bone and debris are debrided from the site. The affected limb is immobilized for complete rest. Sometimes amputation is the only cure (see [Chapter 6](#) for care related to infection).

Nonunion.

Nonunion (failure to heal) of a fracture can be treated by an electrical bone growth-stimulating device, which uses electrical coils or electrodes to induce weak electrical current in the bone to stimulate healing properties. Examples include an external electromagnetic device, a percutaneous stimulator with electrodes placed at the fracture site, or an implanted direct current stimulator with a current that stimulates **osteogenesis** (growth of bone cells). Use of such devices can prevent further surgery and bone grafting. This treatment is based on the fact that bone has inherent electrical properties used in healing.

Fat embolism.

Fat embolism is a rare but serious complication of a fracture of a bone that has an abundance of marrow fat (e.g., the long bones, pelvis, and ribs). In the early postinjury period, patients with multiple fractures resulting from severe trauma are at risk for this complication. To form an embolism, the fat globules must be large enough or sufficient in number to partially or completely occlude a blood vessel. Rupture of small venules in the area permit entrance of fat globules into the circulation. **Signs and symptoms of fat embolism include a change in mental status, respiratory distress, tachypnea, crackles and wheezes on auscultating the lungs, rapid pulse, fever, and petechiae (a fine red rash over the chest, neck, upper arms, or abdomen).** Stay with the patient; put him in a high Fowler's position, use a nonrebreather mask to give high-flow oxygen, and establish a peripheral IV line. Summon the provider immediately because there is an approximate 80% mortality rate from this complication. Anticipate hydration with IV fluids and correction of acidosis. Intubation and mechanical ventilation may also be needed if oxygen levels cannot be maintained with supplemental oxygen.

Older Adult Care Points

Older adults with a fractured hip are at high risk for fat embolism. Be especially vigilant and assess for this complication.

Venous thrombosis.

The veins of the pelvis and lower extremities are very vulnerable to thrombus formation after fracture, especially hip fracture. Immobility, traction, and casts may contribute to venous stasis. The Joint Commission's National Quality Core Measures call for aggressive prevention of thrombus formation. Compression stockings, sequential compression devices, and ROM exercises on the unaffected lower extremities are used to help prevent the problem. To meet the 2013 National Patient Safety Goals, nurses must be vigilant for the adverse effects of prophylactic anticoagulant drugs that may be prescribed, such as aspirin, warfarin, or low-molecular-weight heparin, and must be observant for instances of bleeding. Fondaparinux (Arixtra), a new class of antithrombotic drug inhibiting factor Xa, a blood clotting component, may be administered along with warfarin sodium. Rivaroxaban (Xarelto) is a new once a day drug that doesn't require blood coagulation monitoring.

Compartment syndrome.

Compartment syndrome is a restriction of blood flow that occurs in one or more muscle compartments of the extremities. Compartment syndrome is caused by external or internal pressure. External pressure can occur from dressings or casts that are too tight. Internal pressure occurs from IV fluid infiltration, inflammation, and edema (a shifting of fluid from the vascular spaces to the intracellular spaces). The increased fluid puts pressure on the tissues, nerves, and blood vessels, thereby decreasing blood flow.

Clinical Cues

Elevation is the key to preventing swelling and compartment syndrome; toes and fingers should be higher than the trunk.

The main sign of compartment syndrome is severe, unrelenting pain that is out of proportion to the injury and unrelieved by narcotics. Decreased sensation, numbness and tingling, paleness of the skin, and weakness of the extremity are other signs. Assess for the six *Ps*: pain, pallor, paresthesia, pulselessness, paralysis, and poikilothermia (cold to the touch).

Recognition and immediate notification of the provider can prevent permanent loss of function. If a cast is in place, the cast can be **bivalved** (split through all layers of the material). Dressings will be cut or replaced. Surgical **fasciotomy** (linear incisions in the fascia down the extremity) may be necessary to relieve the pressure on the nerves and blood vessels if other measures do not relieve the problem. [Figure 32-7](#) shows the fascial compartments of the calf and forearm.

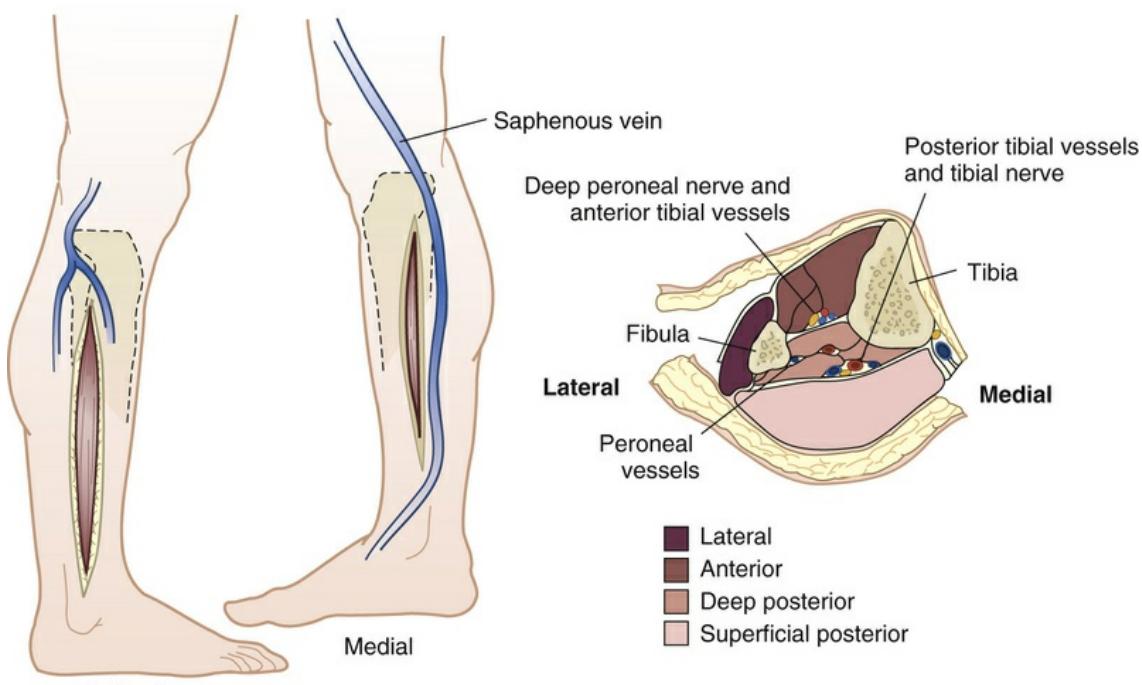

FIGURE 32-7 Fascial compartments of the calf and forearm. (From Townsend CM, Beauchamp RD, Evers BM, et al: *Sabiston textbook of surgery*, ed. 19, Philadelphia, 2011, Saunders.)

Nursing Management

Data Collection (Assessment)

Pretreatment

Ask the patient to describe the mechanism of injury. Physical assessment of a suspected fracture includes noting pain, swelling, discoloration, and deformity in the contour of the bone. With a possible extremity fracture, pulses should be bilaterally checked and compared. Nerve damage in a fractured leg is assessed by having the patient flex and extend his foot. Next obscure the patient's view and touch a toe with a sharp and then a dull object (e.g., the wooden end and then the cotton-tip end of an applicator, respectively); ask him to identify which toe was touched and to discriminate sharp and dull touch. For checking nerve damage in the arm, have the patient wave his hand, have him grip your hand, and use the sharp/dull touch test on the fingers.

Safety Alert

In-depth assessment and history must be delayed if a broken bone has pierced the skin and the bleeding is severe. Apply direct pressure over the wound. (Observe for shock and treat if necessary.) Prevent introduction of infectious agents into the wound and cover the open area with a sterile dressing (clean dressing if sterile supplies are not available).

Clinical Cues

In cases of fracture, assessment (six *P*s) of extremities should be done bilaterally. Also remember to ask if the patient is left- or right-hand dominant; dominance can account for a weaker grip, and if the dominant hand is injured it will affect performance of ADLs.

Pain is not always present when a fracture has occurred. Numbness and tingling can also accompany a fracture. **If it is unclear whether a bone has been broken, it is best to treat the injury as if it is a fracture.** To prevent further trauma and pain, splint the area without moving or manipulating bone. Apply an ice pack, if available, and notify the provider of your findings.

Think Critically

If you were in the park and you observed a child fall from a tree and obviously fracture a forearm, what would you do to assist?

Posttreatment

Attention to pain control is important, especially when the patient is adjusting to fixation devices or a new cast. If elevating the limb or giving prescribed pain medication does not relieve the patient's complaints within 30 minutes, notify the provider.

Focused Assessment

Physical Assessment of Neurovascular Status

Assessment should be performed at least once at the beginning of each shift to establish a baseline for any patient who has suffered a musculoskeletal injury and then performed as required. When a fracture is fresh, this assessment should be performed every 2 to 4 hours.

- *Skin color:* Is the skin pale (decreased blood), blue (decreased oxygenation), bruised (bleeding into surrounding tissues), or red (possible infection)?
- *Skin temperature:* Is the skin increasingly hot to the touch (infection) or cool (decreased blood flow)? Use the back of your hand to do the assessment.
- *Pulses:* Are pulses distal to the injury present and equal bilaterally?
- *Movement:* Can the patient actively move the affected area or the area distal to the injury? If active movement is not possible, passively move the area distal to the injury. How much discomfort is felt with movement?
- *Sensation:* Is numbness or tingling present (paresthesia)? Obscure the patient's view and gently touch a distal area with a paper clip. What and where does the patient feel?
- *Pain:* Where is the pain? What is the nature and intensity? Is pain increasing?
- *Capillary refill:* Does blanching occur when a nail bed distal to the injury is pressed? Assess by pushing on a nail bed, let up, and count the time it takes for color to return. Usual color should return in 3 to 5 seconds.

A thorough assessment of a patient in a cast should include the following:

- Complaints of numbness, a tingling sensation, increased pain with motion of the fingers or toes, or sharp localized pain, which can be caused by pressure from a tight cast. Notify the provider if the patient states that he can feel the bone fragments grating against each other (crepitation).
- Check frequently to determine whether the cast is properly supported or there is undue pressure on any underlying part of the body. A sharp, localized, burning pain could mean the beginning of a pressure sore. This should be reported so that the surgeon or orthopedic technician can cut a "window" in the cast to relieve pressure.
- Sniff at the edges of the cast to detect foul odors that are suggestive of infection.

Every immobilized patient should be routinely assessed for the various problems of immobility: skin breakdown, urinary tract infection, constipation, atelectasis, or deep vein thrombosis (DVT). Adequate nutrition and fluids are needed to promote healing and prevent the problems of immobility.

Nutrition Considerations

Nutrition for Immobile Musculoskeletal Patients

Protein is essential to healing, and the diet should be designed to provide 1 g/kg of body weight. Vitamins D, B, and C and calcium are included in well-balanced meals to ensure optimal soft tissue and bone healing; 500 mg of vitamin C will also help acidify the urine and prevent calcium precipitation that could form kidney stones. Fluid intake of 2000 to 3000 mL/day helps prevent bladder infection, kidney stones, and constipation. A high-fiber diet with lots of vegetables and fruits promotes good bowel function and decreases the chance of constipation. A patient in a hip spica cast or body jacket should receive six small meals a day to prevent abdominal distention and cramping.

Think Critically

During your neurovascular assessment, you note some decreased sensation and tingling in the fingers of a patient with a lower arm cast. What should you do?

Nursing Diagnosis and Planning

Problem statements for patients with fractures usually include:

- Pain due to disruption of bone and tissue.
- Altered physical mobility due to disruption of bone.
- Altered self-care ability due to inability to use an extremity.
- Potential for infection due to open fracture.

Specific nursing diagnoses can be chosen from the NANDA-I list (see inside back cover).

Implementation

Traction devices must be assessed to ensure that they are in correct position and that the weights are hanging free. The patient's body position should be assessed for proper alignment. **Box 32-2** presents points of care.

Box 32-2

Points of Care for a Patient in Traction

- Keep the patient in the center of the bed in a supine position.
- Keep the body part in traction in a straight line with the trunk. Misalignment causes pain.
- Be sure the weights are hanging free. If the weights are resting on or against any support, such as

the foot of the bed or the floor, the purpose of the traction is defeated. Be careful not to bump against the weights when walking around the foot of the bed. This can be painful to the patient and may cause damage to the healing bone. It is not necessary to lift the weights when pulling the patient up in bed. The amount of pull on the limb will remain the same as long as the weights are hanging free. Also check that the ropes run over the midline of the pulley without interference. Keep knots away from the pulleys, and arrange bedding so that it does not interfere with the ropes and pulleys.

- Check the position of the patient, making sure his body weight is counteracting the pull of the weights. Should the patient slip down in bed so that his feet are resting against the footboard, there will be a loss of force exerted on the limb.
- Observe all bony prominences for signs of impaired circulation and pressure or tissue necrosis.
- To prevent pressure sores, be sure slings and ropes are not pressing against or cutting into an area of the extremity.
- When a patient has skeletal traction, observe the sites of entry of pins, tongs, etc. for signs of infection.
- Devise a systematic routine for observing the patient and the apparatus at specified times during the day so that no aspect of the assessment will be overlooked.

The drainage from pin sites may be heavy for 48 to 72 hours after surgery involving external fixation. Meticulous cleaning of pin sites should be performed daily with a 2 mg/mL chlorhexidine solution. The goal is to reduce serosanguineous drainage and crusting that would support infection; also assess for pin loosening ([U.S. Library of Medicine, 2014](#)). Your patient will appreciate a well-organized nurse with a gentle touch who remembers to premedicate 30 minutes before wound and pin care. For a body part with external pins, daily showering is somewhat controversial because the water may wash away the protective residual chlorhexidine, and dressings would need to be changed after every shower (daily dressing changes are of no benefit in preventing infection). Weekly showering may be preferred.

When the patient is transferred from stretcher to bed, use sufficient help; casts or external fixation devices can be significantly heavy. Pillows for support should be placed on the bed **before** moving the patient onto them. Pillows are used to support the curves of large casts so that the weight of the body will not crack or flatten the cast. Patients in a body cast or spica are more comfortable if pillows are not put under their head and shoulders because the pillows push the chest and abdomen against the front of the cast, causing an uncomfortable crushing sensation and dyspnea. **Hardware of an external fixation device or brace bars between the legs of a cast are never to be used as handles for lifting and turning the patient.**

It is important to clarify with the provider how much weight the patient can bear on the affected extremity. Some fractures should have no weight placed on the affected side, whereas other patients will be encouraged to move about without any restrictions.

Care of a Patient With a Cast

While the cast plaster is damp (grayish dull appearance), use the palms of the hands or the flat surface of the extended fingers when touching the cast because fingertips can sink into the damp plaster and make impressions through the cast that rub against the tissue under the cast, predisposing to pressure sores. A plaster cast generates heat as it dries; assess the patient's subjective sensation of heat and pain because burns can occur. **During the first 24 to 48 hours after any cast has been applied to an extremity, the extremity should be elevated to minimize swelling.**

The cast should be inspected every day for flattened areas, soft spots, cracking, and crumbling. The skin around the edges of the cast should receive special attention, including massage with lotion and close observation for signs of pressure or breaks in the skin. Patients must be instructed not to use sharp objects such as pencils or rulers to scratch under the cast. These can tear the skin, leaving an open break for the entrance of bacteria. To relieve itching, use a 60-mL plunger syringe and forcefully direct air under the cast. At home, the patient can use a hair dryer on the coolest

setting to blow air into the cast.

A plaster cast will disintegrate if it becomes wet, so the patient will need assistance with bathing. Patients may have permission to shower with a synthetic cast; a plastic covering is secured over the cast and taped to the skin. Instruct the patient to avoid putting the casted area directly under the stream of water.

Depending on the injury or the type of cast, traction, or fixation device, moving or turning the patient for adequate back care may not be possible. Obtain an order for an overhead trapeze bar so that the patient can lift himself to enable back care to be given and the bottom sheet changed or tightened. Instruct the patient to lift himself straight up so that the amount of pull exerted on a limb in traction will not be altered. This same maneuver can be used when the patient is placed on a bedpan. A small "fracture" bedpan should be used and the lower back supported by a small pillow or folded blanket. When a bedpan is used by a patient in a spica, there is a possibility of a backward flow of urine under the cast unless the head of the bed is slightly elevated. Because the patient cannot bend at the hips to sit up on the pan, the head of the bed should be elevated (on blocks or other device) and the lumbar area of the cast supported to prevent cracking.

When a cast is removed, the underlying skin is usually dry and scaly. Scrubbing of the area must be avoided to prevent damage to the deeper layers of skin, especially because the cast is often reapplied after the provider does an examination. Nursing interventions for selected problems are summarized in [Table 31-4](#).

Clinical Cues

Ice bags can be used to help control swelling. However, because the weight of an ice bag could make an indentation in a wet plaster cast, the ice bags should be only about half full, and they should be laid against the cast and propped in position, rather than set on top of it.

Think Critically

Your patient has an arm cast in place and is complaining of severe itching inside the cast. What could you do to help relieve the problem?

Evaluation

Your patient's pain should be under control, and he should be progressing toward independently accomplishing ADLs at his baseline level within a specified time. There should be no problems associated with immobility (i.e., skin breakdown or constipation, atelectasis, or DVT) or complications (i.e., infection, compartment syndrome). If the outcomes are not being met, the plan must be revised.

Inflammatory Disorders of the Musculoskeletal System

Lyme Disease

Lyme arthritis occurs from a systemic infection caused by the spirochete *Borrelia burgdorferi*. The spirochete is transmitted by the bite of a deer tick. Most cases of this disease are in the New England and mid-Atlantic states, the upper Midwest, Northern California, and Oregon. The disease begins with flulike symptoms and a "bull's-eye" rash with pain and stiffness in the joints and muscles. Doxycycline, cefuroxime, or amoxicillin taken for 10 to 21 days can prevent the disease's progression. If untreated, stage II begins 2 to 12 weeks later with carditis and nervous system disorders such as meningitis, peripheral neuritis, or a facial paralysis similar to Bell palsy. Intravenous antibiotics are necessary at this point. If undiagnosed and untreated, later chronic complications may occur. The patient may experience fatigue, cognition problems, and arthralgias. In some instances the only sign of Lyme disease is arthritis. Lyme arthritis can cause permanent damage to the nervous system and to the joints.

Osteoarthritis

Etiology and Pathophysiology

Osteoarthritis is a noninflammatory degenerative joint disease characterized by breakdown of cartilage in synovial joints. The exact cause is not known, but risk factors include heredity, aging, female gender, obesity, previous joint injury, and recreational or occupational overuse of joints (Lozada, 2015). People with osteoarthritis seem to produce less collagen to strengthen cartilage and cover and protect joints in the body. With time and use, joints become thickened and withstand weight bearing poorly, with consequent damage to cartilage. The synovial cells then release enzymes that cause further cartilage degeneration.

Health Promotion

Healthy People 2020 Goals Related to Arthritis

The objectives aimed at reducing the disability caused by arthritis include:

- Reducing the mean level of joint pain, activity limitations, care limitations, effect on employment, and the proportion of those who find it "very difficult" to perform specific joint-related activities.

- Increasing health care provider counseling for weight and physical activity; increasing the proportion of those seeing a health care provider for joint symptoms and effective evidence-based arthritis education as an integral part of the managing condition.

Signs, Symptoms, and Diagnosis

Osteoarthritis occurs asymmetrically and typically affects only one or two joints. The chief symptoms are aching pain with joint movement and stiffness, with limitation of mobility. Joints may be deformed, and nodules may be present.

Treatment

Treatment consists of pain management, strengthening and low-impact aerobic exercise, weight reduction if the patient is overweight, and maintenance of joint function. Salicylates, acetaminophen, or NSAIDs may be used. Acetaminophen in doses of 1000 mg, up to 3000 mg/day, is the standard for patients with mild to moderate chronic joint pain.

Safety Alert

Acetaminophen Usage

All other medications and over-the-counter drugs should be checked for acetaminophen so that overdose does not occur. Taking more of this drug than recommended (no more than 4000 mg/day in the short term, or 3000 mg/day for longer-term use) can cause irreversible liver damage. The drug should not be taken when drinking alcohol. For older adults, the lowest effective dose should be used. Encourage an adequate intake of water, at least 2000 mL each day, to promote excretion of the drug via the kidneys.

Older Adult Care Points

NSAIDs may not be recommended for older adults because of side effects and interactions with other drugs that older adults may be taking. NSAIDs decrease effectiveness of the angiotensin-converting enzyme (ACE) inhibitors used for hypertension and heart failure, and NSAIDs increase the effects of anticoagulants. Tramadol may be prescribed.

Clinical Cues

Monitor patients taking NSAIDs for gastrointestinal (GI) intolerance. Assess liver, kidney, and central nervous system function frequently. Watch for signs of blood dyscrasias, and check for tinnitus and hearing loss regularly. The side effects of NSAIDs can be serious and sometimes permanent. If early signs of toxicity appear, they should be reported promptly to the provider.

Corticosteroid injection into the arthritic joint may be performed if oral medication does not control the problem. Exercises for joint mobility are encouraged. Surgery or joint replacement may be performed to relieve severe pain and improve mobility. The hip and knee are the most common sites for joint replacement related to osteoarthritis.

Complementary and Alternative Therapies

Therapies for Pain Relief

Yoga and massage can help to control and relieve the pain of osteoarthritis. Capsaicin cream, or ointment made from cayenne red pepper, blocks pain locally when applied topically to the inflamed joint. It can be used four times a day. It is available over the counter or by prescription. In a research study, [Shimoda and colleagues \(2010\)](#) found that red ginger has anti-inflammatory properties that relieve arthritis pain.

Complementary and Alternative Therapies

Glucosamine and Chondroitin

Glucosamine and chondroitin have been shown in a research study to decrease the pain of moderate to severe osteoarthritis in some people. This substance may slow or halt the progression of osteoarthritis. Patients may try 1500 mg of glucosamine sulfate per day as a trial dose ([WebMD, 2015](#)). Patients taking warfarin (Coumadin) should check with their health care provider before starting glucosamine.

Injections of hyaluronic acid (HA) (Euflexxa, Orthovisc, Synvisc, Supartz, and Hyalgan) into the joint can act as a lubricant and decrease pain and improve function for some patients with mild to moderate osteoarthritis. The intraarticular injections are given once a week for 3 to 5 weeks and may be repeated in 6 months. Stem cell treatments are another option being explored.

Another treatment for knee cartilage injury is the injection of autologous chondrocytes. Healthy articular cartilage cells are removed from the patient and sent to a special laboratory, where they are grown for 3 to 5 weeks and then reimplanted. Patients use crutches for 6 to 8 weeks after the surgery. The procedure is successful in about 85% of all cases. It works best in patients younger than 50 years with injury to a small focal area of cartilage ([Orozco et al, 2013](#)).

Nursing Management

Nursing interventions for osteoarthritis include teaching the patient to balance exercise and rest. Gentle exercise is very important in maintaining joint mobility. Walking, knitting, and swimming all help improve mobility and decrease pain. The patient should avoid placing stress on affected joints. Suggest the use of assistive devices to open containers and perform other household functions.

Instruct in moist heat application, and encourage the patient to maintain weight within normal limits. Weight reduction decreases joint stress. Imagery, relaxation, and diversion are helpful to reduce pain. Quadriceps strengthening exercises may relieve pain and disability of the knee (see [Patient Teaching: Quadriceps and Gluteal Muscle Exercises](#) in Chapter 31).

Think Critically

Where would you suggest a patient look for assistive devices available for those with arthritis?

Rheumatoid Arthritis

Etiology and Pathophysiology

Rheumatoid arthritis (RA) is an inflammatory disease of the joints. It can occur at any age but is most common among older women. The cause is not known, but hormonal, environmental, genetic, or infectious agents may trigger an underlying autoimmune reaction. An abnormal immune response causes an inflammatory reaction of the synovial membrane. Vasodilation, increased permeability, and the formation of exudate cause red, swollen joints. Rheumatoid factor (RF), which is an antibody against immunoglobulin G, appears in the blood and synovial fluid in many patients.

There are remissions and exacerbations of the disease. As the disease progresses, pannus is formed. **Pannus** is granulation tissue derived from the synovium that spreads over the articular cartilage. Pannus releases enzymes and inflammatory mediators that destroy cartilage. The cartilage becomes eroded, and the pannus cuts off nutrition to the cartilage. Over time, the pannus between the bone ends becomes fibrotic, causing ankylosis. Joint fixation and deformity become apparent. Along with these changes, exacerbations cause more damage, and there is atrophy of muscles around the joint. Tendons and ligaments stretch, and the joint becomes unstable. Muscle spasm draws the bones out of normal alignment. Contractures and deformity occur. Mobility becomes impaired if the knees or ankles are affected. Subcutaneous nodules may form over bony prominences, and nodules may occur in the pleura, heart valves, or eyes.

Signs, Symptoms, and Diagnosis

The signs and symptoms of RA are joint pain, warmth, edema, limitation of motion, and multiple joint stiffness in the morning lasting more than 1 hour. The joints of the hands, wrists, and feet are most commonly affected by RA, and involvement is usually bilateral. Systemic symptoms of low-grade fever, anorexia with weight loss, malaise, and an iron deficiency anemia resistant to iron therapy may also be present. Joint deformity and consequent dysfunction can occur.

RA pain or immobility of joints interferes with self-care activities necessary to lead an independent lifestyle. Maintaining mobility and controlling pain with the least amount of side effects are the goals for the older adult. [Table 32-1](#) presents a comparison of osteoarthritis and rheumatoid arthritis.

Table 32-1
Comparison of Rheumatoid Arthritis and Osteoarthritis

CHARACTERISTIC	RHEUMATOID ARTHRITIS	OSTEOARTHRITIS
Definition	A systemic disease where pathologic changes and disability result from chronic inflammation of the joints	A progressive degenerative joint disease
Pathology	Chronic inflammation of synovial membranes and formation of chronic granulation tissue (pannus) in the joint; pannus capable of eroding cartilage in joints and spreading to bone, ligaments, and tendons	Microscopic changes in the cartilage in the joint; eventually loss of cartilage, bony enlargement, and malalignment of joints
Etiology	Unknown; evidence that the pathologic changes are immunologic	Unknown; may be caused by "wear and tear" of aging
Rheumatoid factors (autoantibodies)	Usually present	Usually absent
Age at onset	30-40 yr most common, but at any age	50-60 yr; rarely before age 40 yr
Weight	Normal or underweight	Usually overweight
General state of health	Varies; often anemic, "chronically ill," with low-grade fever and slight leukocytosis	Well nourished
Appearance of joints	Early: Soft-tissue swelling	Early: Slight joint enlargement

	<i>Late:</i> Ankylosis, extreme deformity	<i>Late:</i> Enlargement more pronounced, slight limitation of motion
	Joint involvement usually symmetric bilaterally and generalized	Joints typically involved are single-sided and weight-bearing: spine, hips, knees
Muscles	Pronounced muscular atrophy, particularly in later stages	Usually not affected
Other	Morning stiffness; pain on motion; swelling and tenderness of joints; subcutaneous nodules; typical rheumatoid changes seen on radiograph	Stiffness, relieved by moderate motion; joint malalignment; symptoms increase in cold, wet weather

Diagnosis is by history of morning stiffness that lasts more than 30 minutes or arthritis pain in three or more joints that lasts more than 6 weeks (Venables et al, 2013). Blood tests for rheumatoid factor (RF), anticitrullinated peptide/protein antibody test (anti-CCP), C-reactive protein, and erythrocyte sedimentation rate are ordered. Radiographs confirm the cartilage destruction and bone deformities.

Treatment

Treatment is aimed at relieving pain, minimizing joint destruction, promoting joint function, and preserving ability to perform self-care (Table 32-2). Rest and exercise, medication, immobilization with splints and use of other supportive devices during periods of severe inflammation, and hot and cold treatments are standard treatments. Surgical joint repair or replacement can reduce pain and improve mobility.

 **Table 32-2**

Drugs Commonly Used to Treat Rheumatoid Arthritis

CLASSIFICATION	EXAMPLES	ACTION	NURSING IMPLICATIONS
Nonsteroidal anti-inflammatory drugs (NSAIDs)	Acetaminophen, aspirin, ibuprofen (Advil, Motrin), naproxen sodium (Aleve), COX-2 inhibitors (Celebrex)	Reduce inflammation and pain	May take 2 wk to obtain results; give with food or a full glass of water, but some are best taken 30 min before a meal or 2 hr afterward. May cause GI irritation. Monitor hematologic, renal, liver, auditory, ophthalmic functions, weight gain, and peripheral edema. Teach patient to report heartburn, dyspepsia, nausea, vomiting, diarrhea, or abdominal pain. Teach to avoid alcohol because of increased risk of GI irritation. Dosage in older adults may need to be reduced by half.
Corticosteroids	Prednisone, methylprednisolone (Medrol)	Reduce inflammation, decrease pain by suppressing the immune system	Usually rapid action. Instruct to take daily dose between 6 and 8 A.M. when natural steroids are released. Instruct not to stop taking this drug abruptly. Taper dosage downward as soon as symptoms improve. Monitor older adults closely for fluid retention, elevated blood pressure, and peripheral edema. Handle patients gently to prevent bruising; avoid using tape on skin. May cause osteoporosis, Cushing syndrome, mood changes, weight gain, cataracts, onset of diabetes, muscle weakness, and increased risk of infection.
Disease-modifying antirheumatic drugs (DMARDs)	Hydroxychloroquine (Plaquenil), sulfasalazine (Azulfidine), gold salts (Ridaura), D-penicillamine (Cuprimine, Depen), methotrexate (Rheumatrex), azathioprine (Imuran), leflunomide (Arava), others	Reduce inflammation and pain, suppress the immune system, and prevent joint and cartilage destruction	Plaquenil takes 6 mo to be effective; others take 1-6 mo. May cause rash, diarrhea, and retinal problems. Instruct that frequent eye examinations are necessary. Most of the drugs can cause GI symptoms and blood dyscrasias; monitor blood counts. Gold salts can cause liver toxicity; monitor liver functions. Methotrexate can cause pulmonary, renal, and liver toxicity. Imuran and leflunomide may cause birth defects or fetal death. Alcohol use increases chance of hepatic toxicity. Monitor blood and urine weekly. Check specific nursing implications for each drug.
Biologic therapies (classifications include tumor necrosis factor inhibitors, interleukin antagonists, selective costimulation modulators, or targeted B-cell therapy)	Etanercept (Enbrel), infliximab (Remicade), Certolizumab (Cimzia), Rituximab (Rituxan), Golimumab (Simponi), Anakinra (Kineret), Adalimumab (Humira), Abatacept (Orencia), Tocilizumab (Actemra)	Reduce inflammation by blocking the inflammatory response	1-2 wk for onset of action. Increased risk of serious infection and blood dyscrasias; monitor blood counts, temperature, and for malaise closely. May cause demyelinating disorders. Given IV or by subcutaneous injection; may cause injection site reaction. Do not immunize with live virus vaccines. Test for tuberculosis before starting these medications.

IV, Intravenously.

Acetaminophen is the first-line agent used for rheumatoid arthritis pain (Kelly, 2012). Other medications include salicylates, corticosteroids, hydroxychloroquine, methotrexate, gold compounds, sulfasalazine, D-penicillamine, and disease-modifying antirheumatic drugs (DMARDs). Tumor necrosis factor (TNF) inhibitors are a newer type of medication. Long-term steroid therapy increases the risk for diabetes mellitus, osteoporosis, hypertension, acne, cataracts, and weight gain; therefore long-term oral steroid preparations are reserved for patients who cannot find relief from other drugs. DMARDs provide periods of remission, but they also have some serious side effects. Patients should be tested for tuberculosis (TB) before being started on TNF inhibitors because these drugs may exacerbate TB.

Complementary and Alternative Therapies

Help Patients to Evaluate the Safety of Complementary and Alternative Therapies

Some patients find symptom relief with dietary supplements such as omega-3 fatty acids, acupuncture, tai chi, and meditation. Research study results for various supplements have been mixed and without conclusive evidence of efficacy. Patients with arthritis are particularly vulnerable to “miracle cures” or outright quackery; therefore it is the responsibility of all health care professionals to initiate a dialogue about complementary or alternative therapies or other

methods that the patient is using to evaluate their safety and to incorporate these self-care methods into the overall plan of care ([National Center for Complementary and Integrative Health Approaches, 2015](#)).

The injection of steroids directly into a joint (intra-articular administration) has been used successfully in treating painful flare-ups, shortening the period of inflammation, and relieving pain and other symptoms. When intra-articular steroid therapy is used, it is recommended that not more than two or three doses be injected into any joint within 1 year.

Older Adult Care Points

Older adults must be taught to watch for side effects of medications and promptly report them to the provider or nurse. Dizziness, which predisposes to falls, can occur with analgesics for arthritis pain, particularly if the medication contains codeine. Advise patients to arise slowly, hold on to furniture until steady, use assistive devices, and wait for dizziness to pass before walking.

Surgical intervention and orthopedic devices.

Casts or braces and splints (**orthoses**) may be used to immobilize an affected part so that it can rest during an active phase of arthritis. Devices that immobilize the affected joint should allow for motion of adjacent muscles to maintain them and improve strength and permit more independence. Braces help prevent deformities by maintaining an optimal functional position of the joints.

In the past, surgical intervention for arthritis was reserved for patients who already had severe joint deformity and loss of motion. Currently, the trend is to use surgery in the early stages of arthritis to prevent, or modify, deformities and mechanical abnormalities. One such surgical procedure is **synovectomy**, which is the excision of the synovial membrane of a joint. The goal of synovectomy is to interrupt the destructive inflammatory process that eventually leads to ankylosis and invasion of surrounding cartilage and bone tissues. Tendon reconstruction is performed most commonly on the hand to restore function. For younger patients with osteoarthritis, **osteotomy** may be an option. In this procedure a wedge of bone is removed to allow for realignment.

Joint replacement.

An **arthroplasty** (joint replacement) may be done for a knee, shoulder, elbow, finger, ankle, or hip. The hip and knee are the most commonly replaced joints. Noncemented press-fit prostheses are often used now for young, heavier, and very active patients. The cement used for bone prostheses may last 20 years.

Total hip replacement.

The primary purpose of total hip replacement (THR) is to relieve chronic pain. Hip replacement for osteoarthritis can be performed with minimally invasive surgery and a shorter hospital stay for some patients. A hip joint may be replaced with either a low-friction polyurethane socket for the acetabulum and a metallic replacement for the head of the femur or with synthetic materials combined with a porous bone implant ([Figure 32-8](#)). The porous bone implant requires 6 weeks of healing, and patients with cemented prostheses refrain from full weight bearing for 4 to 6 weeks. For some patients, full weight bearing is avoided for at least 3 to 6 months. Crutches or a walker are used for ambulation, depending on the ability of the patient. The greatest dangers to successful replacement are infection and failure to function properly. Possible dislocation when the hip is internally rotated is an issue.

FIGURE 32-8 Hip replacement prosthesis. (Image reprinted with permission from Stryker Corporation. © 2013 Stryker Corporation. All rights reserved.)

Hip resurfacing may be done for patients younger than 60 years. This procedure can help with pain, improve ambulation, and restore joint function. The procedure involves trimming the head of the femur and placing a metal cap over the end. The damaged bone in the socket is removed and replaced with a metal cup, and the capped end rotates in the cup (Manner, 2013). The advantage of this procedure is that there is greater range of hip motion than for a hip replacement, and dislocation is less of a risk.

Preoperative care.

Specific instructions about the kind of surgery to be performed, the prosthesis to be used, the postsurgical procedures, and what is expected of the patient to help achieve the goals of rehabilitation are given. Instructions for postoperative exercises and the use of ambulation equipment, such as a walker, crutches, or canes, are provided. Some patients wish to donate some blood several weeks before surgery in case a blood transfusion becomes necessary after surgery.

A surgical bacteriostatic scrub solution is prescribed for the daily shower for several days before hip replacement, as well as the night before and the morning of surgery, to decrease the chance of infection. Tell the patient that he will be placed in an orthopedic bed with an overhead trapeze bar attached after surgery. He may be transported to and from the operating room on the bed. Explain about use of an abduction pillow and turning procedures postoperatively.

Postoperative care.

A blood salvage unit may be in place to collect blood drainage that is then filtered and returned to the patient. There is usually a drain at the surgical hip replacement site with a suction device attached to it. Intravenous fluids will be administered. A Foley catheter will usually be in place. Immediately after surgery, nursing intervention includes all the measures required to prevent respiratory and circulatory complications. However, extreme care must be exercised in positioning and repositioning the patient. To prevent dislocation, an abduction wedge or pillow may be secured between the legs (usually in the operating room) and is left in place when the patient is supine in bed until the surgeon requests its removal (Figure 32-9). The wedge is positioned with the narrower end between the thighs, and the straps should not go over an incision, bony prominence, or drain.

Safety Alert

Precautions With Hip Abductor Wedge

Circulation should be checked after each application of the wedge to be certain that the straps are not too tight. Skin should be assessed every shift on the surface of the legs with particular attention to areas over bony prominences.

FIGURE 32-9 Abduction wedge in place to prevent dislocation of hip prosthesis.

DVT is a possible complication of joint replacement. Low-molecular-weight heparin, enoxaparin (Lovenox), dalteparin (Fragmin), or tinzaparin (Innohep) can be administered to prevent this problem, or oral aspirin (325 mg twice daily) or rivaroxaban (Xarelto) may be used. Enoxaparin is usually given in a 30-mg dose by subcutaneous injection into the abdomen twice a day. Rivaroxaban works more quickly than sodium heparin and has a lower incidence of hemorrhage because it does not prevent platelets from aggregating at bleeding surgical sites. Daily coagulation studies are not needed with this drug because its anticoagulant action is very predictable and stable. Most patients who have had a hip replacement are allowed to stand at the bedside on the operative day, supported by a walker and two people. Weight bearing on the operated joint is sometimes allowed, but there should be a specific written order regarding this from the provider. The patient will need instruction in transferring himself from bed to chair, wheelchair, and toilet. Whenever he sits, the chair seat should be raised so that the hips are not flexed beyond a 90-degree angle. In addition to these instructions, the patient may be referred for outpatient or in-home physical therapy. Nursing interventions for selected problems related to THR are summarized in [Nursing Care Plan 32-1](#) (see also [Nursing Care Plan 5-1](#)). The rehabilitation team includes the patient, family, surgeon, nurse, physical therapist, and occupational therapist.

Patient Teaching

Total Hip Replacement Discharge Teaching

Before discharge, the patient who has undergone hip surgery should be given instructions for care at home. These include:

- It is alright to lie on your operated side.
- For 3 months you should not cross your legs.
- You should put a pillow between your legs when you roll over on your abdomen or lie on your

side in bed.

- It is alright to bend your hip, but not beyond a right (90-degree) angle (demonstrate); avoid sitting in low chairs.
- Continue your daily exercise program at home in the same way you did the exercises at the hospital.

Nursing Care Plan 32-1

Care of the Patient After a Total Hip Replacement

Scenario

Miko Yoshima, an 85-year-old woman, has just undergone a total hip replacement for a hip joint damaged by osteoarthritis. She normally lives alone but has relatives within a 30-minute driving distance. She had been actively gardening and taking care of herself until pain severely limited her mobility over the past few months. (This care plan is specific to problems of hip replacement. All usual care for a postoperative patient should also be included [wound care, respiratory care, monitoring for complications, etc.].)

Problem Statement/Nursing Diagnosis

Altered mobility/*Impaired physical mobility related to pain and activity restrictions after hip replacement.*

Supporting Assessment Data

Subjective: "I'm quite uncomfortable."

Objective: Orders for non-weight bearing and up in chair tid; abduction wedge in place when in bed.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will regain sufficient mobility to completely care for self at home within 3 mo.	Teach use of walker.	Proper use of walker will help prevent falls and injury.	PT will instruct in use of walker tomorrow.
	Encourage ROM and exercises to improve muscle strength and joint flexibility.	ROM helps prevent joint problems in unaffected joints.	Assisted to perform ROM on shoulders, upper extremities, and other leg.
		Exercises decrease muscle atrophy and help strengthen muscles for ambulation.	Encouraged ankle rotations and foot exercises on affected leg with supervision.

Problem Statement/Nursing Diagnosis

Pain/*Acute pain related to surgical incision and rehabilitation therapy.*

Supporting Assessment Data

Subjective: "My pain is at a 6 on a scale of 1 to 10."

Objective: Face appears pinched and patient is not moving in bed at all.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will experience pain control with patient-controlled analgesia (PCA) pump within 1 hr.	Reinforce instructions on PCA use.	Knowledge of how to use pump provides medication for pain control.	Reinforced instructions; encouraging PCA use as needed.
Patient will have adequate pain control on oral analgesia before discharge.	Assess for pain when vital signs are taken. Administer medication bolus per orders PRN.	Constant monitoring for pain can indicate need for more medication to keep pain from escalating. Administering a bolus of pain medication can stop pain from increasing.	Pain level is 2-6/10. Bolus administered for pain level of 6/10.
	Monitor for excessive sedation, respiratory depression, decreased level of consciousness (LOC), and confusion.	Excessive sedation, respiratory depression, decreased LOC, and confusion can indicate medication toxicity and danger for the patient.	No signs of problems of toxicity or central nervous system (CNS) depression.
	Provide comfort measures: keep linens smooth and clean, reposition q2h and PRN; keep environment quiet and orderly. Keep warm with added warmed blankets. Put on socks if feet are cold.	Comfort measures and warmth help decrease pain perception.	Provided comfort measures. Replaced warm blankets q2h, as needed. Socks with slip-resistant soles applied.

Problem Statement/Nursing Diagnosis

Insufficient knowledge/*Deficient knowledge related to precautions necessary after total hip surgery to prevent dislocation of operative hip.*

Supporting Assessment Data

Subjective: "No one I know has had this surgery."

Goals/Expected Outcome	Nursing Interventions	Selected Rationale	Evaluation
Patient will verbalize movement restrictions to prevent hip dislocation within 24 hr.	Explain positional restrictions: no flexion of the hip past 90 degrees, no internal rotation, no adduction of the affected leg.	Flexion, internal rotation, or adduction of the leg may cause hip dislocation. Knowledge is necessary to comply with instructions.	Explained position restrictions.
	Advise not to cross the legs or to bend over from the hips to tie shoes or pick up something off the floor.	These maneuvers cause internal rotation and more than 90 degrees of flexion.	Advised about additional restrictions after discharge. Written instructions given.
	Instruct to only use a raised toilet seat for toileting.	Normal-height toilet seat may cause too much flexion.	States has raised toilet seat at home. Knows to use handicapped toilet stalls when out in public.
	Advise to report pain in hip, buttock, or thigh or continued limp.	Pain or continued limp may indicate dislocation.	Verbalizes understanding of symptoms to report.

Problem Statement/Nursing Diagnosis

Potential for clot formation/*Risk for ineffective tissue perfusion.*

Supporting Assessment Data

Objective: Decreased mobility and total hip replacement.

Goals/Expected Outcome	Nursing Interventions	Selected Rationale	Evaluation
Patient will not experience deep vein thrombosis (DVT) before discharge.	Encourage foot and calf exercises q2h.	Encourages circulation and helps prevent clot formation.	Performing exercises q2h while awake.
	Assist and encourage in prescribed physical therapy.	—	Working with PT.
	Administer low-molecular-weight heparin injections as prescribed.	Decreases ability of blood to clot.	Heparin injections administered into abdomen as prescribed.
	Assess for signs of thrombus formation, checking calf for warmth, swelling, and pain on foot dorsiflexion.	Finding a thrombus early aids in preventing further extension of clot and preventing embolus.	No redness, swelling, warmth, or pain in affected leg's calf.
	Monitor INR (1.5-2.0 for DVT prophylaxis).	INR indicates potential for blood clotting and thrombus formation.	INR (1.5) within desired limits.

Critical Thinking Questions

1. Besides venous thrombosis, what other complications might occur in this patient?
2. If the patient is anxious about discharge, what could you specifically do to help dispel her anxiety?

INR, International normalized ratio; *PRN*, as needed; *PT*, physical therapist; *ROM*, range of motion; *tid*, three times a day.

Total knee replacement.

Chronic, uncontrollable pain from arthritis is the main indication for knee arthroplasty. Part or all of the knee joint may be replaced. For the best postoperative result, emphasis is placed on exercise of the joint and muscles. A CPM machine may be used soon after surgery (see Figure 32-5) and may be sent home upon discharge. To tolerate the exercise, the patient must be well medicated for pain. On day 1 quadriceps-strengthening exercises and straight-leg raising are started. Quadriceps exercise is accomplished by lying supine, straightening the legs, and pushing the back of the knees into the bed. Exercises are taught by the physical therapist, and the nurse often assists the patient in performing them. The patient then progresses to ambulation with a walker or crutches. Other preoperative and postoperative care is similar to that of the patient undergoing any major surgery. After early release from the hospital, the patient continues physical therapy in the outpatient setting.

❖Nursing Management

■ Assessment (Data Collection)

Many patients who have arthritis live every day with pain, limited motion, and the chronic and incurable nature of arthritis; therefore carefully seek in-depth information about the patient's social history, his personal and family health history, current general health status, ability to do the things he wants to do, and his experience of pain and how he has been dealing with it.

Focused Assessment

Data Collection for a Patient With Rheumatoid Arthritis

During history taking, ask about:

- Pain pattern and pain medication use; other coping methods
- Degree of stiffness and duration after arising
- Family history of rheumatoid arthritis or immune disorders
- Diagnosis of accompanying disorders, such as interstitial lung disease, pericarditis, eye problems, and vasculitis
- Smoking history
- Fatigue level and degree of malaise and methods of coping
- Presence of fever
- Exercise pattern
- Ability to perform ADLs; ability to work; ability for home maintenance
- Adaptive equipment in use
- Usual roles at work, home, and community and social involvement
- Joint deformity or swelling of joints
- Symmetric involvement from one side of the body to the other
- Pain and degree of limitation with joint movement

Nursing Diagnosis and Planning

Nursing problems for patients with arthritis depend on the degree of disability the disease is causing. Common problem statements might include:

- Chronic pain due to inflamed joints.
- Altered mobility due to pain, stiffness, and joint deformity.
- Altered body image due to joint deformities.

Specific NANDA-I diagnoses can be chosen from the NANDA-I list (see inside back cover).

Expected outcomes for these problems and subsequent surgical or nonsurgical interventions might be:

- Patient's pain will be controlled with medications, heat, and exercise within 2 weeks.
- Patient's mobility will improve with the use of assistive devices and physical therapy within 3 weeks.
- Patient will demonstrate acceptance of self and appearance by maintaining a clean, neat appearance.

Plan extra time for patients with arthritis to perform self-care and to ambulate. Rushing the patient causes frustration and embarrassment. Even simple procedures will probably take longer because the patient may not be able to move and turn as easily as a person without arthritis.

Implementation and Evaluation

Nursing interventions for arthritis are aimed at providing a balance of rest and exercise, freedom from pain, minimizing emotional stress, preventing or correcting deformities, and maintaining or restoring function so that the patient can enjoy as much independence and mobility as possible.

Rest and Exercise

The purpose of rest is to allow the body's natural defenses and healing powers to overcome the inflammatory process of arthritis. The more inflamed a joint is, the more rest is needed; this includes rest of the joint and the whole body. Fatigue is a common problem with arthritis and usually requires that the patient has rest periods during the day before he becomes too fatigued or exhausted. During periods of acute exacerbation of arthritis symptoms, the patient may need continuous bed rest. When the patient is lying down, he should maintain good body position and avoid pillows and other devices that support joints in a position of flexion. A firm mattress is recommended, with only one pillow under the head and neck.

It is necessary, however, even in the acute phase of arthritis, to balance rest with exercise. The patient should sit to do tasks whenever possible. Activities should be paced and interspersed with rest. The exercise program is prescribed on the basis of assessment of each patient's status, the severity of inflammation, the particular joints affected by arthritis, and the patient's tolerance for activity. Because anemia and other blood disorders can accompany arthritis, the fatigue experienced by a patient may be somewhat alleviated by correcting underlying blood disorders.

Enlist the patient's cooperation to increase compliance with exercises that must be continued at home. Teach the patient how to perform specific exercises so that they do not increase his pain. Each exercise should be done 3 to 10 times for each joint, with the lower number used on days when pain or fatigue is increased. When joints are inflamed, exercises should not be done. In many instances, doing the exercises in the right way can diminish discomfort. If pain persists for hours after exercises have been done, the patient's status should be reassessed and the exercise program revised. Precautions to prevent joint injury are always necessary for routine physical activities, general exercise, or a prescribed exercise program at home.

Patient Teaching

Instructions for Joint Protection

- Always stop an exercise at the point of real pain. Some discomfort can be expected, but it should be minimal. If your joints are still hurting 1 or 2 hours after exercise, you have done too much.
- Always use your biggest muscles and strongest joints. For example, push doors open with your arm instead of your hand; carry a shoulder bag instead of a hand purse.
- Try to do only those jobs that will allow you to stop and rest if you need to when pain develops. Conserve your energy for the things you really want to do.
- Exercise in a way that does not put strain on the joints. Exercising in water decreases joint strain.
- Slow down and move slowly and smoothly. Avoid rapid, jerky movements. Use the palms of the hands rather than the fingers to push up from a bed or chair when arising.
- Turn doorknobs counterclockwise (or clockwise if left handed) to prevent extensive twisting of the elbow. Do not lift weights. Pick up heavier items with two hands.
- Let swollen, red, hot, and painful joints rest as much as possible. Do not use them any more than absolutely necessary.
- Change your body position frequently, alternating standing, sitting, and lying down.

- Set your own limits and compete with yourself, not with anyone else.
- Use assistive/adaptive devices, such as Velcro closures and built-up utensil handles, to protect joints of the hands. Use a long-handled hair brush.

Applications of Heat and Cold

Either hot or cold is suitable for treating arthritic joints, depending on the patient's preference and the effectiveness of each. The purpose of either hot or cold applications is to minimize pain, increase the joint's ROM, and improve exercise performance. In general, heat is better for subacute or chronic joint inflammation and cold is more effective in the acute phase when joints are hot, red, and obviously inflamed.

Various forms of heat therapy can be used, including moist or dry heat and superficial or deep heat. For dry heat, a therapeutic infrared lamp is convenient and inexpensive for home use. For treatment of the hands, paraffin baths are effective. Wet heat can be applied by hot tub baths with the water temperature not exceeding 102° F (39° C) or by means of a towel dipped in hot water, wrung out, and applied to the joint. Whirlpool baths promote relaxation and motion with minimal pain, especially when prolonged treatment is indicated. However, immersing the whole body in warm water can cause physiologic changes in respiration and pulse rate and may be contraindicated in debilitated patients or older adults. The patient will need specific instructions on how to prevent injury to the skin and other hazards.

■ Safety Alert

Caution With Heat Application

Patients who have decreased sensation in a body part must be very careful when applying heat, or they may experience burns. Teach the family and patient to test the degree of heat being applied and to check the area after 5 minutes to make certain that burning is not occurring. A cloth should always be placed between the heat device and the skin.

■ Think Critically

If a patient asks about using a heating pad on a joint, what instructions would you give?

■ Patient Teaching

Safe Application of Heat and Cold

Heat

- Recommended for chronic or subacute inflammation.
- Heat should be used for 20 to 30 minutes at a time; repeat the application every 1 to 2 hours while awake.
- Use a shower massager for massage pulsation. Regulate water by turning on cold and adding hot water to desired temperature **before** entering the shower. Use a shower stool if balance is poor or fatigue is likely.
- Use a pad between the heat source and the skin to prevent burning.
- Use a heating pad that provides moist heat; it will penetrate best. Do not sleep on the heating pad. Use the low settings because heating pads often cause burns when turned up too high or used for too long.
- Reusable heat packs mold well to body parts because they are pliable. Follow directions explicitly, and test temperature by feeling the pack against the skin before applying it to the area in need.

Use a light pad or thin dishtowel between the pack and skin. Heat in a microwave oven. Reheat as needed.

- Heat-producing ointments and gels containing menthol, camphor, capsaicin, or papain (extract from red peppers) may be applied to the sore muscle or joint as long as they do not produce skin irritation. Covering the area after application with plastic wrap helps hold the heat in longer. Wash hands thoroughly after application to prevent eye irritation.

Cold

- Recommended for acute phase of inflammation or acute pain.
- Do not apply to one area for more than 10 to 20 minutes at a time; apply no more than once an hour.
- Discontinue when numbness occurs.
- Not recommended for patients with impaired circulation.
- An ice water bath is useful for a hand or foot. The extremity can be exercised during treatment.
- An ice pack can be made by partially filling a double plastic bag with ice. Zip-type closures work best. A thin pad or dishtowel may be used between the pack and skin.
- Commercial cold packs mold to body parts better than do ice bags but do not stay cold very long. Often two of these are needed to finish a 10- to 20-minute treatment. Commercial cold pack can be refrozen in the freezer. Disposable chemical packs that are activated when needed are also available. Bags of frozen peas make a good cold pack for some joints.
- Freeze ice in a paper cup; peel back part of cup to use so the cup provides a handgrip. Wear a rubber glove or use a pad to protect the hand from the ice. Rub ice over the body part until skin feels numb, but no longer than 10 to 15 minutes at a time.
- Dry skin well after treatment.

Diet

No special diet will cure or relieve arthritis, despite many claims to the contrary. However, some patients find that eliminating foods from the "nightshade" family, such as tomatoes, decreases their joint pain. The patient should eat an average, well-balanced diet with no excess or limitations in amount or types of foods. Explain that obesity can put additional stress on the weight-bearing joints and aggravate the arthritic condition; then help the patient review strategies for weight control.

Psychosocial Care

As deformities occur, self-esteem can be affected. Encourage verbalization of feelings. Express acceptance of the patient's appearance. Suggest clothing options that may minimize visible changes. A support group sometimes helps to reframe the disease's effects on the body. Encourage patients with arthritis to gain as much control over the disease as possible with appropriate coping mechanisms, pacing of activity, exercise, and medication.

Resources for Patient and Family Education

The Arthritis Foundation provides some excellent printed material written with the layperson in mind. Another source of information is the Arthritis Information Clearinghouse at the National Institute of Medicine (see [Online Resources](#)).

Gout

Etiology and Pathophysiology

Gout is arthritis of a joint caused by high serum levels of uric acid. Uric acid crystals precipitate

from the body fluids and settle in joints and connective tissue. Gout affects men more than women and generally occurs during middle age. It is more common among populations that consume a high-protein diet. Two factors seem to be implicated: (1) a genetic increase in purine metabolism leading to overproduction or retention of uric acid and (2) consumption of a high-purine diet. Excessive alcohol consumption causes an increased production of keto acids that inhibit uric acid excretion, causing hyperuricemia. Deposits of urate crystals occur in joints and subcutaneous tissues and can cause kidney stones. The big toe is the most common site, but many other joints can be affected. Diuretic therapy may cause a secondary gout from fluid loss that increases the serum uric acid level in the body. Certain drug therapies interfere with uric acid excretion and can cause a secondary gout.

Signs and Symptoms

Typical signs and symptoms are elevated serum uric acid and tight, reddened skin over an inflamed, edematous joint, accompanied by elevated temperature and extreme pain in the joint.

Diagnosis, Treatment, and Nursing Management

History and physical examination are usually sufficient to diagnose gout, but a blood sample to check serum uric acid level is usually ordered to confirm the diagnosis. Treatment during acute attacks consists of administration of NSAIDs for 2 to 5 days for the pain. Colchicine given orally may bring dramatic pain relief within 24 to 48 hours. Oral prednisone or cortisone injection into the joint may be used. Allopurinol (Zyloprim) or probenecid (Benemid) may be prescribed to prevent further attacks. In February 2009 the FDA approved febuxostat (Uloric), which is the first new gout medication to be approved since the 1960s. Teach the patient about gout medication side effects and dosage. Advise that dietary management includes weight control and restriction of high-purine foods, such as anchovies, sardines, sweetbreads, liver, red meats, kidneys, and meat extracts. Alcohol should be restricted. Remind patients who take allopurinol that periodic liver function testing is needed because this drug can cause liver failure. Teach the patient that a fluid intake of 2000 to 3000 mL per day is needed to protect the kidneys from urate crystal deposits and to prevent kidney stones.

Older Adult Care Points

Older adults with decreased creatinine clearance should not take allopurinol. When the patient has both hypertension and gout, losartan (Cozaar) may be a good choice for therapy. Losartan promotes urate excretion.

Osteoporosis

Etiology and Pathophysiology

Osteoporosis makes the person more susceptible to fractures because of the decrease in bone mass. Fragility fractures are often **atraumatic** (occur without trauma). Starting at age 35 years, most women lose bone mass at a rate of 1% per year; after menopause, loss of bone mass accelerates to 2% each year. In the United States 44 million people have osteoporosis, and another 34 million have **osteopenia** (low bone mass) (FORE, 2013). There is a hereditary tendency for osteoporosis. Risk factors for osteoporosis include age, chronic disease (e.g., liver, lung, kidney), medications (e.g., steroids, anticonvulsants, anticoagulants, PPIs, selective serotonin inhibitors), long-term calcium deficiency, vitamin D deficiency, smoking, excessive caffeine or alcohol intake, and sedentary lifestyle. Eating disorders and inflammatory bowel disease lead to osteoporosis because they interfere with nutrition and absorption. The risk of osteoporosis increases considerably in women after menopause because estrogen production is reduced.

Older Adult Care Points

Public awareness of osteoporosis for older women has increased, in large part because the pharmaceutical industry has marketed drugs for prevention of osteoporosis and fragility fractures. However, older adult men have hormone changes around the age of 70 years; this increases their risk for osteoporosis. Older men should be assessed for risk factors and undergo diagnostic testing

(NIH, 2013).

Signs and Symptoms

Osteoporosis is a silent disease and there are no early signs or symptoms. Once the patient has developed osteoporosis, height loss, kyphosis (excessive curvature of the spine), and back pain may occur. Compression fractures of the spine may cause debilitating pain. Osteoporosis is commonly diagnosed after the patient sustains a fracture from little or no known trauma.

Older Adult Care Points

Patients older than 60 years who sustain a nontraumatic osteoporotic fracture have an increased risk for death within 5 to 10 years after the fracture event. For older adult women, there may be some underlying risk for fracture and death. For men, there appears to be some connection to the fracture event itself. Additional research is needed to clarify risk factors (Bliuc et al, 2013).

Diagnosis

On radiographs the bone of the patient with osteoporosis appears porous. Dual-energy x-ray absorptiometry (DEXA) is used to assess loss of bone density. DEXA is reported as a T score.

- *Normal bone density:* T score of greater than 1 standard deviation from a healthy young adult
- *Osteopenia:* T score of -2.5 or more.
- *Osteoporosis:* T score of -2.5 or below

Treatment

Treatment is aimed at stopping loss of bone density, increasing bone formation, and preventing fractures. Adequate dietary or supplemental calcium and vitamin D in combination with weight-bearing exercise are standard treatments; estrogen replacement therapy may also be used for postmenopausal women. For premenopausal women, intake, preferably dietary, of 1200 mg of calcium is recommended; this recommendation increases to 1500 mg after menopause. Vitamin K is essential for calcium utilization and is provided by leafy greens in the diet.

Nutrition Considerations

Nutrition for Bone Growth and Density

Adequate amounts of calcium and phosphorus are essential for bone growth and density. Although green vegetables are a source of calcium, that calcium is not readily absorbed. Dairy products such as cheese, yogurt, and milk are better choices. Canned sardines or salmon also provide good amounts of calcium. Calcium supplementation is not recommended for the healing of fractures. It has proven not to be readily absorbed and tends to cause kidney stones.

Calcium supplements, if required, should be taken in divided doses during the day. Exposure to sufficient sunlight or vitamin D supplementation is necessary for the proper absorption and metabolism of the calcium. Current guidelines recommend 800 to 5000 units of vitamin D per day (Vitamin Council, 2015). Vitamin K is important to bone health as well, and most people obtain vitamin K by eating greens. Daily weight-bearing exercise can decrease the chance of developing osteoporosis. Walking down stairs seems to be especially helpful, but walking for 30 minutes three times a week is sufficient.

Salicylates and NSAIDs are prescribed to control back pain. A back brace may be ordered for a patient who has had vertebral compression fractures. The bisphosphonates (i.e., Fosamax or Boniva; Box 32-3), which are related to a bone resorption-inhibiting substance found naturally in the body, and hormone therapy are prescribed in addition to calcium and vitamin D supplements for those with osteoporosis. Other classes of medications include parathyroid hormone, bone formation agents, and selective receptor modulators. Miacalcin or Fortical nasal spray, which contains calcitonin, slows the rate of bone loss. It is an alternative treatment for postmenopausal osteoporosis in women who cannot take estrogens. The spray is used with adequate calcium and vitamin D

supplementation.

Box 32-3

Drugs Commonly Used to Treat Osteoporosis

Hormones

- Estrogen (women)
- Raloxifene (Evista) (selective estrogen receptor modulator)
- Testosterone (men)
- Calcitonin (Miacalcin) (synthetic hormone)
- Teriparatide (Forteo) (synthetic hormone)

Bisphosphonates

- Alendronate (Fosamax)
- Risedronate (Actonel, Atelvia)
- Ibandronate (Boniva)
- Zoledronic acid (Zometa, Reclast)
- Monoclonal antibody
- Denosumab (Prolia)

General Nursing Implications for Bisphosphonates

- Monitor bone density test results.
- Must take regularly (weekly or monthly).
- Observe for hypercalcemia (paresthesias, twitching, colic, or laryngospasm).
- Take with 8 oz of plain water in A.M. 30 to 60 minutes before eating, drinking, or taking any other medication that day (timing depends on the particular drug).
- Swallow the tablet whole. Do not suck or chew on it.
- Remain upright for 30 to 60 minutes after dose to prevent esophageal irritation (timing depends on the drug). Do not eat or drink anything during these 30 minutes to an hour.
- Store medication in a cool location out of sunlight.
- If dose is missed, skip the dose; do not take it later in the day. For the weekly dose medication, take it the next morning after your scheduled dose. Skip the dose if it has been 2 days since it was supposed to be taken and just resume the original schedule. If taking Boniva, take it the next morning after you remember you forgot to take it. Do not take two tablets in any 1 week; wait at least 7 days to take the next dose and then resume your original schedule.
- Take calcium and vitamin D supplements as recommended by the health care provider.
- Perform weight-bearing exercise to increase bone density.
- Advise health care provider if pregnant or planning a pregnancy.

Intravenous zoledronic acid (Zometa) may be used for prevention of osteoporosis and long bone fractures in patients with prostate cancer who are receiving radiation and hormonal therapy. The drug can also be used for men who do not tolerate bisphosphonates well (Ruza et al, 2013).

Safety Alert

Caution With Bisphosphonate Drugs

There have been some instances of jawbone necrosis in patients who have been taking bisphosphonate drugs. There is also some concern that bisphosphonates increase the risk of femur fracture. Esophageal irritation or erosion can occur if the patient does not remain in an upright position for 1 hour after taking a bisphosphonate drug. The FDA announced in March 2010 that patients should continue to take prescribed bisphosphonates (Lowes, 2010). Patients should be reminded that adverse side effects are varied and any new onset of unusual signs or symptoms should be reported to the provider. These drugs should be stopped after 5 years.

Treatment of vertebral fracture.

Vertebral compression fractures are common in patients with osteoporosis. These are often treated with pain medication, activity limitation, physical therapy, and bracing. There are two new minimally invasive spine procedures for those who do not respond to the conservative therapies. **Vertebroplasty** involves the percutaneous injection of polymethylmethacrylate (PMMA), a bone cement, directly into an osteoporotic spinal area under fluoroscopy. This stabilizes the bone and helps reduce or eliminate pain. **Kyphoplasty** consists of the percutaneous insertion of an inflatable device into the fractured vertebral body under fluoroscopy. The device is inflated, elevating the end plates and restoring the vertebral body toward its original height. Thick PMMA is then injected under low pressure into the cavity. The device is deflated and removed. This provides pain relief and reduces kyphosis (Cooper, 2013).

Nursing Management

Assessment (Data Collection)

Assessment for risk factors for osteoporosis should be performed with every general health assessment. Data are gathered about family history of osteoporosis, use of steroid medication, diet, exercise pattern throughout life, and history of smoking and alcohol intake.

Nursing Diagnosis and Planning

The main problem is potential for injury due to possible fracture from thinning of the bone. The expected outcome would be "Patient will not experience a fracture during his lifetime."

Implementation and Evaluation

Nursing care is focused on promoting screening for osteoporosis, teaching about the benefits of a healthy lifestyle, the need for sufficient intake of calcium and vitamin D, and the advantages of weight-bearing exercise. Educating about the harmful effects of smoking and excessive alcohol intake is also important. For the patient with osteoporosis, teach about the medications prescribed for the disorder and their side effects and measures to halt or reverse the disease process.

Paget Disease

Paget disease, more common in men, is a problem of abnormal bone resorption followed by replacement of normal marrow with fibrous connective tissue. The abnormal bone is weak and prone to fractures. The cause of Paget disease is unknown, although it does occur in clusters in some families. Often the disease is found at the time a fracture occurs when radiographs reveal the abnormality of the bone. Diagnosis is by radiograph and laboratory testing. A 24-hour urine collection for hydroxyproline, which indicates osteoclastic activity, may be performed. Serum alkaline phosphatase is elevated if the disease is active. The main problem is pain. Miacalcin or a bisphosphonate may be given to slow bone resorption. Orthopedic care is given for fractures and necessary joint replacements. A firm mattress, wearing a corset or light brace to relieve back pain,

and proper body mechanics are essential. The patient should avoid lifting or twisting.

Bone Tumors

Etiology and Pathophysiology

Bone is subject to both benign and malignant tumors. Tumors arise from several different types of tissue, including cartilage (chondromas), bone (osteomas), and fibrous tissue (fibromas). Benign tumors often are found on radiograph or at the time of fracture.

Malignant bone tumors are either primary or secondary to metastatic disease. Diagnosing and treating cancer in other parts of the body early can prevent the occurrence of metastases to the bone. Primary malignant bone tumors are most common among people 10 to 25 years of age. The most common type is osteosarcoma, or osteogenic sarcoma. The tumors grow rapidly and metastasize. More than half the cases affect the knee area. However, the distal femur, humerus, and proximal tibia are other common sites of occurrence. Osteosarcoma may occur in men older than 60 years as a complication of Paget disease. Other types of primary malignant tumors include Ewing sarcoma, chondrosarcoma, and fibrosarcoma.

Signs, Symptoms, and Diagnosis

Signs and symptoms of malignant bone tumor include pain, warmth, and swelling. Metastatic bone tumors greatly outnumber primary bone malignancies. Malignancies of the prostate, kidney, thyroid, breast, and lung commonly metastasize to bone. Sites of metastases are usually the vertebrae, pelvis, ribs, and femur. Diagnosis of bone tumor is by physical radiograph, bone scan, and biopsy.

Treatment and Nursing Management

Treatment for malignant bone tumors includes surgery, radiation, and chemotherapy. Osteosarcoma has a 60% to 80% cure rate when surgery and chemotherapy are combined for treatment. Chemotherapy is given for about 10 weeks before surgery and then for up to a year after surgery. A combination of a variety of chemotherapeutic agents are used depending on the tumor size, location, and physician decision ([American Cancer Society, 2015](#)). Zoledronic acid (Zometa) may be used to treat hypercalcemia associated with bone tumors.

Nursing management includes helping the patient with the anxiety and fear that accompanies the diagnosis of a bone tumor. Care of surgical patients is presented in [Chapters 4 and 5](#), and [Chapter 8](#) covers care of cancer patients. If a bone tumor is in an extremity, amputation may be part of the treatment.

Amputation

About 80% of all limb amputations involve lower extremities. The most common reasons for amputation of a lower limb are related to peripheral vascular disease, often associated with diabetes mellitus, and resultant gangrene. Other conditions necessitating lower-limb amputation include severe trauma, malignancy, and congenital defects. Military injuries from shrapnel and land mines often result in amputation.

About 70% of upper-extremity amputations are brought on by crushing blows, thermal and electrical burns, and severe lacerations, many from military action. Vasospastic disease, malignancy, and infection also can necessitate amputation of an upper extremity.

Patient Teaching

Care After Accidental Amputation

To care for a severed body part so that reattachment may be possible:

- Rinse the detached part only enough to remove visible debris.
- Wrap the part in a clean, damp cloth.

- Place the part in a sealed plastic bag or in a dry watertight container.
- Immerse the bag or container in a mixture of water and ice (3 parts water to 1 part ice). Do not let the part get wet or freeze.
- Alternatively, place the container in an insulated cooler filled with ice.
- If no ice is available, keep the part cool; do not expose it to heat.
- Tag the bag or container with the person's name and the name and location of the body part and take it to the hospital with the person.

The past 20 years have brought about major improvements in microvascular surgery, making reattachment or reimplantation of amputated parts possible. Teach the public what to do if an accidental amputation occurs.

Preoperative Care

If at all possible, the patient should participate in the decision to amputate a limb. He should understand the need for the amputation and what to expect postoperatively with regard to pain, immobility, and readjustment to self-care. He needs to discuss realistic goals of rehabilitation with members of the rehabilitation team.

Although the loss of a limb can be very difficult for the patient and his family to accept, it helps to know that the procedure is absolutely necessary and that every effort will be made to help the patient take full advantage of his remaining resources. The patient may experience stages of denial, anger, and so on, similar to those of the dying process. In a sense, the patient must recognize the death of his former "self," work through the grief process, and move toward acceptance of a new body image.

"Phantom sensations" in the limb that has been removed are not unusual. The current hypothesis is that phantom pain mimics preoperative pain and that the peripheral nervous system and the spinal cord send messages to the brain, which retains the memory of the pain ([Ratini, 2013](#)). The patient should be informed preoperatively that the sensations are not unusual and are not considered a psychiatric problem, and that he should ask for help should the problem arise.

Physical preparation of the patient for amputation includes muscle-strengthening exercises to facilitate activity after amputation. These exercises are the first stages of the rehabilitation process, designed to help the patient achieve independence as rapidly as possible.

Postoperative Care

When the patient returns from the surgical suite, the two most immediate problems after amputation are hemorrhage and edema. To combat these problems, the stump is sometimes elevated for 24 to 48 hours. A lower extremity is not elevated for more than 24 hours because of the danger of hip contractures, which would prohibit rehabilitation efforts to achieve ambulation. The stump is checked at frequent intervals to determine whether bleeding is excessive. Fresh bleeding on the dressing should be reported immediately. When a cast is over the incision, other measures are used to detect bleeding (i.e., pulse rate, blood pressure, increasing pain, restlessness, and pallor). A surgical tourniquet should be kept at the bedside in case of hemorrhage. Prophylactic antibiotics are given for 3 or 4 days, and wound drainage usually is handled with a wound drainage system. The incision should be dry, intact, and only slightly reddened along the suture line. The initial pressure dressing is removed by the surgeon 48 to 72 hours postoperatively (see [Chapter 5](#)).

Phantom limb sensations may or may not be painful. Intravenous infusion of ketamine early after amputation has been known to reduce or eliminate phantom pain in many patients. If the pain is severe or persists, various methods are used to control it. Another method is the use of a transcutaneous electrical nerve stimulator (TENS). A device called a *stump stocking*, which is a silicone liner interwoven with an electromagnetic shield, works by blocking external electromagnetic impulses from outside sources. Those external impulses are believed to irritate nerve endings and trigger phantom pain. A new treatment uses virtual reality goggles and a computer program to help visualize the limb as being whole ([Mayo Clinic, 2015](#)).

Three alternative modes for managing the stump after amputation are (1) soft dressing with

delayed prosthetic fitting; (2) rigid plaster dressing and early prosthetic fitting; and (3) rigid plaster dressing and immediate prosthetic fitting. Each method has its particular advantages and disadvantages. If a soft dressing is used, it is important that the stump be wrapped properly to control edema and ensure proper shrinkage of the stump for later fitting of a prosthesis. A pressure bandage wrapped in a figure-of-8 pattern is most common (Figure 32-10). The bandage is anchored to the most proximal joint. It should be rewound three times a day, or whenever it is loose. A Jobst air splint may be used instead of the pressure bandage.

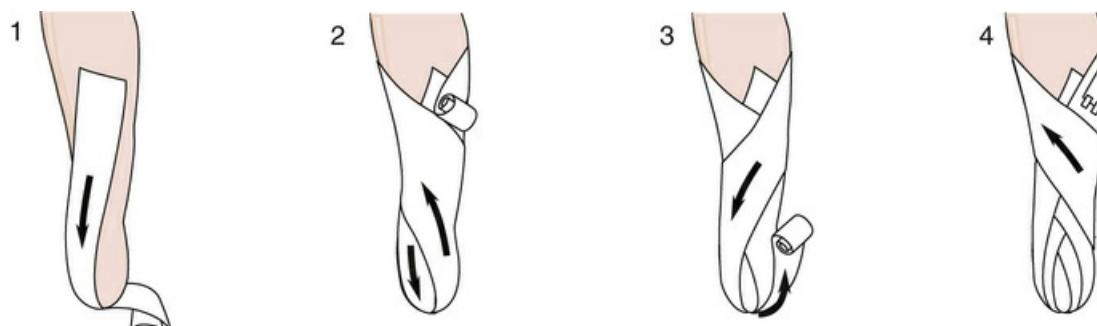

FIGURE 32-10 A common method for wrapping a below-the-knee amputation (BKA) stump. (From Ignatavicius DD, Workman ML: *Medical-surgical nursing: Critical thinking for collaborative care*, ed. 7, Philadelphia, 2013, Saunders.)

When the bandage is off, assess the skin for inflammation or breakdown. The skin should be pink in a light-skinned person and without discoloration. In a dark-skinned person, the skin should not be lighter or darker than other skin pigmentation. The skin should be warm but not hot. Skin breakdown on the stump is extremely serious because it interferes with prosthesis training and may prolong hospitalization and recovery. Patients with diabetes mellitus are particularly susceptible to skin complications because changes in sensation may obliterate the awareness of stump pain.

Many complications can be prevented if the patient is able to get up and about early in the postoperative period. However, weight bearing before the stump is adequately healed can cause weakening of the suture line and rupturing of the operative wound. A patient with a lower extremity amputation should lie prone for 20 to 30 minutes every 3 to 4 hours to prevent hip contracture until he is up and about regularly. The residual limb should be extended. Patients with amputations below the knee are better able to begin early walking and weight bearing than those whose limb has been amputated above the knee. The amputation of a limb displaces the body's center of gravity and interferes with the sense of balance. Adaptation to this change in the center of gravity occurs slowly, and the patient needs to be warned to move cautiously. When the prosthesis is off during the night, the patient may need assistance in turning until he adjusts to his new center of gravity.

Proper positioning is required to prevent **abduction** contractures. ROM exercises are carried out with patients with an amputation as with any patient who must be protected from the disabilities resulting from immobility.

When a lower limb has been removed, the patient must learn how to balance on one leg, how to stoop and bend over without losing balance, and how to use his back muscles to maintain good posture while wearing an artificial limb. Teaching for self-care begins as soon as possible.

Rehabilitation

With the help of computers, prostheses can be manufactured that are a much better fit than ever before. Computerization has also provided a means of controlled movement of various parts of a prosthesis, allowing greater mobility and ease of performing ADLs. Usually both a physical therapist and an occupational therapist work with the patient who has suffered an amputation to help regain mobility, confidence, and the ability to handle ADLs. Assist with practice at bathing, shaving, dressing, and other ADLs.

Older adults and patients who are chronically ill can benefit from a positive, yet realistic, approach to problems related to amputation. The focus of attention should be on what the patient can do for himself and on what strengths he has in his favor. You can be of real assistance by

helping the patient find short-range goals that can be accomplished without great difficulty and that indicate progress toward independence. For example, you can guide him toward devising ways in which personal needs such as bathing and grooming can be met. Later, give encouragement to sit up, exercise the other limbs, and assist with changing of the dressing. Finally, set a goal for wearing the prosthesis successfully and walking without assistance ([Figure 32-11](#)) (see [Chapter 9](#)).

Patient Teaching

Stump and Prosthesis Care

Instruct the patient in stump care as follows:

- Inspect the stump daily for redness, blistering, or abrasions.
- Use a mirror to examine all sides and aspects of the stump.
- Perform meticulous daily stump hygiene. Wash the stump with a bacteriostatic soap, and then carefully rinse and dry it. Allow to air dry for 20 minutes. Apply nothing to the stump after it is bathed.
- Wear only a residual stump sock that is in good condition over the stump for cleanliness and comfort. Replace the sock daily; wash with mild soap, squeeze out excess water and lie flat to dry.
- Put on the prosthesis immediately when arising and keep it on all day (once the wound has healed completely) to reduce stump swelling.
- Continue prescribed exercises to prevent weakness.
- Lay prone with hip extension for 30 minutes three or four times a day.
- For a lower extremity, replace shoes before wear becomes extreme because gait may be altered.

Care of the prosthesis:

- Remove sweat and dirt from the prosthesis socket daily by wiping the inside of the socket with a damp, soapy cloth. To remove the soap, use a clean, damp cloth. Dry the prosthesis socket thoroughly.
- Never attempt to adjust or mechanically alter the prosthesis. If problems develop, consult the prosthetist.
- Schedule a yearly appointment with the prosthetist.

Community Care

Rehabilitation programs for patients with an amputation, arthritis, and other musculoskeletal disorders exist in most large cities and are being introduced into more communities through agencies such as the YMCA. The Arthritis Foundation has been instrumental in working with the YMCAs to bring programs for exercise to local neighborhoods.

Outpatient rehabilitation programs through clinics work with patients who are regaining mobility and the ability to perform ADLs with a prosthesis. Rehabilitation is moving to a program "without walls," indicating a shift from an inpatient institute to rehabilitation in the home and community.

Home care nurses are particularly instrumental in preventing musculoskeletal injury in home care patients. The premises of the older adult are surveyed, and recommendations are made to make it safer for the patient. Flat, nonglare surfaces for walking, well-lit walkways, absence of loose rugs, installation of grab bars in showers and bathrooms, and use of communication systems to summon help are some of the measures instituted to protect older adults.

When a home care patient is on crutches, the nurse should assess the patient's ability to go up and down stairs and to sit down and arise from the sitting position safely. Patient Teaching: Crutch Gaits in [Chapter 31](#) presents the steps for performing these maneuvers correctly. Home care nurses must assess the capability and safety of older adults who are newly using assistive devices for ambulation and determine whether alterations in pathways in the home need to be made. Scatter rugs should be removed, and furniture may need to be rearranged to offer a path wide enough to allow the patient to move from one area to another.

Long-term care facility nurses survey patient units and group spaces daily to check for obstacles to ambulation and potential safety hazards. Slowly, our communities are becoming easier to navigate for older adults, and public places are becoming more accessible for individuals with handicaps and safer for frail older adults.

Get Ready for the NCLEX® Examination!

Key Points

- Sprains are treated with rest, ice, compression, and elevation (RICE).
- Bursitis occurs from injury or overuse.
- Carpal tunnel syndrome causes numbness, tingling, and pain in the hand.
- Fractures occur from trauma or metabolic disease. Signs and symptoms include pain, swelling, discoloration, and deformity in the contour of the bone. Complications include infection, osteomyelitis, fat embolism, venous thrombosis, and compartment syndrome.
- Compartment syndrome is an emergency situation. Signs and symptoms include edema, pallor, tingling, paresthesia, numbness, weak pulse, cyanosis, paresis, and severe pain.
- Osteoarthritis occurs asymmetrically and typically affects only one or two joints. Treatment consists of pain management, weight control, exercise, and maintenance of joint function.
- Rheumatoid arthritis is an inflammatory disease of the joints. Symptoms include joint pain, warmth, edema, limitation of motion, and joint stiffness and systemic symptoms, usually bilaterally. Treatment includes relieving pain, minimizing joint destruction, promoting joint function, and preserving the ability to perform self-care functions. Medications, rest, exercise, and applications of heat and cold are mainstays of treatment.
- Postoperative care after joint replacement is very important to prevent pain, prevent infection, prevent dislocation, and promote mobilization.
- DVT is a common complication of hip and knee joint replacement.
- Gout is caused by high serum levels of uric acid. Symptoms of gout are tight, reddened skin over an inflamed, edematous joint accompanied by elevated temperature and extreme pain in the joint.
- Calcium deficiency and estrogen depletion predispose to the development of osteoporosis, which increases susceptibility to fractures. Treatment includes calcium, vitamin D supplements, bisphosphonates, and other hormonal medications (see Box 32-3).
- The most common primary bone tumor is osteogenic sarcoma; many bone tumors are from metastasis of cancer elsewhere.
- Eighty percent of amputations involve lower extremities. Hemorrhage and infection are complications of amputation. Proper stump care is essential to the success of rehabilitation.

Review Questions for the NCLEX® Examination

1. A young man is admitted to the emergency department after an injury to the left leg sustained playing football. He is complaining of pain around the knee and upper tibia. Which data from the nurse's assessment would indicate a fracture of the tibia rather than a connective tissue injury of the knee?

1. Pain and soft tissue swelling around the knee and an abrasion on the knee

2. Pain, ecchymosis below the knee, and crepitation with any movement of the area
3. Pain, swelling, and loss of function of the foot
4. Limping when walking, facial grimace, and some swelling of the knee and lower leg

NCLEX Client Need: Physiologic Integrity

2. A 24-year-old woman limps into the emergency department after twisting her ankle during a soccer game. On examination, there is local swelling and difficulty maintaining balance. What immediate therapeutic measure(s) should the nurse provide? (*Select all that apply.*)

1. Application of elastic bandage
2. Application of an ice pack
3. Elevation of the ankle
4. Ankle rest and limited weight bearing
5. Application of a topical anesthetic

NCLEX Client Need: Integrated Processes: Clinical Problem Solving

3. A patient with a plaster cast of the right arm complains of itching underneath the cast. What should the nurse do to alleviate the symptom?

1. Encourage deep breaths and scratch the other arm.
2. Insert a cotton-tip applicator under the cast.
3. Forcefully inject 50 mL of air underneath the cast.
4. Administer pain medications.

NCLEX Client Need: Physiologic Integrity

4. A nurse responds to a roadside emergency and finds a middle-aged man with pain and tenderness over the left leg. The nurse notes a closed bone deformity with inability to move the leg. While waiting for the paramedics, what is the most important nursing action?

1. Immobilization of the leg

2. Realigning the bones
3. Applying warm packs
4. Elevating the extremity

NCLEX Client Need: Physiologic Integrity

5. The nurse should watch for signs of potential complications in a young adult patient with a fractured femur with internal fixation and a long leg cast, such as: (*Select all that apply.*)

1. infection or osteomyelitis.
2. compartment syndrome.
3. pneumonia or stroke.
4. pulmonary fat embolus.
5. electrolyte imbalance.
6. nonunion of bone.

NCLEX Client Need: Safe and Effective Care Environment: Safety and Infection Control

6. A difference in the postoperative care of a patient with a knee replacement compared with a patient after a hip replacement is that the patient with a hip replacement:

1. has less chance of developing a deep venous thrombosis.
2. remains on bed rest for several days.
3. is allowed to stand at the bedside on the first postoperative day.
4. has a CPM machine to exercise the joint.

NCLEX Client Need: Integrated Processes: Clinical Problem-Solving

7. A nurse has just received shift report on four assigned orthopedic patients. Which patient should the nurse check on first?

1. A young trauma patient with a below-the-knee amputation who is having phantom pain
2. An older adult woman with a total hip replacement who needs

assistance with the bedpan

3. A woman with an external fixation device who has a fever and foul odor at pin sites
4. A man with a full leg cast who reports persistent pain despite elevation and pain medication

NCLEX Client Need: Integrated Processes: Clinical Problem-Solving

8. A nurse is assisting an older adult at home who has rheumatoid arthritis in the hands and wrists. The nurse would intervene to teach the patient about joint protection if the patient:

1. turned the doorknob counterclockwise.
2. used the palms of the hands to push up and off the bed.
3. carried groceries into the house using both hands.
4. pushed the door open with the arm.

NCLEX Client Need: Integrated Processes: Teaching and Learning

9. Early osteoporosis is treated with _____. (*Fill in the blank.*)

NCLEX Client Need: Physiologic Integrity: Pharmacological Therapies

10. A young patient returns from the operating room after a below-the-knee amputation and is alert and quiet. The stump is elevated with the dressing dry and intact. What is the priority problem for this patient?

1. Altered body image.
2. Potential for bleeding.
3. Altered mobility.
4. Insufficient knowledge.

NCLEX Client Need: Integrated Processes: Clinical Problem-Solving

11. After sustaining a rotator cuff tear, a patient's arm is placed in a sling. The patient is instructed to rest and to take ibuprofen (Motrin) for pain. Which patient statement indicates a need for further teaching?

1. "I will have less stomach upset if I take the pills with food."

2. "I will not be able to play tennis for a while."
3. "I need to rest in bed for the next 2 days."
4. "The sling must be worn most of the time."

NCLEX Client Need: Integrated Processes: Teaching and Learning

12. A nurse is assuming recovery room care of a 52-year-old patient who had carpal tunnel repair. On receiving the patient, what is the priority nursing assessment?

1. Sensation in the fingertips
2. Color, warmth, and capillary refill
3. Condition of the dressing
4. Range of motion

NCLEX Client Need: Physiological Integrity: Reduction of Risk Potential

Critical Thinking Questions

Scenario A

Mr. Patel, age 56 years, has been admitted to the hospital with a diagnosis of fracture of the left tibia. You have been told that when the patient returns from surgery, he will have an external fixation device in place.

1. How would you perform a neurovascular assessment?
2. How can you support the affected extremity?
3. What can you do to decrease swelling?
4. List the observations you must make while the fixator is on Mr. Patel's leg.
5. What complications might occur?

Scenario B

Mrs. Hernandez, age 52 years, is a moderately obese woman who comes to the orthopedic clinic for treatment of arthritis of the knees and ankles. She has great difficulty walking and would use a wheelchair if she could afford one. Her daughter states that she is becoming more and more inactive and—though her mother says she does not want to become an invalid—she refuses to move about and do things for herself. Mrs. Hernandez lives alone and prefers not to live with her son because the grandchildren make her nervous. In fact, she prefers to be left alone because she feels that she cannot be of use to anyone. Her son feels that his mother could find many useful things to do in her neighborhood if she would only try.

1. How does obesity interact with arthritis in causing immobility?
2. What medications might decrease Mrs. Hernandez's pain?

3. What sort of exercise would be best for this patient?
4. How could you make Mrs. Hernandez feel more useful and motivate her to move about and get out of the house more?

Scenario C

Mr. Gerhardt is a 78-year-old who is discharged home after a total hip replacement. You are assigned as his home care nurse to do wound care, assess for complications, and monitor rehabilitation.

1. What teaching for self-care would you reinforce for Mr. Gerhardt on your first visit?
2. How would you determine whether the home environment is safe for Mr. Gerhardt?
3. Mr. Gerhardt is very depressed because he feels he will no longer be able to get out to go fishing and visit with his friends. How would you approach the psychosocial aspects of his care?

Scenario D

During your daily run, you step on an irregular surface and twist your ankle. At home, you notice tenderness at the site, minimal swelling, and loss of function but no abnormal motion.

1. What first aid will you perform?
2. How will you know if you have a sprain or a fracture?

UNIT XI

Urinary System

OUTLINE

Chapter 33 The Urinary System

Chapter 34 Care of Patients With Disorders of the Urinary System

CHAPTER 33

The Urinary System

Objectives

Theory

1. Illustrate the anatomy and physiology of the urinary system.
2. Differentiate the causes of urologic problems and disorders.
3. Discuss ways in which nurses can help patients to prevent or cope with urologic disorders.
4. Examine the psychosocial effects of urinary incontinence.
5. Compare and contrast drugs for urinary incontinence with those for benign prostatic hypertrophy.

Clinical Practice

6. Present nursing responsibilities in the preprocedure and postprocedure care of patients undergoing urologic diagnostic studies.
7. Perform initial and ongoing nursing assessment of a patient's urologic status.
8. Describe five nursing responsibilities related to the care of a patient with an indwelling catheter.
9. Write a nursing care plan for a patient with urinary incontinence.

KEY TERMS

anuria (ă-NŪ-rē-ă, p. 777)

blood urea nitrogen (BUN) (blūd ū-RĒ-ă Nī-trō-jēn, p. 770)

creatinine (krē-ĀT-ĭ-nēn, p. 768)

dysuria (dīs-Ū-rē-ă, p. 777)

hematuria (hē-măt-Ū-rē-ă, p. 775)

micturition (mīk-tū-RĪSH-ūn, p. 768)

nephrotoxic (nēf-rō-TŌK-sīk, p. 775)

nocturia (nōct-Ū-rē-ă, p. 777)

oliguria (öl-ĭ-GŪ-rē-ă, p. 777)

residual urine (rē-Zī-dū-ăl Ū-rīn, p. 777)

urinary frequency (Ū-rī-nār-ē FRĒ-kwēn-cē, p. 777)

urinary hesitancy (Ū-rī-nār-ē HĒZ-ĭ-tān-cē, p. 777)

urinary incontinence (Ū-rī-nār-ē īn-KŌN-tī-nēns, p. 768)

urinary retention (Ū-rī-nār-ē rē-TĒN-shūn, p. 777)

voiding (VŌYD-īng, p. 768)

Anatomy and Physiology of the Urologic System

Structures of the Urologic System and How they Interrelate

- The kidneys, ureters, urinary bladder, and urethra are the structures of the urinary system (Figure 33-1).

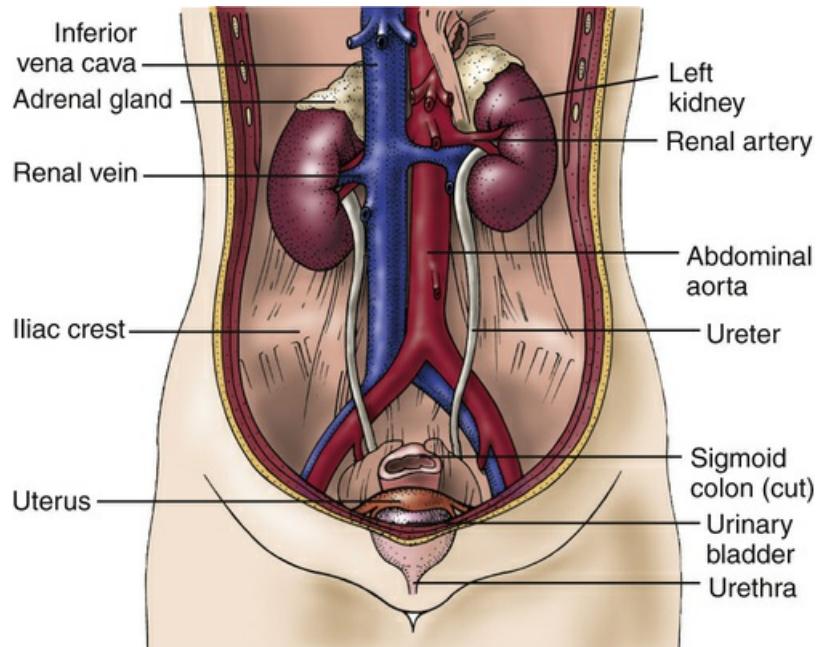

FIGURE 33-1 Structures of the urinary system. (From Ignatavicius DD, Workman ML: *Medical-surgical nursing: Critical thinking for collaborative care*, ed. 7, Philadelphia, 2013, Saunders.)

- The kidneys are bean-shaped organs positioned on either side of the vertebral column at the level of the first lumbar vertebra. The left kidney is slightly higher than the right.
- The kidney consists of the cortex, the outer layer, the medulla, and the renal pelvis. The cortex contains blood vessels and nephrons; the medulla contains the collecting tubules; and the renal pelvis gathers the urine and directs it to the bladder (Figure 33-2).

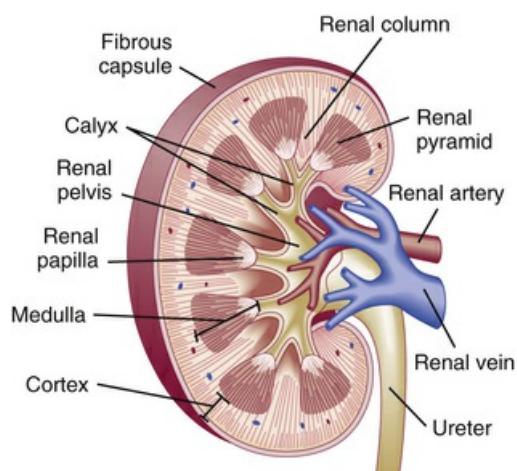

FIGURE 33-2 Structures of the kidney. (From Lewis SL, Dirksen SR, Heitkemper MM, Bucher L: *Medical-surgical nursing: Assessment and management of clinical problems*, ed. 9, St. Louis, 2014, Mosby.)

- The nephron is the functional unit of the kidney (there are 1 million nephrons in a kidney).
- The nephron consists of the glomerulus, which is a network of capillaries encased in a thin-walled sac called the *Bowman capsule*, and the tubular system.
- The tubular system of the nephron consists of the proximal convoluted tubule, the loop of Henle, the distal convoluted tubule, and the collecting duct (Figure 33-3). Urine is carried by the ureters from the kidney to the bladder through peristaltic action.

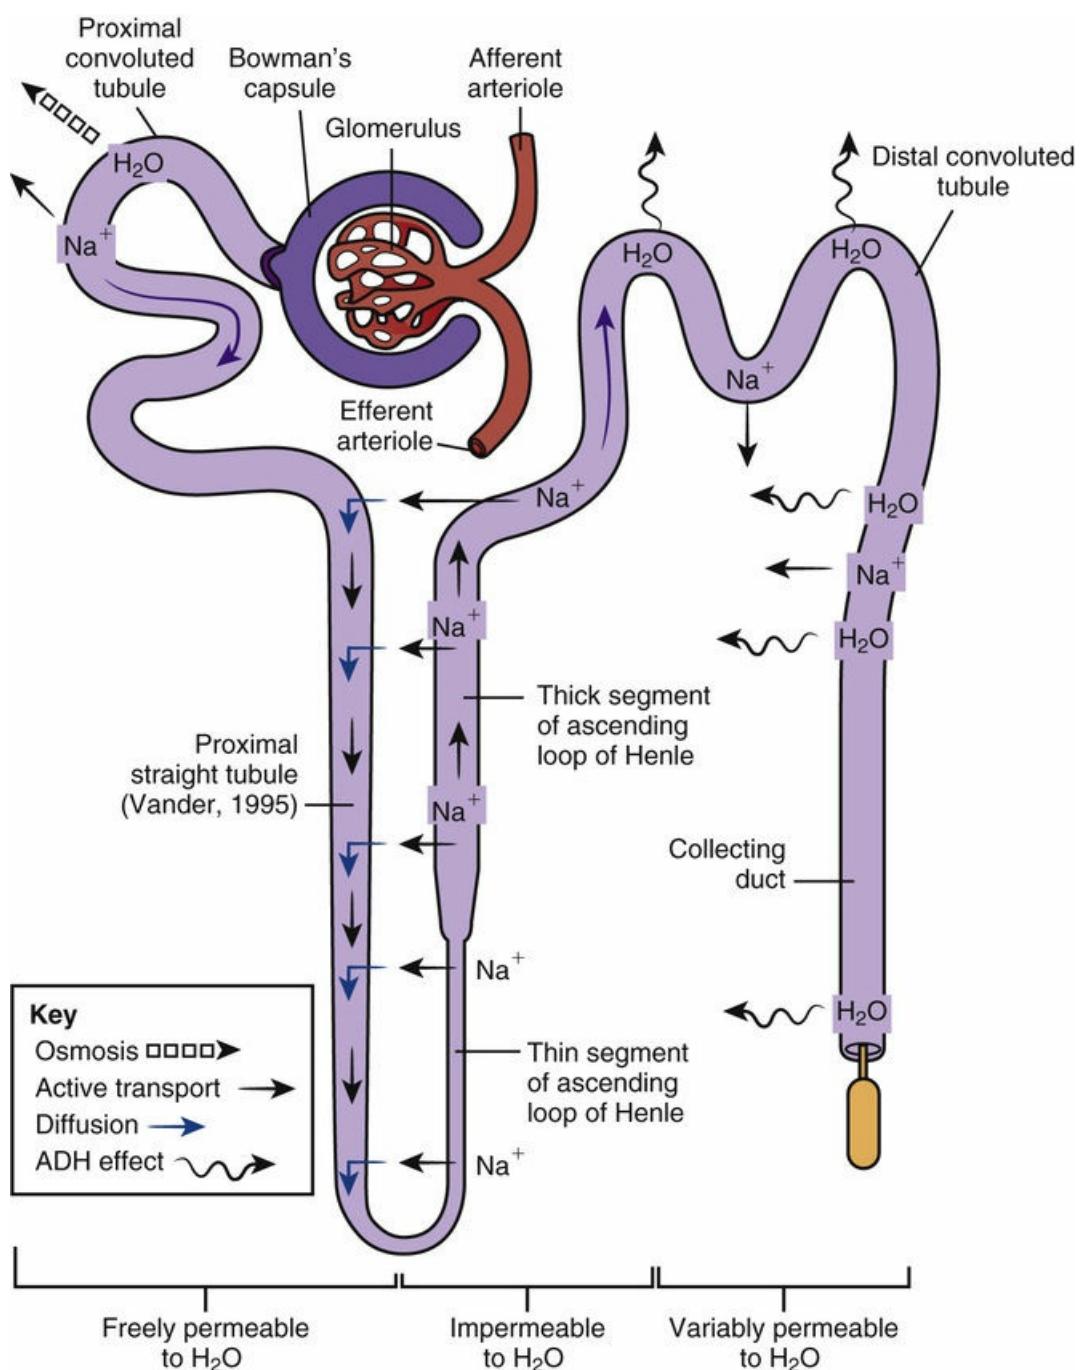

FIGURE 33-3 The nephron. ADH, Antidiuretic hormone. (From Ignatavicius DD, Workman ML: *Medical-surgical nursing: Critical thinking for collaborative care*, ed. 7, Philadelphia, 2013, Saunders.)

- The bladder, a hollow muscular organ, serves as a reservoir for urine; the inner lining of the bladder is a mucous membrane.
- The urine passes from the bladder down the urethra, which is approximately 3 to 5 cm long in

women and 20 cm in men.

- The internal, involuntary urethral sphincter is controlled by the detrusor muscle in the wall of the bladder.
- The external urethral sphincter voluntarily controls release of urine to the outside.
- Blood is brought to the kidney by the renal arteries that branch off the aorta. Blood is returned by veins to the inferior vena cava.

Functions of the Kidneys

- The kidneys regulate serum electrolytes by filtration and reabsorption ([Table 33-1](#)).

Table 33-1
Hormones and Metabolic Actions Associated With Kidney Function

HORMONES	ACTION
Circulating in the Blood to Influence Urine Volume and Concentration	
Aldosterone	Increases the reabsorption of sodium
Antidiuretic hormone (ADH)	Increases permeability in the tubules and reabsorption of water
Atrial natriuretic hormone	Increases the secretion of sodium
Produced by the Kidney	
Erythropoietin	Stimulates the bone marrow to increase red blood cell (RBC) production; increased production of erythropoietin is triggered by a demand for oxygen or when RBC level falls below normal
Calcitriol (active vitamin D)	Increases absorption of calcium and phosphorus
Renin	Assists in the regulation of blood pressure
Affecting Kidney Function	
Parathyroid hormone	Works in conjunction with calcitriol to increase absorption of calcium and phosphorus
Cortisol	Promotes sodium and water retention

- The kidneys eliminate metabolic wastes by filtration; they filter about one fourth of the body's blood at any one time.
- Each nephron filters blood plasma through the semipermeable glomerular membrane.
- Glomerular filtration rate (GFR) is the amount of blood filtered by the glomeruli in a given time (average GFR is about 125 mL/min).
- The kidneys regulate fluid volume by filtration, reabsorption, and excretion.
- Most of the water and some of the electrolytes are reabsorbed into the bloodstream in the descending and distal convoluted tubules.
- The kidneys assist in maintaining acid-base balance by secreting hydrogen ions into the urine.
- Unwanted substances—urea, **creatinine** (waste products of protein metabolism and skeletal muscle contraction, respectively), and uric acid—are retained in the tubules along with some water.
- Approximately 200 L of liquid are filtered in a 24-hour period; 1.5 to 2 L are excreted as urine.
- The kidneys regulate blood pressure by secreting the enzyme renin.
- The kidneys increase red blood cell production by secreting erythropoietin.
- The kidneys metabolize vitamin D into an active form.

Functions of the Ureters, Bladder, and Urethra

- Each ureter is a small tube about 25 cm long; it carries urine from the renal pelvis to the bladder.
- The bladder holds the urine; capacity varies from about 1000 to 1800 mL.
- A feeling of bladder fullness and an initial signal to void (empty the bladder) occurs when the bladder contains 150 to 200 mL of urine.
- The **micturition** (voiding) reflex is then initiated and transmitted to the bladder. Urine then passes from the bladder through the urethra during urination (**voiding**).
- The flow of urine is controlled by the internal urethral sphincter and the external urethral sphincter.

Aging-Related Changes

- Kidney function begins to degrade after age 45 years, and renal blood flow and GFR gradually decrease with each decade.
- In men, the prostate gland hypertrophies with age and can cause varying degrees of obstruction to the normal flow of urine.
- Secretion of renin, aldosterone, and vitamin D activation are decreased.
- Degenerative changes in the bladder muscles may lead to residual urine (incomplete emptying of urine) and **urinary incontinence** (involuntary passing of urine).
- Bladder capacity decreases to as little as 200 mL, and frequent emptying is needed.
- A decreased ability to concentrate urine leads to nocturia (urination during the night).
- Lowered estrogen levels in women result in tissue atrophy in the urethra, vagina, and trigone of the bladder (triangular portion at the base of the bladder), which predisposes to infection and incontinence.

The Urologic System

The kidneys and urinary tract function to maintain the proper balance of fluids, minerals, and organic substances necessary for life. Problems in the heart, lungs, or circulatory system can arise from kidney disorders or kidney failure. Likewise, generalized diseases, such as atherosclerosis, other circulatory impairments, infections, or disturbances in the metabolic processes such as diabetes mellitus, may seriously impair the proper functioning of the kidneys.

Disorders of the Urologic System

Causes

The high volume of blood that is filtered by the kidney contains some bacteria. These bacteria can colonize the kidney, causing an infection. Also, bacteria can easily enter the urinary tract through the urethra, and the infection may spread up into the kidneys.

When an immune reaction occurs in the body, the glomeruli that filter the blood are exposed to antibodies and antigen–antibody complexes contained in that blood. These antibodies and antigen–antibody complexes can cause an autoimmune inflammatory reaction known as *glomerulonephritis* that damages the semipermeable glomerular membrane and interferes with normal kidney function.

Once urine is formed, the urinary system must be patent and unobstructed for urine to be excreted. Tumors may form in the bladder, ureters, or kidney and interfere with normal function by altering cell structure or impeding urine flow. Stones in the kidney or ureters may obstruct the flow of urine. In older men, an enlarged prostate may impede flow of urine through the urethra.

Tubular necrosis can be caused by lack of oxygen or bacterial or chemical destruction of cells, which affects the functional ability of the nephron and decreases kidney function. Many drugs can be toxic to the kidney, and heavy metals such as mercury can cause considerable damage.

Hypertension is a major cause of end-stage kidney disease; conversely, renal disorders can also cause secondary hypertension. Because so much of the kidney's function is directly related to the capillaries and arterioles, any disorder, such as atherosclerosis and diabetes mellitus, that systemically affects the blood vessels can affect the kidneys. When these vessels become **sclerosed** (hardened), blood flow through the kidney is decreased; kidney function diminishes, and eventually this leads to chronic renal failure. Reduced blood circulation related to decreased volume (e.g., hypovolemic shock) or decreased cardiac output (e.g., cardiogenic shock) puts the patient at risk for acute renal failure (ARF).

Patient Teaching

Kidney Health and Healthy Blood Vessels

For patients who have hypertension or diabetes mellitus, design a teaching session that will help them recognize that the atherosclerotic changes that occur in the blood vessels also cause decreased blood flow to the kidneys and eventually reduce kidney function. In accordance with the *Healthy People 2020* goals, emphasize that compliance with the treatment plan for hypertension or diabetes mellitus helps to prevent kidney problems from occurring later in life.

Prevention

One of the best ways to prevent disorders of the urologic system is to drink an adequate amount of water. A minimum fluid intake of 2000 to 2500 mL/day is recommended to initiate good flow through the system.

Health Promotion

Bladder Health

Promote bladder and urinary tract health by encouraging patients to empty the bladder sooner, rather than waiting to urinate. Emptying the bladder prevents urinary stasis and prolonged exposure of waste toxins on the bladder wall, which may contribute to cancer of the bladder. Delayed voiding also causes the bladder wall to stretch beyond normal capacity, and places undue strain on the sphincters. Both can contribute to urinary incontinence later in life.

Controlling blood pressure and maintaining a normal serum glucose level can support healthy blood vessels. A good blood supply promotes good kidney function.

Carefully monitoring for adverse drug effects and avoiding the use of chemicals known to be harmful to the kidney help preserve optimal kidney function. [Box 33-1](#) gives examples of substances that are toxic to the kidney. When drugs that can be harmful to the kidney—such as sulfa compounds—are prescribed, increasing the fluid intake to 3000 to 3500 mL/day reduces the risk of kidney dysfunction. (Increasing fluid intake must be carefully considered when the patient has other conditions, such as congestive heart failure or cirrhosis of the liver.)

Patient Teaching

Over-the-Counter Drugs

Teach your patients to avoid routine use of over-the-counter drugs, such as nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen, to decrease the possibility of hepatic or renal dysfunction through unnecessary exposure to chemicals. This is in accordance with National Patient Safety Goals—to actively involve patients in their own care to ensure safety.

Think Critically

What changes could you make in your dietary habits or lifestyle that might help to prevent urologic problems?

Box 33-1

Examples of Potentially Nephrotoxic Substances

- Anti-infectives
- Aminoglycosides (gentamicin, streptomycin)
- Sulfonamides (trimethoprim-sulfamethoxazole)
- Antifungals (amphotericin B)
- Antitubercular (rifampin)
- Cephalosporins (cefaclor)
- Tetracyclines (doxycycline)
- Miscellaneous (e.g., vancomycin, polymyxin B, rifampin)
- ACE inhibitors (captopril)
- Antineoplastic agents (cisplatin, methotrexate)

- Immunosuppressants (cyclosporine)
- NSAIDs (salicylates, ibuprofen, indomethacin)
- Other drugs (acetaminophen, furosemide, phenazopyridine HCl, cimetidine)
- Contrast media dye (Gastrografin)
- Anesthetics (halothane)
- Heavy metals (lithium, gold salts, lead)
- Industrial (carbon tetrachloride for cleaning)
- Environmental (pesticides, snake venom)
- Recreational drugs (cocaine, heroin)

ACE, Angiotensin-converting enzyme; NSAIDs, nonsteroidal anti-inflammatory drugs.

Diagnostic Tests and Procedures

Patients experiencing problems with the urinary system undergo urine tests, such as a urinalysis and culture and sensitivity, and general diagnostic tests, such as a complete blood count (CBC), **blood urea nitrogen (BUN)**, serum creatinine, and creatinine clearance. Urea is produced when protein breaks down; it then combines with ammonia and is carried by the bloodstream to the kidneys for excretion. Creatinine is a by-product of skeletal muscle contraction. BUN and serum creatinine are interpreted together, and laboratory values should be obtained before the use of radiologic contrast dyes. Creatinine clearance (CC) is a good measure of GFR. Cystatin C is a relatively new test used to evaluate GFR. Cystatin C is a low-molecular-weight proteinase inhibitor that is produced at a constant rate and filtered out by the glomerulus. During impaired kidney function, cystatin C levels will rise. Normal value is 0.70 to 0.85 mg/mL (depending on age). This diagnostic test shows promise of being a better indicator of GFR when measured with serum creatinine in patients with chronic kidney disease ([Shlipak et al, 2013](#)).

Clinical Cues

BUN level and serum creatinine are the two most common tests used to screen for kidney problems. The normal adult range for BUN is 10 to 20 mg/dL. Normal ranges of serum creatinine are 0.6 to 1.2 mg/dL for adult males and 0.5 to 1.1 mg/dL for adult females. An increase in BUN or serum creatinine can be a signal of decreased kidney function.

Radiologic procedures range from a single view of the kidneys, ureters, and bladder (KUB) to interventional radiology, such as balloon angioplasty. A KUB is used to locate stones and detect structural abnormalities. Angioplasty is used to open blocked vessels and increase blood flow to the organs. Urodynamic tests, such as cystometrography, are used to measure flow volume and muscle function. Biopsies of the kidney or bladder are done in combination with radiologic examinations to locate lesions ([Figure 33-4](#)).

Patient Teaching

Renal Biopsy

Teaching points for patients having a renal biopsy:

- *Explain purpose:* To diagnosis the cause of kidney disease, to detect cancer, or to evaluate kidney transplant rejection.
- *Explain procedure:* Local anesthetic is given. Needle is inserted through skin into the kidney to

obtain a small sample under fluoroscopy. Total procedure time is 10 minutes.

- **Explain preparation:** Nothing by mouth (NPO) for 6 to 8 hours before procedure; blood tests will be performed before procedure (e.g., hemoglobin and hematocrit, prothrombin time, partial thromboplastin time).
- **Explain postprocedure care:** Must lie on back for 6 to 24 hours (time varies according to facility protocols and provider orders), avoid activities that increase abdominal pressure (e.g., sneezing, laughing), expect that urine will have blood for first 24 hours. Drink 3000 mL of fluid to flush urinary system (unless otherwise contraindicated).
- **Give home care instructions:** Avoid strenuous activity (heavy lifting or contact sports) for 2 weeks. Report bleeding (e.g., bright red or with clots) immediately. Report fever, malaise, or dysuria.

From Pagana KD, Pagana TJ: *Mosby's diagnostic and laboratory test reference*, ed. 11, St. Louis, 2013, Mosby.

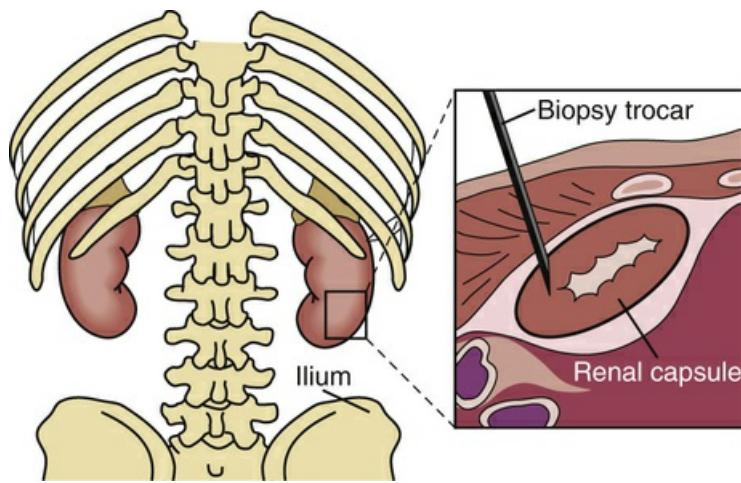

FIGURE 33-4 Renal biopsy. A needle is inserted through the skin to obtain a tissue sample. (From Pagana KD, Pagana TJ: *Mosby's diagnostic and laboratory test reference*, ed. 11, St. Louis, 2013, Mosby.)

General nursing responsibilities for diagnostic testing include assessing for allergies to contrast media and ruling out pregnancy before radiologic procedures and scans. **Table 33-2** lists common diagnostic tests and procedures, along with nursing implications.

Think Critically

What is the rationale of having the patient use the clean-catch method, rather than just simply voiding into a collection container?

Older Adult Care Points

Older kidneys have less ability to concentrate urine. This predisposes the patient to dehydration when fluid intake is restricted for diagnostic tests. The contrast agents used for radiographic tests, in conjunction with dehydration, can cause acute renal failure in older adults. Older adults should be carefully rehydrated by encouraging several ounces of oral fluid (preferable to intravenous [IV] administration, if possible) every 1 to 2 hours and monitoring vital signs, urinary output, lung sounds, and respiratory effort to prevent fluid overload.

Clinical Cues

A 24-hour urine collection is usually started first thing in the morning. Have the patient void and discard the urine, note the time on the laboratory slip and in the nurses' notes, and then put each successive voiding into the collection container. At the time when the test is to end, have the patient void, and add this last urine to the collection bottle. Check with the laboratory as to

whether the container must be kept on ice during the collection period. Place a sign on the patient's door and over the toilet stating "24-hour urine test in progress" so that everyone will save the urine properly.

Table 33-2
Diagnostic Tests for Urologic Disorders

TEST	PURPOSE	DESCRIPTION	NURSING IMPLICATIONS
Urine			
Urinalysis	To detect bacteria, blood, casts, and other abnormalities of the urine	Normal urine is clear, straw to dark amber in color, has a pH of 4.5–6.0, has a specific gravity of 1.010–1.030, and is negative for protein, glucose, ketones, and bilirubin. It should have only a rare RBC, no more than 0–4 WBCs, and an occasional cast.	Obtain a fresh 10-mL morning specimen. Send specimen to laboratory immediately. If vaginal bleeding is reported, provider may order a catheterized specimen.
Urine culture and sensitivity (C&S) (clean catch midstream)	To verify UTI and to determine the specific infectious organism and the sensitivity to specific antibiotics	Normally, urine is sterile in the bladder. Several drops of urine are placed in a culture medium. After incubation (several days), the colonies are counted. If >100,000 organisms per milliliter are counted, there is a UTI. Sensitivity test: bacteria are exposed to various antibiotics to determine which is most effective in killing the organism.	Instruct patient to perform the clean-catch method for specimen collection. A sterile specimen can also be obtained via urinary catheterization. Send specimen to laboratory immediately to prevent change in pH, which can affect bacterial growth.
Urine osmolality	To determine whether the kidneys can concentrate urine; reflects hydration status	Normal findings for fasting specimen: >850 mOsm/kg. Increases in osmolality can indicate dehydration, azotemia, or chronic renal disease. Decreases in osmolality can indicate low-salt diet, excessive water intake, or diabetes insipidus.	Give a high-protein diet for 3 days before the urine collection. Restrict foods and fluids for 8–12 hr before obtaining fasting specimen. To collect a fasting urine specimen, have the patient empty bladder at 6 A.M., discard, then collect specimen at 8 A.M. Label as a fasting specimen and send to laboratory.
Uric acid	To check for renal failure, gout, kidney stones	Uric acid is an end product of protein metabolism. Normal findings: 250–750 mg/24 hr (normal diet). Level is elevated in renal failure.	Take a diet history; specifically ask about purine-rich foods (e.g., liver, beef kidneys, or sardines). Patient needs to fast the night before specimen collection. Instruct on a 24-hr urine collection. (Serum uric acid may be ordered.)
Creatinine clearance	To determine how well kidneys can excrete creatinine	Normal creatinine clearance: 15–25 mg/kg body weight in 24 hr. Elevated serum creatinine with decreased urine creatinine indicates decreased kidney function.	Collect a 24-hr urine specimen. A 5-mL venous blood sample is collected sometime during the 24-hr collection period. Instruct patient to avoid rigorous exercise (according to laboratory protocol: avoid meat, tea, coffee, or drugs) during the collection period.
Urine cytology	Detects presence of bladder cancer noninvasively	Identifies cellular structures indicating bladder cancer.	Obtain a fresh urine specimen (not first morning specimen). Transport to laboratory within the hour.
Blood			
Blood urea nitrogen (BUN)	To evaluate kidney function and hydration status	High BUN levels can indicate poor kidney function, dehydration, or increased breakdown of body protein (i.e., severe burns or excessive exercise). Lower BUN levels are found in severe liver damage, excessive hydration, and protein deficiency. Normal BUN levels average 7–20 mg/dL (depending on sex and age).	No fasting or patient preparation is required. Take a drug history; many drugs can alter results. (Record drugs on laboratory slip as appropriate.) Requires 5 mL of venous blood. When drawing specimen, make sure it is not hemolyzed.
Serum creatinine	To evaluate kidney dysfunction when there are a large number of nonfunctional nephrons	Creatinine is a waste product of skeletal muscle activity. It is produced in fairly constant amounts and is excreted through the kidneys. Normal serum creatinine is 0.8–1.2 mg/dL (depending on gender).	Meats, tea, or coffee may be restricted 6 hr before the test. Cephalosporins may be stopped before the test. Record baseline height and weight. Instruct patient to avoid strenuous exercise before test. Requires 5–10 mL venous blood; may include a 24-hr urine collection.
Cystatin C	To detect renal disease in early stage	Cystatin C in the blood binds to specific anti-cystatin C antibody, causing agglutination.	No special preparation needed. Requires a blood draw of 3 mL in lavender-top tube.
Radiology Studies			
Kidneys, ureters, bladder (KUB)	To visualize the urinary structures or radiopaque stones	Single radiographic view of the lower abdomen done without contrast medium.	Patient needs an x-ray gown that has no radiopaque fasteners. Test for pregnancy before any radiologic study.
Intravenous pyelogram (IVP)	To visualize the kidneys, ureters, and bladder To detect obstructions related to stones or tumors	An iodine-based dye is given via IV injection, then radiographs are taken at timed intervals, showing the flow of the dye through the renal system.	Check for allergy to iodine-based dye; verify BUN and creatinine results; inform provider. Bowel preparation and NPO status may be required. Patient may feel a hot flush or nausea when dye is injected. After procedure, encourage PO fluids for rehydration.
Retrograde pyelogram	To visualize the kidneys, ureters, and bladder	During cystoscopy: catheters are threaded into the ureters to inject the dye backward into the kidneys.	Check for allergy to iodine-based dye, verify BUN and creatinine results; inform provider. Bowel preparation and NPO status may be required.
Cystogram	To visualize the contour of the bladder	Radiographs are taken before and after sodium iodide is instilled into the bladder through a urethral catheter.	Check for allergies to iodine-based dyes. Give a clear liquid breakfast on the day of test. A Foley catheter is usually inserted before the procedure. Patient's bladder may feel very full during the examination, but bladder is drained after the radiographs are taken. Postprocedure, encourage PO fluids for flushing.
Magnetic resonance imaging (MRI)	To detect trauma or tumors in soft tissues	Noninvasive imaging uses a powerful magnetic field to scan radiowave frequencies and form 3D images. Can be done without contrast.	Considered relatively safe. Metal objects are forbidden during the procedure. Pacemakers and implants are contraindicated.
Computed tomography (CT) scan	To determine presence of a cyst, tumor, or renal calculi	A combination of radiologic and computer techniques yields cross-sectional information and indicates the density of tissues.	Contrast medium may or may not be given; check for allergy to iodine. Patient may need to be NPO before examination. Procedure lasts about 30 min; patient must remain quiet and cooperative.
Renal ultrasonography	To show size, shape, and location of kidneys, ureters, and bladder and obstructions to flow	A handheld transducer is passed over the skin, and high-frequency sound waves create visual images of the structures.	Patient may be asked to drink fluid to fill bladder before sonogram; other laboratories may require NPO for 8–12 hr before the procedure. Test takes approximately 30 min.
Renal angiography	To assess renal arterial system function and identify areas of obstruction to blood flow	Under local anesthesia, a catheter is threaded through the femoral artery and up the aorta to the renal artery, and a contrast agent is injected. Fluoroscopy is conducted during the injection to observe for filling of blood vessels. Angiography is performed to detect complications in a transplanted kidney, to evaluate a mass, or to check the extent of kidney trauma.	Requires a signed permission form. Check for allergy to iodine-based dye. Bowel preparation or NPO status for 6–8 hr may be ordered. Postprocedure care includes direct pressure applied to the puncture site for 20 min, followed by a pressure dressing and additional mechanical pressure. Patient remains flat in bed for 4–12 hr or more. Vital signs and popliteal and pedal pulses are checked q15min for the first hour and q2–4h, as ordered, for signs of bleeding or shock.
Radionuclide renal scan	To detect perfusion and function; can detect abnormal areas of kidney tissue (e.g., tumors or cysts)	A radioisotope is injected into the blood, and a scintillation scanner is passed over the area of the kidney. This yields a pattern of isotope uptake. Procedure may take 1–4 hr to complete.	Explain that low-dose radiation is used and is quickly eliminated from the body, and that the procedure is not painful, but patient must lie very still. There are no dietary restrictions, but the patient should drink 2–3 glasses of water before the test.
Endoscopy			
Cystoscopy	To examine the interior of the bladder	Under short-acting or local anesthesia, a cystoscope is passed up the urethra into the bladder. The scope can be guided into a ureter to extract a stone or to biopsy lesions in the bladder.	Requires a signed permission form. Patient is usually NPO for several hours before the procedure. Give preoperative medication as prescribed. Postprocedure: burning, frequency, and pink-tinted urine may occur. Frank bleeding should be reported. Warm sitz baths and mild analgesics are given for voiding discomfort.
Urodynamics			
Cystometry (CMG)	To measure bladder capacity, pressures, and sensations	A urinary catheter is inserted and attached to a cystometer. Fluid is instilled, and the patient reports when the need to void is first noted, then mild urgency, and finally when bladder feels very full. Readings of bladder capacity and pressure are recorded and plotted.	Sterile technique must be used for catheter insertion and bladder fluid instillation. The patient is monitored for signs of postprocedure infection.
Urethral pressure study	To determine urethral pressure needed to maintain urinary continence	A catheter with pressure-sensing capabilities is inserted into the bladder. As the catheter is withdrawn, the varying pressures of the smooth muscle of the urethra are	Sterile technique must be used for catheter insertion. The patient is monitored for signs of postprocedure infection.

		recorded.	
Electromyography of the perineal muscles	To evaluate the quality of the voluntary muscles used in voiding	Electrodes are placed either in the rectum or the urethra to measure contraction and relaxation of the muscles involved in voiding.	Inform the patient that there is mild discomfort during electrode placement and nerve conduction testing. Analgesics may be given before or after the procedure to relieve discomfort.
Miscellaneous			
Bladder scan	Noninvasive method to measure postvoid residual volume or urinary retention	Portable handheld scanner uses ultrasound to create an image and calculate bladder volume. Can be done at the bedside.	Clean the probe. Palpate for the symphysis pubis and apply gel about 1 inch above. Ensure that the probe makes good contact with the gel-covered skin. Point the probe toward the coccyx. Press the scan button for the bladder volume readout.

CBC, Complete blood count; *NPO*, nothing by mouth; *PO*, by mouth, orally; *PRN*, as needed; *RBC*, red blood cell; *UTI*, urinary tract infection; *WBC*, white blood cell.

❖ Nursing Management

■ Assessment (Data Collection)

History and Present Illness

At the time of admission, obtain a personal history of previous disorders of the urinary tract such as frequent urinary tract infections (UTIs), illness or injury to any system, or problems that required surgery. A family history of diabetes, cardiovascular disease, or kidney stones is relevant to an assessment of kidney function.

Many substances can be toxic to the kidneys (**nephrotoxic**); obtain a patient history that includes use of prescription or over-the-counter drugs or illicit substances and any occupational exposure to hazardous materials. The complete drug history should be communicated to all health care professionals and conveyed if the patient is transferred to another facility; on discharge, the patient should receive a copy of the information in accordance with National Patient Safety Goals.

▣ Clinical Cues

If the patient appears hesitant to disclose illicit drug use, use a matter-of-fact approach and explain that the information is important because of potential drug–drug interactions and adverse effects on organs such as the kidneys, heart, or liver.

▣ Focused Assessment

Data Collection for the Urinary System

Ask the following questions when assessing a patient with a urologic problem:

- Do you or your family have a history of hypertension, cardiovascular disease, diabetes, kidney stones, frequent urinary tract infections, or other kidney problems?
- Have you ever had genital herpes or another sexually transmittable infection?
- Do you have any pain when urinating? Any abdominal or flank pain?
- Do you have any difficulty in starting the stream of urine?
- Do you feel as though you empty your bladder completely when you urinate?
- Have you noticed any change in the appearance or smell of your urine?
- Have you needed to empty your bladder more frequently than usual?
- Have you been experiencing any urgency, accompanied by dribbling or leaking urine?
- How many times do you need to get up at night to urinate? (Once a night is average.)

- Have you had any episodes of urinary incontinence?
- Has there been a change in urinary output, in voiding pattern, or in the characteristics of the urine?
- Do you have pain or discomfort in the bladder or kidney areas?
- Have you ever noticed blood in your urine (other than when menstruating [for women])?
- Do you have any problem with sexual dysfunction?
- Are you experiencing excessive fatigue?
- Have you noticed any itching of the skin?
- How much fluid do you drink in a day?

Clinical Cues

Collecting information about sexual health, sexually transmittable infections, and other genital and reproductive disorders is important, because these may be a source of infection or blockage. You may find that it will be easier for you and the patient to talk about these issues toward the end of the interview, after a sense of rapport has been established.

Physical Assessment

Perform a general physical assessment, including a complete set of vital signs and a baseline weight. Observe for signs of generalized or facial edema. Gently palpate the abdomen and the bladder for distention or tenderness. Visually inspect the external genitalia, particularly if there are complaints of pain, discharge, bleeding, or prolapse or if there is an indwelling or recently removed catheter.

Focused Assessment

Physical examination should include the following:

- Inspect the abdomen for any visible abnormalities.
- Palpate all four quadrants for areas of tenderness.
- Palpate above the pubic bone for evidence of bladder distention.
- Inspect genitals as appropriate (e.g., reports of bleeding, discharge, presence of or recent discontinuation of indwelling catheter).
- Examine the urine for color, clarity, volume, and smell.

Nursing responsibilities in the daily assessment of urinary function include (1) measuring intake and output; (2) evaluating abnormal flow of urine; (3) noting the character of urine (i.e., color, odor, clarity); (4) noticing changes in the pattern of voiding; and (5) assessing pain and discomfort.

Documentation includes objective observations of amount and characteristics of urine and the patient's subjective reports of pain, discomfort, and abnormalities.

Characteristics of urine. The color of urine can give helpful information about the status of the patient and the functioning of the kidneys. [Table 33-3](#) lists color variations in urine and the significance of abnormal coloration.

Table 33-3

Common Causes of Variations in Color of Urine

COLOR	MEDICATION	OTHER CAUSES
-------	------------	--------------

Colorless or pale yellow	Diuretics	Dilute urine because of diabetes insipidus, diabetes mellitus, overhydration, chronic renal disease, nervousness, alcohol
Bright yellow	Riboflavin (multiple vitamins)	None
Dark amber to orange	Phenazopyridine HCl (Pyridium) Nitrofurantoin (Macrodantin) Sulfasalazine (Azulfidine) Thiamine (multiple vitamins)	Concentrated urine because of dehydration or increased metabolic state (e.g., fever) Urobilinogen (a by-product of bilirubin normally excreted through stool and urine) Bilirubin (a component of bile normally metabolized and excreted via stool and urine) Foods: excessive carrots
Pink to red	Phenothiazines (e.g., Compazine) Docusate calcium (Surfak) Phenolphthalein (Doxidan) (in alkaline urine) Phenytoin (Dilantin) Rifampin Cascara (in alkaline urine) Senna (Senokot)	Fresh red blood cells Menstrual contamination Myoglobin (a by-product of excessive exercise or skeletal tissue damage) Porphyria (porphyria is a hereditary metabolic disorder) Foods: beets, blackberries, red food dyes
Brown	Cascara (in acid urine) Metronidazole (Flagyl) (if left standing) Phenothiazines (e.g., Compazine)	Extremely concentrated urine because of dehydration or increased metabolic state Red blood cells (old blood) Bilirubin Urobilinogen Myoglobin Porphyria
Blue or green	Triamterene (Dyrenium) Amitriptyline (Elavil) Methylene blue	Bilirubin Biliverdin (a blue-green pigment that occurs in bile) Pseudomonas infection
Dark brown to black	Nitrofurantoin (Macrodantin) Iron preparations (if left standing) Levodopa (if left standing) Methocarbamol (if left standing) Quinine Senna (X-Prep, Senokot) Methyldopa (Aldomet)	Melanotic tumors Addison disease Porphyria Red blood cells (old blood)

Another characteristic that should be noted is **odor**. Normal urine develops an ammonia-like odor after it has stood for a length of time, but this odor should not be present in freshly voided urine. A foul smell may indicate infection. Acetone in the urine, which occurs during metabolic acidosis, causes it to have a sweet, fruity odor. Various supplements can affect urine odor, as can asparagus.

Hematuria means blood in the urine. Microscopic hematuria occurs when blood in the urine is not visible to the naked eye. Gross hematuria is a sign of bleeding from some point in the urinary tract. Red blood in the urine is not easily missed, but if the blood has been in the bladder or kidney for a long time, it will deteriorate and cause the urine to be a smoky gray or dark brown. If the blood is noticed as soon as voiding starts, it is likely that the blood is from somewhere in the urethra. If it is noticed at the end of urination, the site probably is near the neck of the bladder. Bleeding throughout voiding indicates that the blood is coming from a site above the neck of the bladder, because the blood has been well mixed with the urine in the bladder.

Proteinuria is the abnormal presence of protein in the urine. Proteins are too large to pass through the structure of the glomerular membrane; therefore presence of protein is suggestive of damage to the membrane that occurs in renal disease, such as nephrotic syndrome or glomerulonephritis. Proteinuria is also seen in other conditions such as preeclampsia, multiple myeloma, and diabetes mellitus (Pagana and Pagana, 2013). Specialized assays are required to detect **microalbuminuria** (presence of albumin in the urine), which is suggestive of **early** kidney disease. This test could be considered essential for those at high risk for renal disease, such as persons with diabetes or hypertension. **Pneumaturia** means gas in the urine. This can occur if there is a fistula (abnormal passage) between the bladder and the bowel or vagina.

Changes in voiding pattern. Ask about or observe urinary frequency during the day and night. Other alterations include the size and force of the urinary stream, feeling of fullness even after voiding, and change in the amount urinated each time. Increased frequency can be a manifestation of some abnormality in the urinary drainage system, particularly in the bladder and urethra. The frequency with which a person feels the urge to urinate can be related to psychological as well as physiologic factors. Excitement, anxiety, and fear can produce increased frequency of urination. Caffeine and other diuretics found in foods and drinks and an increased intake of fluid can increase the number of times a person must urinate. Pathologic conditions that can cause increased frequency include inflammation of the bladder (cystitis) or urethra (urethritis).

Patient Teaching

Urgency can be symptomatic of inflammation. *Urgency* refers to an almost uncontrollable desire to void. Incontinence sometimes occurs because the patient is not able to get to a toilet quickly enough after the urge to urinate occurs. Box 33-2 defines terminology related to changes in urine output and flow.

Box 33-2

Terminology Related to Urine Output and Flow

- **Anuria:** Absence of urine. This rarely occurs but may be associated with acute renal failure.
- **Oliguria:** Diminished or abnormally decreased flow of urine; may result from dehydration, renal failure, or obstruction.
- **Polyuria:** Abnormally high and dilute urine output; the result of excessive solutes and increased excretion of water. Possible causes include hypercalcemia, diabetes insipidus, uncontrolled diabetes mellitus, and increased fluid intake.
- **Nocturia:** Urination that occurs during the night; may be related to the decreased ability of the aging kidney to concentrate urine.
- **Urinary frequency:** Voiding more often than every 2 hours. This can be the result of inflammation, decreased bladder capacity, psychological disorders, pregnancy, or increased fluid intake.
- **Urinary hesitancy:** A delay in starting the stream of urine; may be related to partial obstruction.
- **Urinary retention:** Retaining or holding urine in the bladder; various causes include neurologic, psychological, medication, obstruction, or anesthesia.
- **Residual urine:** That which is left in the bladder after voiding; related to poor muscle tone or partial obstruction.

Pain and discomfort. In general, the locations in which the patient with a urinary problem is most likely to experience discomfort are either the bladder area or the region over the kidney.

Bladder pain can be caused by the stretching of an overfull bladder. Assessment of the size and location of the bladder is indicated when a patient reports pain in the bladder region. Normally the bladder cannot be felt. If a smooth, rounded mass is felt on palpation in the area above the pubic bone, the bladder is distended. Bladder pain can also be caused by spasms of the bladder musculature as it attempts to empty itself of clots, bits of tissue, and other cellular debris. This can occur postoperatively or when there is moderate to severe inflammation and bleeding in the urinary tract. Relief sometimes can be obtained by irrigating the bladder to remove the clots and debris.

Flank (side and back area of the body below the ribs and above the hips) pain can also be caused by obstruction and distention; in this case the affected organs are the ureters and kidney pelvis. Spasmodic peristaltic contractions along the ureter can be caused by stones, clots, a tumor, inflammatory swelling, or any other condition that prevents the flow of urine from the kidney to the bladder. When evaluating flank pain, note the location and assess for radiation of pain from the kidney or ureter to the genitalia and thigh.

Another kind of discomfort may be painful urination, or dysuria. **Dysuria** usually is caused by inflammation in either the bladder or the urethra. It often is described as burning and can range from mild to severe. Ask the patient when the pain occurs and whether it is felt immediately before, during, or after voiding.

?

Think Critically

What characteristics of a fresh urine specimen might indicate an infection? Why should UTIs be treated promptly?

■ Nursing Diagnosis

Problem statements commonly associated with urologic problems and disturbances in urinary flow include the following:

- Altered urinary elimination due to inflammation.
- Fluid volume excess due to inability of kidneys to produce urine.

- Pain due to ureteral spasm, bladder spasm, or inflammation.
- Fatigue due to effect of the accumulation of waste products.
- Insufficient knowledge due to prevention of UTI.
- Fear due to potential cause of hematuria or possibility of malignancy.
- Altered body image due to urinary diversion.

Specific NANDA-I diagnoses can be chosen from the NANDA-I list (see inside back cover).

■ Planning

Expected outcomes for these problems might be:

- Patient will void spontaneously, with decreased symptoms (e.g., urgency, dysuria, hematuria), within 48 hours after starting antibiotics.
- Patient will have no signs of fluid volume overload (e.g., weight gain, edema, or crackles in lungs) within 2 days.
- Patient will report bladder pain level less than 3/10 during this shift.
- Patient will have adequate energy to independently perform activities of daily living (ADLs) before discharge.
- **Patient will identify four or five ways to prevent recurrent UTIs before leaving the clinic today.**
- Patient will verbalize concerns or fears about signs and symptoms (e.g., hematuria) during this shift.
- Patient will demonstrate acceptance of stoma as evidenced by looking at stoma and handling ostomy equipment within 1 week.

Planning care for a patient with a disorder of the urologic system involves considering the effect of the disorder on the other body systems. **Fatigue and irritability are common when kidney function is impaired because of the buildup of waste products in the body and their effect on body cells.** In addition, educate the patient and the family to maximize participation in treatment goals and prevent complications. General nursing goals for addressing urologic disorders include:

- Absence of infection
- Absence of pain
- Restoration of normal urinary output
- Return to normal fluid balance
- Assimilation of knowledge for appropriate self-care
- Promoting resolution of body image disturbance
- Prevention of complications

■ Implementation

Caring for patients with urologic problems includes monitoring intake and output, body weight, and signs of edema. Monitoring the drug combinations for potential nephrotoxicity and for possible urinary retention is also very important.

You must use strict aseptic technique when catheterizing patients, emptying drainage bags, handling drainage tubes and stents, and performing peritoneal dialysis or hemodialysis.

Care of Urinary Catheters

The catheter should be fastened to the upper leg with tape or a catheter-securing device ([Figure 33-5](#)). Connecting tubing should be positioned so that there is no pulling on the catheter when the patient turns, moves in bed, or arises to ambulate; this prevents pulling on the balloon that holds the catheter in place, which would cause tissue irritation and predispose to infection. Irrigation of the bladder is not recommended unless there is an obstruction or a special solution needs to be instilled. Irrigation can be done with a closed system or by opening the indwelling catheter system. If open irrigation is performed, strict asepsis must be maintained ([Perry et al, 2012](#)). See [Table 34-3](#) for common urinary catheters and tubes used for urologic disorders. [Box 33-3](#) reviews principles of catheter care.

Legal and Ethical Considerations

Urinary catheters are one of the common causes of health care-associated infection. In 2011 there were 93,300 UTIs in hospitalized patients, and 75% of those were catheter related ([Centers for Disease Control and Prevention, 2014](#)). Alternatives to catheterization should always be considered to prevent infection, and the care should be carefully documented. When a patient dies of a health care-associated infection, the death is investigated to determine how the infection developed and contributed to the death of the patient. The purpose of the investigation is to prevent future incidents.

Clinical Cues

You can collect a urine specimen from a new drainage bag immediately after the catheter is inserted. If the catheter has been in place for several hours or days, you should not take the specimen from the drainage bag, because the urine specimen must be fresh. The tube must temporarily be clamped, and the specimen must be drawn from the upper port. Do not forget to unclamp the tube after you have obtained the specimen.

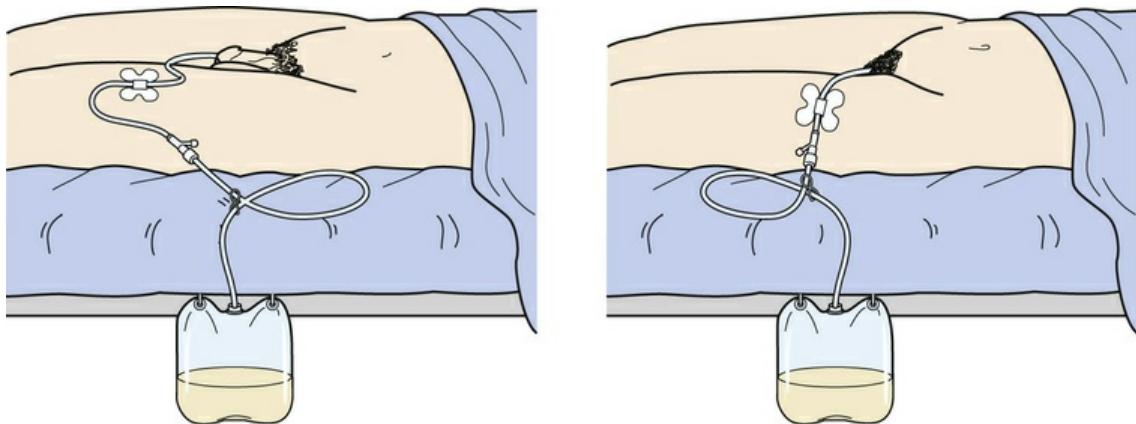

FIGURE 33-5 Catheter tubing attached to a collection bag and secured to the thigh.

Box 33-3

Principles of Urinary Catheter and Tube Care

- Use aseptic technique and gentle handling when caring for any urinary drainage tube.
- Insert urethral catheters using sterile technique.
- Do not open a urinary drainage system unless there is no alternative (e.g., the drainage bag must be changed for some reason).
- Empty the drainage bag by opening the drainage port at the bottom of the bag; use aseptic technique and do not allow the drainage tube to touch the collection container. After reclamping the tube, wipe away residual urine from the tube with an antiseptic swab before securing it.
- Use patient's individual collection container for draining the urine storage bag.
- Observe all tubes and level of drainage in the collection bag each time the patient is seen.
- Keep the drainage bag below the level of the catheter or insertion site (indwelling catheter drainage bags should have a backflow valve, but keeping the bag lower prevents backflow). If the bag must be raised above the insertion site, clamp off the tube briefly while repositioning the patient.

- Perform perineal care at least twice daily, cleaning the urinary meatus and catheter with soap and water; rinse well, just as the area would be cleansed if the patient were bathing normally (see agency's policy).
- Keep an intake and output record to help monitor kidney function.
- Encourage fluids of 3000 mL/day unless contraindicated.
- When irrigating, use the correct amount of sterile solution (according to agency policy, or the amount of solution determined by provider's order for nephrostomy tubes, ureteral tubes, or catheters).
- Use a steady, gentle stream to irrigate. Avoid exerting pressure that may traumatize or cause discomfort.
- Do not pull back forcefully on an irrigating syringe attached to a urinary catheter or tube; this creates negative pressure that may damage delicate tissues or collapse the tube.
- When discontinuing an indwelling catheter, never cut the catheter. Use a syringe to deflate the balloon.

Measuring Intake and Output

The quantity of fluids entering the body, by whatever route, has a direct bearing on fluid balance (see [Chapter 3](#)). Patients with urologic disorders are very likely to suffer fluid imbalances, and therefore their intake and output should be measured and the totals recorded every 8 hours during hospitalization or acute illness. In critically ill patients, the urinary output is typically measured hourly. **Urine output should be at least 30 mL/hr. For total output, measure all urine excreted, drainage from all tubes, any emesis, and watery stools.** An estimate of the amount of fluid lost through perspiration should also be considered if perspiration is excessive (e.g., sweating with fever). Any fluid used to irrigate catheters and tubing must be measured, and the amount should be added to the total intake and subsequent output.

■ Evaluation

Compare intake and output data over time to determine clinical improvement or the presence of problems. The frequency of comparison will be hour-to-hour for critical patients or over a period of days for patients with chronic conditions. Laboratory data, such as BUN, creatinine, potassium, and urinalysis results, provide further information to evaluate the effectiveness of treatment. A decrease in subjective symptoms, such as flank pain or dysuria, also indicates resolution of the problem.

Common Urologic Problems

Urinary Incontinence

Etiology

In the United States 65 million adults experience transient or chronic incontinence; 75% of those people are women (Markland et al, 2011). On average women wait 6.5 years to obtain a diagnosis. Men are more reluctant to talk about the problem or seek help. An estimated 53% of homebound older persons are incontinent. A large percentage of the residents in nursing homes are incontinent, and it is the leading cause of admission to a long-term care facility (National Association for Continence, 2014). Women who have had several children may have anatomic changes that make incontinence more likely. Men may experience the problem because of an enlarged prostate. Other contributing factors include spinal cord injury, neurologic disorder (e.g., dementia), or functional disorder (e.g., difficulty manipulating clothing fasteners).

When incontinence is occurring, the first step is to identify factors that may be contributing to the problem. Immobility; UTI; atrophic urethritis or vaginitis associated with menopause; stool impaction; prostate surgery; delirium or confusion; endocrine problems; and various types of medication, such as alpha-adrenergic agents, beta-adrenergic agonists, and calcium channel blockers, may contribute to the problem of incontinence. Obesity also is a factor, because it causes increased pressure on the bladder.

Pathophysiology

Urine flow out of the bladder is controlled by two circular muscles called *sphincters*. The internal sphincter lies close to the lowermost part of the bladder, and the external sphincter surrounds the urethra. Many factors can cause loss of sphincter control. Unconsciousness, UTI, paralysis, interference with nerve transmission to and from the brain, and loss of muscle tone of the bladder and sphincters are some of the common causes of incontinence.

Signs and Symptoms

There are several types of incontinence: urge, stress, mixed, overflow, functional, or incontinence caused by neurologic dysfunction. **Urge incontinence** is the involuntary loss of urine when there is a strong urge to urinate (urinary urgency). **Stress incontinence** occurs when the urethral sphincter fails and there is an increase in intra-abdominal pressure, caused by such things as sneezing, laughing, coughing, or aerobic exercise. **Mixed incontinence** is a combination of different types, such as stress and urge incontinence. **Overflow incontinence** occurs when there is poor contractility of the detrusor muscle or obstruction of the urethra, as in prostate hypertrophy in the male or genital prolapse in the female. **Functional incontinence** is caused by cognitive inability to recognize the urge to urinate or a self-care deficit caused by extreme depression. Inability to reach the bathroom because of restraints, side rails, or an out-of-reach walker can also result in functional incontinence. **Neurologic incontinence** is caused by disorders of the neurologic system (e.g., multiple sclerosis or spinal cord injury).

Diagnosis

Diagnosis of incontinence is based on a careful history, and the patient must be able to report symptoms accurately (Table 33-4). The patient may be asked to keep a bladder diary. Routine urinalysis is also performed. When conservative measures do not improve continence, the provider may choose to evaluate the condition with a series of diagnostic tests, including measuring the postvoid residual volume, stress testing, urodynamic studies, cystogram, or cystoscopy.

Table 33-4

Common Problem Statements, Expected Outcomes, and Nursing Interventions for Patients With Incontinence

PROBLEM STATEMENT	GOALS/EXPECTED OUTCOMES	NURSING INTERVENTIONS
Altered urinary function due to decreased muscular strength and fine motor coordination.	Patient will be able to physically get to the toilet (or commode chair) and accomplish toileting (i.e., undo clothing and sit on toilet) with assistance during this shift.	Assess abilities to stand, walk, and sit. Instruct patient to call for help when needing to go to the toilet. Offer assistance q2-4h.

		Obtain bedside commode as needed. Suggest clothing with elastic waistband or Velcro fasteners to eliminate zippers and buttons. Encourage independence, as appropriate (consider strength and motor ability).
Altered urinary function due to weak pelvic muscles.	Patient will increase control over incontinence within 8-12 wk.	Assess pattern of incontinence and identify actions associated with incontinence (e.g., laughing, coughing). Teach Kegel exercises. Teach to avoid bladder irritants such as coffee, nicotine. Refer to nutritionist for weight loss diet if overweight. Discuss use of incontinence pads or undergarments. Supply information about vaginal cone therapy.
Altered urinary function due to bladder spasms.	Patient will experience urge to void and be able to get to the toilet in time to prevent loss of urine.	Instruct patient to keep a voiding diary, or observe for incontinence if unable to self-report. Help patient establish a voiding schedule (e.g., q3-4h). Give antispasmodic medications (e.g., tolterodine) as ordered. Teach patient about side effects of medication (e.g., possible urinary retention).
Altered self-care ability for toileting due to impaired cognition.	Patient will participate in a routine toileting schedule during hospitalization.	Assess cognitive deficits related to toileting (e.g., unable to remember to go to toilet; senses urge to go, but cannot find the toilet). Observe for odors, stains, or wetness on clothing and linens. Assist (or remind) patient to go to the toilet q2-3h. Provide visual cues to prompt toileting (e.g., commode chair at bedside, large arrows pointing toward bathroom, picture of toilet on the bathroom door). Give positive feedback for efforts.
Potential for altered skin integrity due to moisture and irritation of urine on skin.	Patient's skin will remain dry and intact without breakdown during hospitalization.	Assess for patterns of urinary incontinence (e.g., if patient cannot self-report, check q2-3h). Give fluids primarily during the day and space fluids (e.g., q2-3h) for predictability of voiding. Provide (or assist) with skin care (e.g., clean with mild soap and warm water; use skin barrier creams). Consult with enterostomal therapist (ET nurse) as needed (skin breakdown is progressive). Turn q2h if patient is bedridden or immobile. Ensure adequate nutrition for healing and skin integrity (e.g., high-quality proteins).
Disrupted sleep pattern due to nocturia.	Patient will rest and sleep at least 6 consecutive hr each night during hospitalization.	Assess for medication (e.g., calcium channel blockers) side effects that may be contributing to incontinence. Teach patients to avoid taking fluids in late evening hours. Assist (or instruct patient) to ambulate for at least 10 min 1-2 hr before bedtime, then instruct to void before going to bed. Use incontinence pads or undergarments for women and condom catheters for men during the night.
Insufficient knowledge regarding management of incontinence.	Patient will verbalize two or three methods to manage incontinence before leaving the clinic today.	Teach patient about medication side effects (e.g., if on estrogen, patient should report vaginal bleeding or signs of deep vein thrombosis, calf pain, or swelling). Teach Kegel exercises; reinforce that results may take up to 3 mo. Teach bladder training; remind that accidents are expected during training period.
Potential for social isolation due to embarrassment.	Patient will maintain usual social contact with friends and family.	Encourage verbalization of feelings (e.g., shame or embarrassment). Assist patient to identify times, settings, and activities when incontinence may occur (e.g., during exercise). Help patient make a plan to deal with incontinence during social occasions (e.g., use of incontinence briefs, mapping out toilet locations, planning fluid intake around social occasions). Refer to support groups.

Treatment

Evidence-based practice indicates that stress incontinence that occurs with exercise, laughing, or coughing may be corrected by exercises to strengthen the pelvic floor muscles (DuBeau et al, 2010).

Vaginal weight training with a set of five small, cone-shaped weights that are used along with pelvic muscle exercise is another therapeutic option for incontinence. The lightest cone, which has a string attached, is inserted into the vagina and held in place by muscle tightening for 15 minutes twice a day. When there is no problem holding this cone in place, the next heaviest cone is used. This continues until the heaviest cone can be held in place for the 15-minute period. Maintaining normal weight and using topical estrogen therapy after menopause also decrease the incidence of this disorder.

Various medications have been found to be helpful in treating incontinence. Table 33-5 provides additional information about selected drugs for urinary incontinence.

Patient Teaching

Kegel Exercises

- To locate the correct muscle, stop the flow of urine while urinating on the toilet by tightening the anus as if preventing a bowel movement.
- Practice for several days each time you urinate. Then begin the exercise program.
- While lying down, slowly count 1-2-3 while tightening the pelvic muscles.
- Release pelvic muscles slowly to the count 1-2-3. Do this 15 times.

- While sitting, repeat this sequence 15 times, tightening pelvic muscles while counting 1-2-3, and then slowly releasing to the count 1-2-3.
- Stand and repeat the sequence 15 times; tighten to the count 1-2-3, and slowly release to the count 1-2-3.
- Do the pelvic muscle exercises once a day. If you can do them twice each day, improvement in continence will occur more quickly.
- Improvement may be noted in 6 to 8 weeks, but may take as long as 3 months.

 **Table 33-5**

Drugs Commonly Used to Treat Urinary Incontinence and Retention

CLASSIFICATION	ACTION	NURSING IMPLICATIONS	PATIENT TEACHING
Urinary antispasmodics, antimuscarinics Oxybutynin (Ditropan), solifenacina (Vesicare), tolterodine (Detrol), trospium (Sanctura), darifenacina (Enablex), fesoterodine (Toviaz)	Used to relieve spasms of the bladder; treats overactive bladder and incontinence	Give mouth care, as needed. Monitor I&O. Auscultate bowel sounds. Side effects include dry mouth, increased heart rate, dizziness, abdominal distension, and constipation.	Increase fiber-containing foods and fluids to prevent constipation. Do not drive if dizzy or drowsy. Use ice chips or hard candy for dry mouth. May need eyedrops to moisten dry eyes.
Bladder stimulant Bethanechol (Urecholine)	Used to treat urinary retention	Monitor for orthostatic hypotension and bradycardia. Give 1-2 hr after meals or with food for GI complaints. May cause diarrhea, cramping, or increased salivation.	Immediately report severe dizziness or difficulty breathing. Rise slowly from a lying to standing position.
Medication for benign prostatic hyperrophy Tamsulosin (Flomax), doxazosin (Cardura), terazosin (Hytrin), alfuzosin (Uroxatral)	Relieves symptoms of urinary retention associated with obstruction from an enlarged prostate	May cause orthostatic hypotension. Side effects include back pain, chest pain, cough, diarrhea, nausea, dizziness, headache, weakness.	May take 6 mo for symptom relief. Do not crush, chew, or open the capsule. Immediately report a prolonged erection.
Tricyclic antidepressants Imipramine (Tofranil), amitriptyline (Elavil)	Reduce overactive bladder contractions; reduce sensory urgency and burning pain of interstitial cystitis	May cause dry mouth, blurred vision, or constipation.	Do not use within 14 days of MAOI drugs; observe for hypotension.

GI, Gastrointestinal; I&O, intake and output; MAOI, monoamine oxidase inhibitor.

Bulking injections into tissue surrounding the urethra are an option. An old assistive device is a pessary, a stiff ring, that is worn in the vagina during the day to support the bladder. A newer treatment for overactive bladder is botulinum toxin type A (Botox) injections in the bladder muscle.

Further treatment options for urinary incontinence include biofeedback therapy or an implanted electrical stimulation device called *InterStim* ([Mayo Clinic, 2015](#)). A clamp-type device across the penile urethra can be used for men, or occlusive devices can be inserted into the vagina or urethra for women; patients or caregivers must be able to apply and remove these devices to prevent tissue damage. Periurethral bulking is a procedure performed under local anesthesia in which collagen is injected into the urethra to increase resistance.

Complementary and Alternative Therapies

Transvaginal Electrical Stimulation

In transvaginal electrical stimulation (TES), the nerves and muscles of the pelvic floor are stimulated by an electrically charged probe. Stimulation must be done in two 15-minute sessions twice a day for 12 weeks ([Seifert, 2012](#)).

Surgeries to correct incontinence.

A variety of procedures may be performed to correct the anatomic position of the bladder, such as bladder neck suspension. These surgeries are most often performed to correct urinary incontinence in women. The **retropubic suspension** (Marshall-Marchetti-Krantz) procedure is performed to correct a cystocele (prolapse of the bladder into the vagina) and urinary incontinence. A low abdominal incision is made, and the urethral position is elevated in relation to the bladder. Urethral and suprapubic catheters are in place for several days postoperatively. For a pupovaginal sling placement, a low transverse incision is used to correct stress incontinence in women. Alternatively a bulking agent can be injected underneath the mucosa of the urethra. An **artificial sphincter implant** is used more commonly to correct incontinence for males than for females. A mechanical device is placed around the urethra to open and close it. After incontinence surgical procedures, monitor for

urinary tract infection and difficulty voiding.

When these measures do not solve the problem, incontinence is managed by intermittent catheterization, indwelling urethral catheterization, a suprapubic catheter, an external collection system (such as condom catheters), protective pads and garments, or pelvic organ support devices such as a pessary.

Clinical Cues

Your patient may develop leaking around the suprapubic catheter. If leaking persists and urine is continuously leaking onto the skin, this could mean that the tube is too small. If the tube has been there a long time, the tissue contours may have changed since the initial insertion. Notify the provider for evaluation.

Nursing Management

Use a gentle and matter-of-fact approach when taking an incontinence history. Evidence-based practice supports the use of protocols or guidelines for screening for urinary incontinence (Dowling-Castronovo and Specht, 2009). The patient experiencing urinary incontinence may be embarrassed by the symptoms, but will likely welcome the help and suggestions. Observe the clothing for stains and odors and perform a general physical assessment that includes palpation of the bladder. Inspect the genitalia if there is reason to suspect a prolapse, or if there is a catheter present or recently removed.

Focused Assessment

Assessment for Urinary Incontinence

- What kinds of problems are you having with your bladder?
- Are you having trouble holding your urine (water)?
- When did the urine leakage problem start?
- How often do you leak urine?
- Are you soiling your clothing or bed linens?
- When do the leaks occur? Does it happen during the day or the night? Both?
- How often do you wear a pad or other protective device?
- What activities or situations are associated with leakage? For example, does laughing, coughing, sneezing, or exercising cause leakage?
- Are you having difficulty getting to the bathroom in time?
- Are there things about your house that are preventing you from getting to the bathroom in time? For example, do you have to climb stairs or walk a long distance?
- Do you have (or need) assistive devices (e.g., handrails) in the bathroom?

Older Adult Care Points

Assess older adults for gross motor strength, fine motor dexterity, and ability to balance and independently ambulate. An older adult may be having trouble walking to the bathroom or sitting on or rising from the toilet seat. In addition, clothing fasteners may be problematic.

When incontinence is not remedied by correcting an underlying cause, attempt to help the patient by setting up a voiding and fluid schedule. Assess when the patient is experiencing incontinence.

Evidence-based practice suggests that a voiding diary is a useful tool for patients who can self-report (Dowling-Castronovo and Specht, 2009). Box 33-4 provides guidelines for establishing a toileting schedule.

Box 33-4

Assisting Patients to Establish a Toileting Schedule

- Assess pattern of incontinence or instruct patient to keep a voiding diary.
- Assist (or remind) patient to go to the toilet at set times (just before the time when incontinence usually occurs).
- Space fluid intake and give most fluids during the day.
- Discourage intake of bladder stimulants, such as alcohol and caffeine.
- Help the patient ambulate at least 10 minutes an hour or two before bedtime, because activity helps to mobilize fluid.
- Apply a condom catheter for males and moisture-proof pants or incontinence pads for women at night; it is not practical to continue a voiding schedule (every 3-4 hours) at night.
- Give positive reinforcement for any small successes.

Toileting assistance can be offered at set times just before incontinence usually occurs. Getting the patient on a voiding schedule takes a great deal of patience and persistence on the part of the nurse and the patient. Accidents will happen during the retraining period, and patients need to be assured that this is expected. (See Chapter 22 for care of patients with incontinence related to spinal cord injury.)

Assignment Considerations

Bladder Training

When planning and implementing a bladder training program for a confused patient who is unable to self-report, there are several ways the nursing assistant (UAP) can provide valuable help. Ask the UAP to record and report any fluids that are offered and consumed and the number of times that clothes, wet bed linens, or incontinence pads need to be changed. Once the schedule is established, direct the UAP to help the patient follow the schedule by assisting her to the toilet at the designated times.

Patients may experience transient incontinence or urinary retention after removal of an indwelling catheter that has been in place for several days. Usually the catheter is clamped for intervals and then opened to drainage before it is removed to help rebuild bladder muscle tone. After this has been done for 12 to 24 hours, the catheter is removed. The patient should then be instructed to void every hour to prevent incontinence. **Any bleeding, dribbling, or incontinence of urine or inability to void within 4 to 6 hours (maximum of 8) after removal of the catheter should be reported to the provider.** It takes time to retrain the bladder to hold greater capacity. Gradually the interval between voidings is lengthened to 2, 3, or 4 hours.

Health Promotion

Drinks and Substances to Avoid

Advise patients that avoiding caffeine, alcohol, carbonated beverages, and aspartame may help bladder control. These substances may stimulate or irritate the bladder.

Urinary Retention

Urinary retention is retaining or holding urine in the bladder. It can be acute after a surgical procedure, after removal of an indwelling catheter, or with certain medications (e.g., atropine), or it may be a chronic condition related to anxiety, neurologic disorders, or obstruction of urine flow through the urethra, as in enlargement of the prostate gland. A straight catheter is used for a single "in-and-out" catheterization for temporary inability to empty the bladder. Also, patients who have permanent paralysis may use intermittent catheterization to empty the bladder.

Urinary retention will not cause the bladder to rupture, but urine will begin to dribble out of the urethra. Retention of urine stretches the bladder walls, causing extreme discomfort. Assess the degree of bladder distention using gentle palpation before and after intervention. Assist the patient by providing privacy and adequate time for voiding efforts. A caffeinated drink, followed by a warm bath, may help. Instruct the patient to double void: void, sit on the toilet for several minutes, and void again. Schedule a trip to the toilet every 3 to 4 hours. Obtain an order for catheterization if other measures do not relieve the problem. A medication for urinary retention is bethanechol (Urecholine). See [Table 33-5](#) for examples of medications that relieve the symptoms produced by benign prostatic hypertrophy (enlarged prostate gland).

Poor bladder tone or partial obstruction of the urethra can result in dribbling of urine or passing only the overflow, leaving the bladder partially full. During bladder retraining, residual urine can be measured by having the patient void as much urine as possible and then performing a bladder scan or immediately inserting a catheter (see [Table 33-2](#)). One hundred milliliters is considered a normal amount of residual urine. Any amount more than this can become stagnant and concentrated over time, predisposing the patient to bladder infection and the formation of stones.

Think Critically

The provider ordered removal of an indwelling catheter. Three hours later the patient complains of bladder fullness with inability to void. What should you do?

Get Ready for the NCLEX® Examination!

Key Points

- The urologic system is responsible for maintaining proper balance of the fluids, minerals, and organic substances necessary for life.
- The nephron is the functional unit of the kidney. It consists of the glomerulus, which is a network of capillaries encased in a thin-walled sac called the Bowman capsule, and the tubular system.
- Kidney function, GFR, bladder capacity, ability to concentrate urine and secrete renin, and aldosterone all decrease with aging.
- Infection, immunologic disorders, metabolic disorders such as diabetes mellitus, and reduced blood flow secondary to shock or atherosclerosis can result in kidney damage.
- Stones, an enlarged prostate, or tumors may obstruct the flow of urine.
- Tubular necrosis affects the functional ability of the kidney. It can result from lack of oxygen or bacterial or chemical destruction of the nephron.
- Hypertension is a major cause of end-stage kidney disease; conversely, renal disorders can also cause secondary hypertension.
- To promote healthy kidneys, advise patients to drink plenty of water, to empty the bladder at regular intervals, to obtain prompt treatment for bladder infection, to practice good hygiene, to maintain normal serum glucose, and to take blood pressure medication as prescribed.
- BUN and serum creatinine are the most common screening tests for kidney function.
- Monitor intake and output, weight, and signs of edema; monitor drugs for nephrotoxic effects.
- Nursing measures for incontinence include assisting in determining and correcting underlying cause, establishing a voiding and fluid schedule, coaching Kegel exercises, giving medications for incontinence as prescribed, and advising to decrease bladder irritants.
- Medications to treat incontinence, urinary retention, and BPH are listed in [Table 33-5](#).
- Many medications can affect the urinary system (see Online Resources).
- Nursing measures for urinary retention include assessing for bladder distention, providing privacy, instructing to double void, and obtaining an order for catheterization as needed.

Review Questions for the NCLEX® Examination

1. What information should a nurse give to a community group about prevention of urologic problems?

1. Drinking orange juice every morning prevents urinary tract

infection.

2. Drinking several glasses of fluid a day helps to preserve kidney function.
3. Emptying the bladder prevents prolonged exposure to toxins.
4. Eating spinach, chocolate, or strawberries may cause kidney stones.

NCLEX Client Need: Health Promotion and Maintenance: Health Promotion/Disease Prevention

2. A night shift nurse is planning care for four patients. Which patient is most likely to have nocturia related to a decreased ability to concentrate urine?

1. A patient with a high BUN
2. A pregnant patient
3. An older adult
4. A patient who had a bladder scan

NCLEX Client Need: Safe and Effective Care Environment: Coordinated Care/Establishing Priorities

3. When starting a 24-hour urine collection, what is essential to ensure correct results?

1. Include the first void of the 24-hour period.
2. Record the time of initial void as the start time of the test.
3. Discard the last void of the 24-hour period.
4. Encourage fluid intake before starting the test.

NCLEX Client Need: Physiological Integrity: Reduction of Risk Potential

4. A patient is scheduled to have a renal biopsy. What is included in the preoperative care for this patient? (*Select all that apply.*)

1. Administer bowel preparation.
2. Report abnormal coagulation studies.
3. Enforce nothing by mouth (NPO) for 6 to 8 hours before the procedure.

4. Check for allergy to contrast media.
5. Insert indwelling urinary catheter.

NCLEX Client Need: Physiological Integrity: Reduction of Risk Potential

5. A nurse is trying to console an older adult who is embarrassed about wetting the bed. Which patient comment is consistent with functional incontinence?

1. "I knew that I needed to go, but I couldn't get out of bed by myself."
2. "Every time I laugh, cough, or sneeze I pass a little bit of urine."
3. "When I need to pee, I really have to go right away!"
4. "My doctor says that my enlarged prostate is causing the problem."

NCLEX Client Need: Psychosocial Integrity: Therapeutic Communication

6. After placing an indwelling urinary catheter, the nurse performs several interventions. Place the interventions in order of priority.

1. Secure the drainage bag below the level of the bladder so that it hangs freely.
2. Secure the catheter to the patient's leg.
3. Check that the catheter tubing is unimpeded and is looped above the drainage bag.
4. Use aseptic technique when emptying the drainage bag.
5. Observe the amount of urine drainage in the bag whenever in the patient's room.

NCLEX Client Need: Safe and Effective Care Environment: Establishing Priorities

7. What is the first action that the nurse should take to assist a patient to develop a toileting schedule?

1. Encourage use of condom catheters or incontinence pads
2. Assess pattern of incontinence
3. Schedule trips to the bathroom

4. Provide positive reinforcement for small successes

NCLEX Client Need: Safe and Effective Care Environment: Coordinated Care/Establishing Priorities

8. When writing a nursing care plan for a patient with stress incontinence, what interventions should the nurse include? (*Select all that apply.*)

1. Instruct patient to keep a voiding diary.
2. Teach patient Kegel exercises.
3. Offer patient assistance every 3 to 4 hours.
4. Obtain bedside commode as needed.
5. Teach patient to avoid bladder irritants, such as coffee and nicotine.

NCLEX Client Need: Safe and Effective Care Environment: Establishing Priorities

9. In determining the presence of stress urinary incontinence, what signs are characteristic?

1. Involuntary loss of urine when the urge to urinate occurs
2. Discomfort and burning frequently when urinating
3. Inability to recognize the urge to urinate because of cognitive impairment
4. Loss of urine when coughing, sneezing, or laughing or during aerobic exercise

NCLEX Client Need: Physiological Integrity: Physiological Adaptation/Alterations in Body Systems

10. Fesoterodine (Toviaz) prescribed for a patient with urinary urgency must be administered very cautiously if the patient already has _____.

NCLEX Client Need: Pharmacological Therapies: Medication Administration

Critical Thinking Questions

Scenario A

Mr. Jones, 65 years old, has a history of difficulty passing urine. The provider orders placement of a retention catheter. You attempt to insert a 14-Fr Foley catheter, but you meet resistance and the catheter will not pass. The patient reports an uncomfortable sensation in his genital area during the attempt.

1. What is your initial action?

2. Based on your knowledge of pathophysiology, what would you suspect is preventing the passage of the catheter?
3. Why is it important to keep the drainage bag below the level of the bladder once the catheter has been successfully inserted?
4. How would you perform daily catheter care for Mr. Jones?
5. Discuss four or five general principles that you would use while caring for Mr. Jones's catheter.
6. Which tasks would be appropriate to delegate to UAP? Select all that apply and give a rationale.
 - a. Gathering the equipment for the catheterization procedure
 - b. Inserting the Foley catheter
 - c. Emptying the drainage bag at the end of the shift
 - d. Checking the urinary meatus for complaints of bleeding

Scenario B

Mrs. Russlyn, a 56-year-old woman, reports that she has to run to the restroom quickly when she feels the need to urinate. She makes a joke about needing to be close to a restroom when in public.

1. What type of incontinence is associated with losing urine when feeling the need to urinate?
2. What questions will you ask to collect additional data about Mrs. Russlyn's incontinence?
3. What kinds of treatment options are likely to be recommended for Mrs. Russlyn?

Scenario C

You are working in a long-term care facility and caring for Mrs. Mendez, an 86-year-old with Alzheimer disease. She has developed urinary incontinence.

1. What factors might be contributing to your patient's incontinence?
2. Explain how to develop a toileting and fluid intake schedule for Mrs. Mendez.

CHAPTER 34

Care of Patients With Disorders of the Urinary System

Objectives

Theory

1. Examine the signs and symptoms of selected urologic inflammatory disorders (e.g., cystitis, urethritis, and pyelonephritis) and nursing interventions for these patients.
2. Explain nursing management for patients with acute or chronic glomerulonephritis.
3. Analyze types of patient conditions that create a risk for acute renal failure.
4. Compare the needs of patients on long-term hemodialysis with patients who use peritoneal dialysis.
5. Present the benefits and special problems associated with kidney transplantation.

Clinical Practice

6. Provide postoperative nursing care of patients after surgery of the kidney.
7. Select specific nursing responsibilities for the care of patients with kidney stones.
8. Provide postoperative nursing care of patients after surgery for urinary diversion.
9. Perform interventions to increase patient compliance in the treatment of chronic kidney failure.
10. Devise a nursing care plan for a home-care patient with renal failure.

KEY TERMS

acute renal failure (ă-KŪT RĒ-năl FĀL-yür, p. 796)

anuria (ă-NŪ-rē-ă, p. 791)

azotemia (ă-zō-TĒ-mē-ă, p. 804)

chronic renal failure (CRF) (KRŌN-īk, p. 803)

cystitis (sīs-Tī-tīs, p. 787)

end-stage renal disease (ESRD) (ĒND-stāj RĒ-năl dī-ZĒZ)(p. 800)

glomerulonephritis (glō-mĕr-ū-lō-ně-FRĪ-tīs, p. 791)

hemodialysis (hē-mō-dī-ĀL-ī-sīs, p. 802)

hydronephrosis (hī-drō-ně-FRŌ-sīs, p. 792)

lithiasis (līth-ī-ă-sīs, p. 793)

lithotripsy (LĪTH-ō-trīp-sē, p. 795)

nephrectomy (něf-RÖK-tō-mē, p. 792)

nephrostomy (ně-FRŌS-tō-mē, p. 792)

nephrotic syndrome (něf-RÖ-tīk SĪN-drōm, p. 792)

oliguria (öl-ī-GŪ-rē-ă, p. 791)

peritoneal dialysis (pě-rí-tō-NĒ-ăl dī-ĀL-ĭ-sĭs, p. 802)

pyelonephritis (pī-ă-lō-ně-FRĪ-tīs, p. 790)

renal stenosis (RĒ-năl stē-NŌ-sĭs, p. 793)

uremia (ū-RĒ-mē-ă, p. 804)

uremic syndrome (ū-RĒ-mik SĬN-drōm, p. 804)

urethritis (ū-rě-THRĪ-tīs, p. 787)

urinary diversion (ūr-ĕ-NĀ-rē dī-VŌR-shūn, p. 797)

The kidneys play a role in maintaining fluid balance, regulating the electrochemical composition of body fluids, providing protection against acid-base imbalance, forming red blood cells, regulating calcium levels, and eliminating waste products. The kidneys also help to control blood pressure, in conjunction with the endocrine system. Circulatory disorders, metabolic disorders such as diabetes mellitus, immunologic disorders, obstruction, bacterial infections, or toxic substances can all cause kidney dysfunction.

Inflammatory Disorders of the Urinary Tract

Cystitis

Etiology and Pathophysiology

Cystitis is an inflammation of the urinary bladder. It is one of the most common urinary tract infections (UTIs) in women because the female urethra is shorter and the urinary meatus is exposed to contamination from the vagina and anus. The *Escherichia coli* bacterium normally resides in the intestinal tract as a nonpathogenic microorganism; it accounts for about 80% of all UTIs in females.

Cystitis and **urethritis** (inflammation of the urethra) are common in women after they have become sexually active. *Honeymoon cystitis* is a term sometimes used to refer to bacteria that have entered the urethra by way of friction during intercourse. In older women, the incidence of cystitis and urethritis increases as the decreased muscle tone in the urinary tract prevents complete emptying of the bladder. Urine that sits in the bladder (urinary stasis) provides a good medium for bacterial growth. The estrogen depletion that occurs with aging results in structural atrophy and urinary dysfunction.

In addition, many older adults purposely restrict fluid intake to decrease the incidence of incontinence, and the thirst sensation is often reduced in older adults (“[Provision of Adequate Hydration](#),” 2014).

Older Adult Care Points

In older adult women, the urethra sometimes becomes displaced because of decreased muscle tone and atrophy of surrounding tissues and opens into the vaginal outlet. This increases the risk for infection.

Others restrict fluids to help control heart failure, renal failure, or other disorders that cause fluid retention. Restricting fluid intake decreases urine flow and makes the person more susceptible to urinary tract infection.

Signs, Symptoms, and Diagnosis

The most common symptoms of cystitis are **painful urination, frequent and urgent urination, and low back pain**. The urinary meatus may appear swollen and inflamed. Cystitis has a tendency to recur, producing less-acute symptoms such as fatigue, anorexia, and a constant feeling of pressure in the bladder region between flare-ups. The urine may appear cloudy or even bloody and have a foul smell. Urinalysis and urine cultures are used to establish a definite diagnosis and to identify the specific causative organism.

Older Adult Care Points

Confusion may be one of the first signs of cystitis or UTI in older adults. If a patient who is normally alert becomes confused, assess the urine for cloudiness, foul odor, or hematuria (blood in the urine), and check for signs of infection (fever, increased white blood cell [WBC] count).

Treatment and Nursing Management

Treatment and nursing care of cystitis and urethritis (see description of urethritis on p. 787) are similar. First, specimens are collected for tests to identify the causative organism: urinalysis, urine culture and sensitivity, smear and Gram stain, or culture of the discharge. Specific antibiotics, such as trimethoprim-sulfamethoxazole (Bactrim), are used to combat infection and are combined with urinary analgesics such as phenazopyridine (Pyridium) to relieve discomfort.

Postmenopausal women may benefit from topical estrogen. [Table 34-1](#) shows the most commonly used drugs and their nursing implications. The patient is encouraged to drink large amounts of fluids (eight to twelve 8-oz glasses unless contraindicated) to flush the bladder and to continue the habit once the acute symptoms subside. Evidence-based practice indicates that cranberry-based products, which alter urine pH, also have been used to prevent or treat urinary tract infections.

(Jepson and Craig, 2012). Measures to relieve the discomfort include sitz baths and hot water bottles on the back or directly over the bladder region.

Patient Teaching

Preventing Urinary Tract Infections

The patient should be taught the following to prevent recurrence of urinary tract infections:

- Always wipe the anal area from front to back after a bowel movement.
- Avoid wearing nylon pantyhose, tight slacks, or any clothing that increases perineal moisture.
- Do not wash underclothing in strong detergents or bleaches; rinse clothing repeatedly until water is clear.
- Change wet bathing suits or wet clothing as soon as possible.
- Wear white cotton underwear or with cotton crotch.
- Showering may be preferable over bathing for women.
- Do not use bubble bath, perfumed soap, feminine hygiene sprays, or over-the-counter vaginal douche products.
- Prolonged bicycling, motorcycling, horseback riding, or travel involving prolonged sitting can contribute to urethritis and cystitis.
- Drink at least eight full glasses of water each day.
- Do not ignore vaginal discharge or other signs of vaginal infection. *Candida* and *Trichomonas* infections should be treated promptly to prevent their spread to the bladder.
- Empty the bladder (urinate) promptly after sexual intercourse and drink two glasses of water to help flush out microorganisms from the urethra and bladder.

Complementary and Alternative Therapies

Vitamin C and German Chamomile

Vitamin C can help acidify the urine and decrease the frequency of cystitis. German chamomile is used topically for its anti-inflammatory and antibiotic properties to soothe the inflamed genital area.

Table 34-1

Drugs Commonly Used for Urinary Tract Infections

CLASSIFICATION	ACTION	NURSING IMPLICATIONS	PATIENT TEACHING	
Sulfonamides	Trimethoprim-sulfamethoxazole (Bactrim, Septra) Sulfisoxazole (Gantrisin) Sulfamethoxazole (Gantanol)	Active against gram-negative and gram-positive organisms Assess for allergies to sulfonamides. Record I&O. Fluid intake is a minimum of 3000 mL daily. Monitor laboratory results and symptoms related to anemia, blood dyscrasias, and renal dysfunction (e.g., hemoglobin, hematocrit, WBCs, BUN).	Drink at least 12 large glasses of water each day to prevent crystallization of urine. Immediately report rash, abdominal pain, blood in urine, confusion, difficulty breathing, or fever.	
Fluoroquinolones	Ciprofloxacin (Cipro) Levofloxacin (Levaquin) Newer agents: Moxifloxacin (Avelox) Trovafloxacin (Trovan)	Bactericidal Considered second-line drugs; are used as alternatives to other antibiotics	Can be taken with or without food, if antacids are ordered, wait 2 hr after giving Cipro. Monitor WBCs for decreased leukocytes. Can potentiate warfarin and increase theophylline levels. Use cautiously in those patients with history of seizure disorder or alcoholism.	Take all of medication. Drink at least 8 full glasses of water/day to prevent crystalluria.
Cephalosporins				
First Generation	Cefazolin (Ancef)	Bactericidal; used to treat infections that do not respond to penicillin	Use cautiously in those with allergy to penicillin. <i>Candida</i> can cause dizziness or light-	

	to other, less-expensive drugs	(yeast) vaginitis is a common side effect.	headedness.
Second Generation			
Cefdin (cefuroxime axetil) Zinacef (cefuroxime sodium)	Bactericidal; inhibits cell wall mucopeptide synthesis Bactericidal; inhibits cell wall muopeptide synthesis	Use cautiously in those with allergy to penicillin; caution if seizure disorder or renal impairment. Use cautiously in those with allergy to penicillin; caution if seizure disorder or renal impairment.	Increased vaginal candida infections; increased diarrhea. Report excessive diarrhea, exhaustion.
Third Generation			
Cefazidime (Fortaz) Cefixime (Suprax)	Bactericidal; inhibits cell wall muopeptide synthesis	May interfere with vitamin K metabolism; therefore may reduce prothrombin levels.	Immediately report rash, restlessness, gastrointestinal symptoms, confusion, or irregular heartbeat.
Fourth Generation			
Cefepime (Maxipime)	Bactericidal; used to treat infections that do not respond to previous cephalosporin-generation drugs	Monitor I&O, BUN, serum creatinine.	Avoid alcohol.
Aminoglycosides			
Tobramycin Gentamicin	Effective against resistant infections; use cautiously, because they are nephrotoxic, ototoxic and can cause agranulocytosis and thrombocytopenia	Monitor BUN, electrolyte, and creatinine levels. Older adults are especially vulnerable to problems with hearing, balance, and kidney dysfunction caused by aminoglycosides.	Use sunscreen and avoid direct exposure to sunlight. Report nausea, vomiting, tremors, or tinnitus. Take extra fluid unless contraindicated.
Penicillins			
Extended Spectrum			
Carbenicillin (Geocillin) Ticarcillin/clavulanic acid (Timentin) Piperacillin/tazobactam (Zosyn)	Bacteriostatic and bactericidal	Carbenicillin PO only. Ticarcillin/clavulanic acid IV only. Watch for signs of hypersensitivity (e.g., rash, itching, difficulty breathing). Do not give to patients with known allergy to penicillin. May decrease effectiveness of oral contraceptives and warfarin.	Take full course of prescribed medication. Take with water 1-2 hr after meals to increase absorption. Immediately report abdominal pain, decreased urine, or watery or bloody diarrhea.
Miscellaneous Urinary Antibiotics			
Nitrofurantoin (Macrodantin, Furadantin)	Wide range of antibacterial action against gram-negative and gram-positive organisms, especially <i>Escherichia coli</i>	Monitor I&O. Liquid form can stain teeth; rinse mouth after administration.	Tints urine brown. Take with food and increase fluids. Can cause drowsiness; therefore avoid driving. Report numbness or tingling.
Fosfomycin tromethamine (Monurol)	Effective against most gram-negative and gram-positive organisms	Single-dose treatment. Not for use in children younger than 12 yr.	Can cause headaches and diarrhea.
Doripenem (Doribax) for complicated UTIs, including pyelonephritis	For serious infections caused by gram-positive and gram-negative bacteria	Injection only. Can reduce valproic acid levels to a subtherapeutic level, so level should be monitored.	The most common side effects include headache, nausea, diarrhea, rash, and phlebitis.
Urinary Analgesics			
Phenazopyridine (Pyridium)	Has analgesic effect on urinary mucosa	Is nephrotoxic, hepatotoxic, and can cause gastrointestinal disturbance and anemia.	Colors urine orange and can stain fabric. Discontinue if sclera becomes yellow. Maximum 2 days' use.

BUN, Blood urea nitrogen; I&O, intake and output; UTIs, urinary tract infections; WBCs, white blood cells.

Urethritis

Urethritis is an inflammation of the urethra that can be caused by many different organisms. It is a common symptom of gonorrhea and should be investigated as soon as it is first noticed. Inflammatory involvement of the urethra from the herpes virus is found in males and females. Nonspecific urethritis (NSU) is a sexually transmitted inflammation of the urethra caused by a variety of organisms other than gonococci; although it may be sexually transmitted, it is not a reportable disease in the United States. NSU usually responds to treatment with antibiotics. In women, trauma during childbirth and the proximity of the urethra to external genitalia and the anus predispose the urethra to infection and inflammation. Chemical irritation caused by use of spermicidal jellies, bath powders, feminine hygiene sprays, and bubble bath may also cause urethritis.

The chief symptoms of urethritis are **burning, itching, frequency in voiding, and painful urination**. There is a discharge that becomes increasingly more purulent if gonorrhea is present. The urinary meatus is swollen and inflamed. Diagnosis of urethritis is based on the presence of symptoms and a patient history that includes possible exposure to sexually transmissible infections (STIs). Culture and sensitivity of urine are obtained to identify causative organisms, and culture specimens are used to rule out STIs. The treatment and nursing management for urethritis are similar to cystitis. In addition, be especially aware of the possibility of a gonorrheal infection (until a definite diagnosis has been established) and should carry out the necessary teaching to prevent spread of the infection to the eyes.

Think Critically

A young man is diagnosed with NSU. As you are handing him his prescription, he wants to know what he should tell his wife. What would you say to him?

Pyelonephritis

Etiology and Pathophysiology

Acute **pyelonephritis** is an infection of the kidneys. It is thought to occur when bacteria (such as *Escherichia coli*) from a bladder infection travel up the ureters to infect the kidneys. A common cause

of pyelonephritis is an obstruction, causing stasis of urine and stones that cause irritation of the tissue. When bacteria enter the renal pelvis, inflammation and infection occur. After the infection is treated, the inflammation subsides; however, scar tissue is left in the place of healthy tissue. With chronic infection and inflammation, more scar tissue develops, and eventually kidney function becomes impaired.

Signs and Symptoms

In acute pyelonephritis, symptoms include fever (often 103° F or higher), chills, headache, malaise, nausea and vomiting, and pain in the flank (lateral abdomen) radiating to the thigh and genitalia. Eventually the urine becomes loaded with bacteria, blood, and pus. The chronic phase is often subtle, with weight loss, low-grade fever, weakness, and gradual scarring of the kidney tissues.

Diagnosis

Diagnosis is based on manifestation of symptoms, physical assessment, and urine culture and sensitivity. Special diagnostic tests—such as a radiograph of the kidneys, ureters, and bladder (KUB), an intravenous pyelogram (IVP), or a renal computed tomography (CT) or magnetic resonance imaging (MRI)—may be obtained to determine the location of the obstruction if one is suspected.

Treatment

Prompt treatment of cystitis and prevention of recurrence can help prevent acute pyelonephritis. Bed rest, analgesics, and antipyretics are prescribed. Specific drugs to destroy the bacteria are usually chosen according to the sensitivity of the causative organism, so that the most effective antibiotic is given—for example, gentamicin, ciprofloxacin (Cipro), or trimethoprim-sulfamethoxazole (Bactrim). Doripenem (Doribax) is used for complicated UTIs, including pyelonephritis. The most common side effects include headache, nausea, diarrhea, rash, and phlebitis (see [Table 34-1](#)).

With chronic pyelonephritis, the patient may live for years without significant symptoms before renal damage leads to hypertension or kidney failure. Correction of obstruction, removal of stones, and prevention of stone formation are essential to correct chronic pyelonephritis and to prevent destruction and scarring of the kidney cells.

Nursing Management

Encourage fluid intake, record intake and output (I&O), monitor the urine for changes, and keep the patient comfortable. Intravenous (IV) fluids may be given to flush the kidneys, especially if the patient has nausea and vomiting.

Acute Glomerulonephritis

Etiology and Pathophysiology

Glomerulonephritis is primarily seen in children and young adults and affects males more than females. It most commonly occurs about 2 to 3 weeks after a group A beta-hemolytic streptococcal infection, such as “strep throat” or impetigo; however, it can occur in response to bacterial, viral, or parasitic infections elsewhere in the body. It is an immunologic problem caused by an antigen-antibody reaction. Antigen-antibody complexes are deposited in the glomerular basement membrane, causing cell damage and altered permeability. Renal tissue becomes scarred, and function is impaired.

Signs, Symptoms, and Diagnosis

A patient with acute glomerulonephritis usually becomes suddenly ill with fever, chills, flank pain, widespread edema, puffiness around the eyes, visual disturbances, and marked hypertension. Diagnosis is based on physical findings. Presence of marked hypertension is a late manifestation. Diagnostic tests include urinalysis, creatinine, blood urea nitrogen (BUN), and complete blood count (CBC). The urine may be smoky, will contain red blood cells and protein, and will have an increased specific gravity. Serum creatinine and BUN levels rise above normal. If the condition is severe, hematocrit and hemoglobin will indicate anemia.

Treatment

A sodium-restricted diet is indicated if the patient has edema, and fluids may be limited if there is **oliguria** (diminished urine secretion in relation to intake) or **anuria** (absence of urine). A low-protein, high-carbohydrate diet also may be ordered.

Plasmapheresis is a blood cleansing procedure used in autoimmune disorders, such as acute glomerulonephritis or myasthenia gravis (see [Chapter 24](#)). If treatment is not successful, the disease will rapidly progress to kidney failure and death.

Nursing Management

Obtain a history of past illnesses, particularly infections, or autoimmune disorders such as lupus. Perform a general physical assessment, including vital signs and a baseline weight, and observe for fluid retention or edema. Edema that is obvious from external signs may be present in the internal organs. For this reason, mental status must be checked frequently for indications of cerebral edema with increased intracranial pressure. Cardiac failure or pulmonary edema may develop; therefore observe for extreme restlessness, increased respiratory difficulty, or cyanosis and be alert for sudden changes or worsening trends in blood pressure, pulse, and respiratory rate.

Decreasing the work of the kidney is a primary goal in treating acute glomerulonephritis. **Absolute bed rest usually is ordered until the clinical signs of hematuria, proteinuria, and hypertension are gone.** If the patient responds quickly to treatment and wishes to be more active, you must emphasize the need for continued rest. Low-protein diets may be ordered if the BUN is elevated to reduce nitrogenous waste by-products. Low-sodium or fluid-restricted diets may be ordered to reduce the edema.

Patient Teaching

Sodium

Help your patient to recognize that a low-sodium diet involves more than avoiding the salt shaker. Demonstrate how to read food labels to identify hidden sources of sodium in items such as catsup, canned soups and food, salad dressing, baked goods, and packaged meats.

Antihypertensives and diuretics also are ordered to control edema and hypertension. Plasmapheresis and corticosteroids may be used to reduce the antigen response and the inflammatory process. If the patient has plasmapheresis therapy, you should monitor for bleeding at the puncture site every 2 to 4 hours. Also monitor for potential complications, such as hypovolemia or electrolyte imbalance. The prognosis for acute glomerulonephritis varies, depending on the extent of permanent damage done to the kidneys or other vital organs.

Chronic Glomerulonephritis

Etiology and Pathophysiology

Chronic glomerulonephritis may develop rapidly or progress slowly over 20 to 30 years or longer. The exact cause is unknown; however, in chronic glomerulonephritis, the kidney atrophies; there is a decreased number of functional nephrons and eventual kidney failure. The prognosis for this disease is poor, and the progress to renal failure varies with the individual.

Signs and Symptoms

Generalized edema, headache associated with hypertension, fatigue, dyspnea, weight loss, loss of strength, increasing irritability, and nocturia are symptoms of glomerulonephritis. Proteinuria, hematuria, and kidney failure occur as the kidney function becomes impaired. Some patients who develop chronic glomerulonephritis may have acute exacerbations.

Diagnosis

Diagnostic testing may be prompted by findings on a routine examination, for example, retinal hemorrhage discovered during an eye examination. Testing includes urinalysis, creatinine, BUN,

CBC, and electrolytes. Abnormal laboratory values include proteinuria, urinary casts (protein plugs secreted by damaged tubules), elevated creatinine and BUN levels, anemia, hyperkalemia, hypermagnesemia, increased phosphorus, and decreased serum calcium and albumin.

Treatment and Nursing Management

The treatment for chronic glomerulonephritis in the latent stage is primarily symptomatic, with emphasis on avoiding fatigue and infections, particularly of the upper respiratory tract. When renal failure develops, dialysis (filtration of the blood) and possibly a kidney transplant are the only alternative therapies. Care of the patient with chronic renal disease is discussed on pp. 805 to 812.

Nephrotic Syndrome

Etiology and Pathophysiology

Nephrotic syndrome sometimes occurs after the glomeruli have been damaged by glomerulonephritis or some other disease. This damage results in increased membrane permeability and excretion of protein and decreased serum albumin (hypoalbuminemia). Hypoalbuminemia causes fluid to shift out into the body tissues and the result is severe edema. Some patients recover without further incidence, whereas others experience repeated episodes and eventual kidney failure.

Signs, Symptoms, and Diagnosis

Nephrotic syndrome is characterized by extensive proteinuria, hyperlipidemia (elevated blood lipids), hypoalbuminemia (low blood albumin), and severe edema. Facial edema, especially periorbital edema, may be present in the morning, whereas lower extremity edema is more evident at the end of the day. Ascites (accumulation of serous fluid in the abdominal cavity) may also occur because of fluid retention. The patient may be irritable, tired, or lethargic. Diagnostic tests include urinalysis and serum tests for protein and lipids. A renal biopsy may be used to verify the diagnosis or to evaluate the extent of kidney damage.

Treatment and Nursing Management

Treatment for nephrotic syndrome consists of an adequate-protein, low-fat, low-sodium diet, diuretics, supplemental multiple vitamins and minerals, and antibiotics if infection is present. Some patients are treated with cortisone and cyclophosphamide (Cytoxan).

Nursing care includes monitoring I&O, recording daily weight, encouraging rest, providing skin care, and encouraging compliance with dietary and medication regimen.

Obstructions of the Urinary Tract

Hydronephrosis

Etiology and Pathophysiology

Whenever the normal flow of urine is obstructed (e.g., kidney stone or enlarged prostate), there is a potential backward flow of fluid into the renal pelvis. **Hydronephrosis** occurs if the obstruction is not resolved; the renal pelvis and ureters will become dilated and continue to fill with fluid. Soon, the kidney cells will atrophy until all normal function ceases and the kidney becomes a thin-walled cyst. Hydronephrosis may be unilateral or bilateral (one or both kidneys). If it occurs on one side, the other kidney may enlarge and efficiently carry on the work of two kidneys. This is called *compensatory hypertrophy*.

Signs, Symptoms, and Diagnosis

Severe pain is present only if hydronephrosis develops rapidly. Otherwise, there are no outstanding symptoms, and the patient may develop signs of kidney failure only after serious damage has occurred. A definitive diagnosis is obtained by extensive urologic examination and detailed radiographic studies of the kidney and ureters, which usually reveal the site and cause of obstruction and distention of the renal pelvis.

Treatment

The primary goal of treatment for hydronephrosis is to remove the obstruction so the kidney may drain properly. The ideal remedy is to drain the kidney in the early stages with a **nephrostomy** tube or ureteral stent. Nephrostomy is a surgical incision into a kidney to drain the kidney artificially. This procedure may be performed to correct obstructions from large stones or strictures of the ureters. It is also used to drain purulent material from an infected kidney. If the damage is irreparable, surgery is necessary to remove the kidney (**nephrectomy**).

Safety Alert

Verify the Purpose and Type of Tube or Drain

DO NOT confuse urinary drainage systems with gastrointestinal feeding or drainage systems! They can look very similar. When working with tubes and drains, trace all tubes down to the patient's body surface **before** irrigation or instillation of fluids, feedings, or medications. Verify the purpose and type of tube or drain with the charge nurse if you are unsure.

Nursing Management

Postoperative nursing care.

In nephrectomy the surgical incision may be lumbar, transabdominal, or thoracic. When the patient returns from surgery, you must carefully check for the location of the surgical wound and the presence of any drains or tubes that may have been inserted during the operation. Nursing interventions focus on promoting unimpeded urine flow by properly caring for catheters and tubes.

Clinical Cues

A nephrostomy tube should never be clamped or irrigated without a specific provider's order that defines the circumstances and the amount of irrigation fluid.

Hemorrhage is a danger after surgery of the kidney, because the kidneys have a very rich supply of blood directly from the aorta and vena cava. The vital signs are frequently monitored, and any indication of shock or hemorrhage is immediately reported. It is expected that the drainage on these dressings will be blood-tinged at first, but if bright red blood appears or if there is a sudden change

in the amount of drainage, the surgeon should be notified. Dressings over the surgical wound may be reinforced. **Extreme care must be taken when changing dressings to ensure that the drains or tubes are not dislodged or pulled from the surgical incision.** If the tube dislodges, you must contact the surgeon immediately.

Positioning of the patient depends on the surgeon's orders, such as to have the patient lie only on the affected side. Turning may be difficult at first because movement is usually painful and the patient may be reluctant. You should explain the need for frequent turning and deep breathing, so that complications may be prevented.

Adequate drainage from the opposite kidney after surgery is of great importance. Urinary output must be very carefully measured and recorded. Fluids are usually restricted immediately after surgery and then gradually increased as the remaining kidney compensates. If a nephrostomy has been done, fluids are restricted until the affected kidney can sufficiently recover to resume function.

Renal Stenosis

The renal artery can become blocked or narrowed (**renal stenosis**) because of atherosclerosis or scarring. This blockage can result in hypertension or **chronic renal failure** (gradual loss of kidney function). The patient may be asymptomatic, but blood pressure should be monitored. MRI or CT scan or ultrasound may show a decreased kidney size. Anticipate that the patient will be prescribed antihypertensives to control elevated blood pressure. Balloon angioplasty or stent placement can improve blood flow to the kidney.

Renal Stones

A renal or kidney stone (**lithiasis**) is a crystalline mass that forms in the urinary system[®] and, depending on the size and location, may obstruct the flow of urine. Stones can be as small as a grain of sand or large enough to fill the renal pelvis. This enlarged stone formation is called a *renal staghorn calculus* (Figure 34-1). Renal stones also vary in composition and in the environment in which they form. Some stones form more readily in acidic urine, whereas others occur in alkaline urine. There are four major types of renal stones, one of which is hereditary. Table 34-2 shows the risk factors and dietary interventions for each type. Identifying the type and cause of particular kinds of stones can be very effective in preventing further formation and deciding the appropriate method of treatment for each patient. However, in about half the cases, the precise cause of stone formation cannot be identified.

FIGURE 34-1 **A**, A renal staghorn calculus. The renal pelvis is filled and resembles the horn of a stag ("S" on the figure marks the calculus). **B**, Staghorn calculus as seen on an intravenous pyelogram. (A, From Stevens A, Lowe JS, Scott I: *Core pathology: Illustrated review in color*, ed 3, London, 2009, Mosby Ltd. B, From Bullock N, Doble A, Turner W, Cuckow P: *Urology: An illustrated colour text*. London, 2008, Churchill Livingstone.)

Table 34-2**Risk Factors and Treatments for Renal Stones**

STONE TYPE	RISK FACTORS	INTERVENTIONS
Calcium oxalate (most common type)	An increased intake of protein, sodium; inadequate fluid intake, prolonged immobility	Increase fluid intake. Medications to bind oxalate (cholestyramine) or calcium (e.g., cellulose phosphate). Diuretics (e.g., hydrochlorothiazide) to encourage flushing. Avoid oxalate sources such as spinach, chard, parsley, peanuts, chocolate, and strawberries.
Calcium phosphate	An increased intake of protein, sodium; inadequate fluid intake, primary hyperparathyroidism	Limit intake of foods high in protein and sodium. Treat underlying hyperparathyroidism.
Uric acid	Excess dietary purine (e.g., organ meats, gravies, red wines, and sardines) Gout (primary or secondary)	Decrease intake of purine sources. Alkalinize urine with potassium citrate or lemonade. Administer allopurinol for gout (decreases production of uric acid).
Struvite (more common in women)	Urinary tract infections	Administer antibiotics for infection and acetohydroxamic acid (inhibits the chemical action of bacteria that contributes to struvite stone formation) as prescriptions.
Cystine	Hereditary cystine crystal formation	Encourage oral fluids, up to 3 L/day. Medications to prevent crystallization (e.g., tiopronin). Alkalinize urine with potassium citrate or lemonade.

Etiology and Pathophysiology

Certain conditions predispose a person to having renal calculi. Among the most common causative factors are (1) supersaturation of the urine with crystalloids that do not readily dissolve (e.g., calcium, uric acid, and cystine); (2) urinary infections, which can produce bacteria and other debris that form a core for stone formation; (3) inadequate fluid intake, which results in concentrated urine and inadequate flushing of the urinary tract; (4) sluggish flow of urine, as may occur with bed rest or immobility; and (5) certain substances in the urine (e.g., urate, a salt of uric acid), which encourage the formation of crystals of calcium oxalate or calcium phosphate. In the past, patients with calcium oxalate stones were encouraged to decrease dietary calcium; however, evidence-based practice now indicates that these patients should actually be encouraged to increase fluids and dietary calcium, but decrease protein and sodium intake and foods that are high in oxalate, such as spinach and nuts (NIH, 2014).

A small percentage of patients with calcium stones have a tumor of the parathyroid. This gland produces a hormone that raises the level of serum calcium, and thus calcium in the urine. Treatment of the parathyroid condition removes the cause of the stones. Risk factors for kidney stone formation include:

- Male gender
- A family history of renal stones
- History of intestinal bypass surgery for obesity (these patients have an increased absorption of oxalate from foods)
- Immobility for any reason, which contributes to urinary stasis and calcium loss from bones
- History of recurrent urinary tract infections

Prevention

A continuous flow of dilute urine flushes the tract and removes substances that could form stones. **Ideally, adults must put out at least 3500 mL of urine every 24 hours to prevent stone formation; likewise, preventing urinary infections and maintaining adequate drainage through tubes and catheters is also necessary.** In those cases in which the urine pH is causing stone formation, changing the urine pH can prevent or reduce the incidence of renal calculi. Ascorbic acid or dietary modifications (e.g., cranberry juice, prunes, or lemon juice) can be used to acidify urine.

Signs and Symptoms

Some renal stones do not cause noticeable symptoms and can be passed without the person being aware of them. Others may lodge in the renal pelvis and cause symptoms only after the destruction of kidney cells. The kidney stones that cause severe pain are those that are small enough to move along the ureter with the urine. As the stone rolls along, sharp little spikes scrape the ureteral lining, causing excruciating pain and bleeding. Pain is typically felt in the flank over the affected kidney and ureter and radiates downward toward the genitalia and inner thigh. Nausea and vomiting often occur because of the severity of the pain. **Moving stones can get trapped along the ureter, causing obstruction of flow and swelling of the ureter.**

Think Critically

A colleague tells you that your patient is seeking narcotics and is “faking” kidney stone pain and intentionally introducing blood into his urine sample. How would you respond to this?

Diagnosis

Diagnostic tests include urinalysis for blood in the urine and a kidney, ureters, bladder (KUB) study to locate stones that are radiopaque (materials such as metal will appear as a white area on the radiograph); an IVP will show a gap (nonradiopaque stone) in the stream of dye being excreted in the urine. Further studies of the blood and urine might be done to determine the levels of substances, such as calcium, uric acid, and cystine, that can contribute to stone formation.

Treatment

At first, the provider may try to flush the stone out by increasing the patient's IV fluids or oral fluid intake and managing pain by prescribing opioid analgesics or nonsteroidal anti-inflammatory drugs (NSAIDs) and antispasmodics, such as propantheline bromide (Pro-Banthine) or oxybutynin chloride (Ditropan). If there is pus in the urine, an antibiotic is prescribed to deal with infection.

Some stones can be flushed by irrigation through a ureteral catheter or percutaneous nephrostomy tube or crushed by ultrasound. Usually, a stent will be placed in the ureter to allow the stone fragments to pass more freely. Extracorporeal shock wave **lithotripsy** (ESWL) has largely replaced surgery for renal stones. For this treatment the patient is placed in a water bath; newer machines use a water-filled mat. Shock waves are generated, pass through the water, bounce off a reflector, and break the stone. Sedation is used to help the patient remain calm and still during the 30- to 45-minute procedure, or the patient may be given general anesthesia. After the procedure, the patient may experience cramping pain and is given pain medications (e.g., hydrocodone-acetaminophen [Vicodin]) if this occurs. A fluid intake of 3000 to 4000 mL is necessary to help wash the stone fragments from the kidney. A tube may be placed into the kidney either through the bladder or through the back that will drain the fluid and the stones from the body ([Miller, 2013](#)).

Think Critically

Based on your knowledge of anatomy and physiology, what is the difference between a **urethral** catheter and a **ureteral** catheter? (Note the spelling difference!) Why is it important to know the difference between these two catheter sites?

Adjunctive therapy for ESWL includes corticosteroids and calcium channel blockers and alpha antagonists (e.g., tamsulosin), which increase the rate of stone passage. Percussion, diuresis, and inversion (PDI) therapy is used after ESWL. In this procedure, diuresis is promoted, and the patient is placed in a prone, reverse Trendelenburg position and massaged or percussed to encourage stone movement.

When the stone is not passed spontaneously, cystoscopy or surgical intervention is necessary. Nephrolithotomy (incision into the kidney to remove a stone) or pyelonephrolithotomy (surgical removal of a stone from the renal pelvis) can be performed for large stones that will not pass. These procedures may be done percutaneously or, rarely, with an open procedure. A special forceps is introduced through the nephroscope to retrieve the stone. A nephrostomy tube is inserted as the scope is removed and remains in place for 1 to 5 days. A fluid intake of 3000 to 4000 mL/day is required to flush any residual stone fragments out of the kidney. The patient is monitored for infection, hemorrhage, and leakage of fluid into the retroperitoneal cavity. When a stone cannot be retrieved by a percutaneous procedure, an open procedure is used. If a stone is lodged in a ureter and will not descend after fluid increases, a ureterolithotomy (surgical removal of a stone from a ureter) is performed.

If the stone is 5 mm or larger, the patient may also receive a ureteral stent (usually a soft flexible silicone tube), which is inserted through a cystoscope or nephrostomy tube, or during surgery. The purpose of a ureteral stent is to maintain the patency of the ureter to allow stones to pass through. Stents are not visible on the outside of the body. They are usually removed in 4 to 6 weeks in an outpatient setting. Nursing interventions include monitoring for infection, bleeding, urine output, and pain. Once stones have been removed, chemical analyses of the urine, blood, and the stone itself are necessary to plan effective preventive measures. [Table 34-3](#) provides additional information about common catheters and tubes used for urologic disorders.

Table 34-3
Common Catheters and Tubes Used for Urologic Disorders

TYPE	PURPOSE
Urethral catheter	Drains urine from the bladder
Foley catheter	Indwelling catheter for continuous urine drainage from the bladder
Suprapubic catheter	Continuous drainage of urine from the bladder; inserted in suprapubic area of abdomen through abdominal and bladder wall
Ureteral catheter	Drains urine directly from the ureter or kidney
Ureteral stent	Tube placed in ureter to hold it open during healing; not visible on the outside of the body
Nephrostomy tube	Placed into the pelvis of the kidney to provide drainage of urine directly from the kidney

Nursing Management

During initial assessment of a patient with kidney stones, the patient may have extreme pain, so use concise questions to gather information about pain, changes in urinary output, and characteristics of the urine. Asking family about risk factors and history may be appropriate.

Attempts are made to have the patient pass the stone spontaneously, and all urine is strained to recover the stone or fragments for analysis. This is accomplished by having the patient void into a urinal or collection device and then pouring the collected urine through a fine mesh filter. Fluids are encouraged during this time to facilitate flushing of the stone.

Urologic System Trauma

Trauma to Kidneys and Ureters

Etiology and Pathophysiology

Accidental injury to the kidneys, ureters, bladder, or urethra should always be considered whenever there has been trauma to the abdominal cavity, lower back, or thoracic cage. Injury to the kidneys is usually caused by blunt trauma that is sustained during a motor vehicle, sports, or occupational accident. Damage can occur as a result of a direct blow, laceration from an adjacent rib or vertebra fracture, or from sudden deceleration, which shears and tears the body tissue. Ureteral injuries are mostly associated with penetrating trauma; the right side is three times more likely than the left side to be involved. Trauma to the urinary system can range from minor contusion to severe hemorrhage that leads to hypovolemic shock.

Signs, Symptoms, and Diagnosis

Signs and symptoms characteristic of trauma to the kidneys include massive hemorrhage, hematuria, abdominal or flank pain, and possibly an enlarged mass in the kidney area. Diagnostic tests include serial urinalyses, hemoglobin and hematocrit tests, and measurements of electrolytes. Rising BUN and serum creatinine levels indicate diminishing renal function. Radiologic studies (KUB, IVP, or CT scan) can demonstrate the extent of damage to the urinary system. MRI or angiography is used in high-risk cases or if CT scan is indeterminate. Hourly measurements of urinary output and observation of the characteristics of the urine can help determine the type and extent of injury.

Clinical Cues

When a patient sustains significant trauma to skeletal muscle tissue, he may develop rhabdomyolysis. Damaged muscles release myoglobin into the bloodstream, and these large muscle proteins can cause **acute renal failure** (sudden loss of kidney function); however, the condition is reversible. Be alert for brown or tea-colored urine after trauma, strenuous exercise, or extensive burns, and report your findings to the provider.

Treatment

Bleeding in the kidney is often self-limiting. Lacerations and contusions without interruption of urinary function usually can be treated conservatively by bed rest. For this reason, the nephrologist may advocate a period of watchful waiting to see whether the kidney can be saved. If the kidney is severely damaged, the patient may undergo a nephrectomy. The remaining kidney then enlarges and is usually able to carry on the work formerly done by two kidneys.

Nursing Management

Preoperative nursing care.

Patients with kidney trauma are likely to have damage to the colon, spleen, or pancreas. A comprehensive plan for dealing with problems associated with multiple trauma is usually necessary. Preoperatively, the patient is monitored closely for signs of hypovolemic shock, cardiovascular changes, urinary output, and size of the flank hematoma. Grey Turner sign is bruising over the flank or lower back and suggests retroperitoneal bleeding. For most trauma patients, a urethral catheter is inserted into the bladder. An indwelling catheter allows for close observation of urinary output—for example, critically ill patients may need hourly urine output measurements, and a drainage bag with a urometer should replace the standard drainage bag.

Postoperative nursing care.

Postoperative nursing care for nephrectomy or nephrostomy is described on p. 793.

Trauma to the Bladder

Etiology and Pathophysiology

Any violent blow or crushing injury to the lower abdomen may result in rupture or perforation of the bladder wall, with resulting leakage of the urine into the pelvic tissues or peritoneal cavity. This results in severe inflammation (peritonitis). Bladder trauma is more likely to occur if the bladder is full at the time of an accident, rather than if it is empty.

Signs and Symptoms

Early symptoms of bladder injury are painful hematuria or inability to void, marked tenderness and spasm in the suprapubic area, or the development of a large mass in that area.

Clinical Cues

In cases of pelvic or perineal trauma, bleeding at the urethral meatus, inability to void, or a distended bladder may indicate a urethral tear. Notify the provider before inserting a catheter, because catheter insertion can increase the damage by extending the tear.

Diagnosis and Treatment

Diagnosis is based on presence of gross hematuria, suprapubic pain, and difficulty voiding. Retrograde or CT cystography is obtained if bladder injuries are suspected. If the bladder has ruptured or is perforated, treatment consists of a suprapubic cystostomy to drain blood and urine.

Nursing Management

Patient care requires meticulous attention to drains and dressings to prevent infection and maintain good drainage. Cold applications to the surgical site both before and after surgery may be ordered. Observe the patient carefully for postoperative shock and massive hemorrhage. Any mass formation in the suprapubic area before or after surgery, or any change in vital signs, should be reported immediately.

Urologic System Cancers

Cancer of the Bladder

Etiology and Pathophysiology

It is estimated that approximately 74,000 new cases of bladder cancer will be diagnosed in 2015, to result in death for 11,510 men and 4490 women ([American Cancer Society, 2015](#)). Bladder cancer is more common in men (ages 60 to 80 years) than in women. **Smokers have double the risk of developing this cancer.** People living in urban areas or with occupational exposure to nitrates, dyes, rubber, or leather processing (e.g., painters, hairdressers, or textile workers) are at higher risk. The bladder wall is exposed to these carcinogenic chemicals in the urine. Tumors of the bladder usually start in the superficial transitional cell layer and are considered to be papillomas (benign tumors on the epithelial tissue). Bladder tumors are removed—even though they are papillomas—because there is a high risk for invasion into the deeper tissues and metastasis.

Signs, Symptoms, and Diagnosis

The main symptom of a bladder tumor is hematuria. Frequency, urgency, or dysuria also may be present. Diagnosis is confirmed by IVP and by examining the bladder wall with a cystoscope and biopsy of the tumor.

Complementary and Alternative Therapies

Healthy Bladder

Smoking cessation and including cruciferous vegetables such as cabbage or broccoli in the diet contribute to a healthy bladder and a decreased risk of bladder cancer ([Movva, 2014](#)).

Treatment

Treatment for bladder cancer is surgery, either alone or in combination with chemotherapy or radiation. The type of surgical treatment depends on the clinical stage of the tumor. Every effort is made to preserve the bladder if the tumor is confined to the mucosa or submucosa. In this case a partial cystectomy or transurethral resection of the bladder tumor (TURB or TURBT) is performed and followed by intravesical immunotherapy (bacille Calmette-Guérin [BCG] instillations [Intravesical, TheraCys]) or chemotherapy. The drugs that are used most often for intravesical therapy are mitomycin and thiotepa, but combinations of other drugs such as valrubicin, doxorubicin, and gemcitabine may be used ([ACS, 2014](#)). BCG was originally used as a vaccine against tuberculosis. It has helped patients with bladder carcinoma in situ (site of origin) by reducing tumor recurrence and by eliminating residual malignant cells after surgery. The solution is instilled into the bladder via a urinary catheter. The catheter is clamped for 2 hours, and the patient's position is changed every 15 to 30 minutes. Treatments are continued weekly for 6 weeks with possible maintenance doses. Advise patients that BCG intravesical therapy is likely to cause future tuberculin skin tests to result in a false positive.

Clinical Cues

In addition to using Universal Precautions, for 6 hours following a BCG treatment the patient's toilet should be disinfected with bleach each time it is used for the disposal of the patient's urine.

Photodynamic therapy can be used for superficial tumors. In this therapy, a solution of light-sensitive molecules is injected IV. These molecules adhere to cancer cells longer than they do to normal cells. A cystoscope with a red laser light can then be used to activate the photosensitizers that destroy tumor cells.

Surgeries for urinary diversion.

Bladder surgery may be minor, such as removing polyps from the bladder interior using a cystoscope, or major, such as cystectomy (removal of the bladder) for bladder cancer. After cystectomy, there is always the danger of hemorrhage and infection. There are also problems in devising a satisfactory arrangement for urine collection. When the bladder is surgically removed, the surgeon performs a **urinary diversion** to handle the excretion of urine and creates an artificial opening (stoma) on the skin surface. Diversions also can be performed for neurogenic bladder, congenital anomalies, strictures, or trauma. There are several ways in which urinary diversion can be accomplished ([Figure 34-2](#)), including by ileal conduit or ileal loop, cutaneous ureterostomy, vesicostomy, uretersigmoidostomy or sigmoid conduit, and ileal reservoir (i.e., Kock, Indiana, Mainz, or Florida pouch). The difference in these various procedures is the segment of bowel that is used.

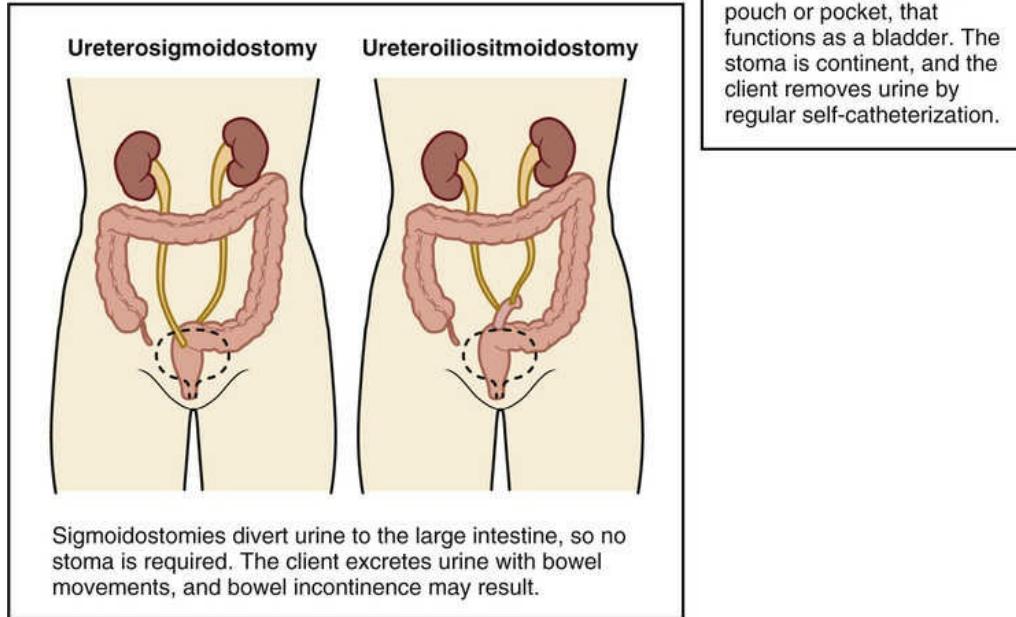

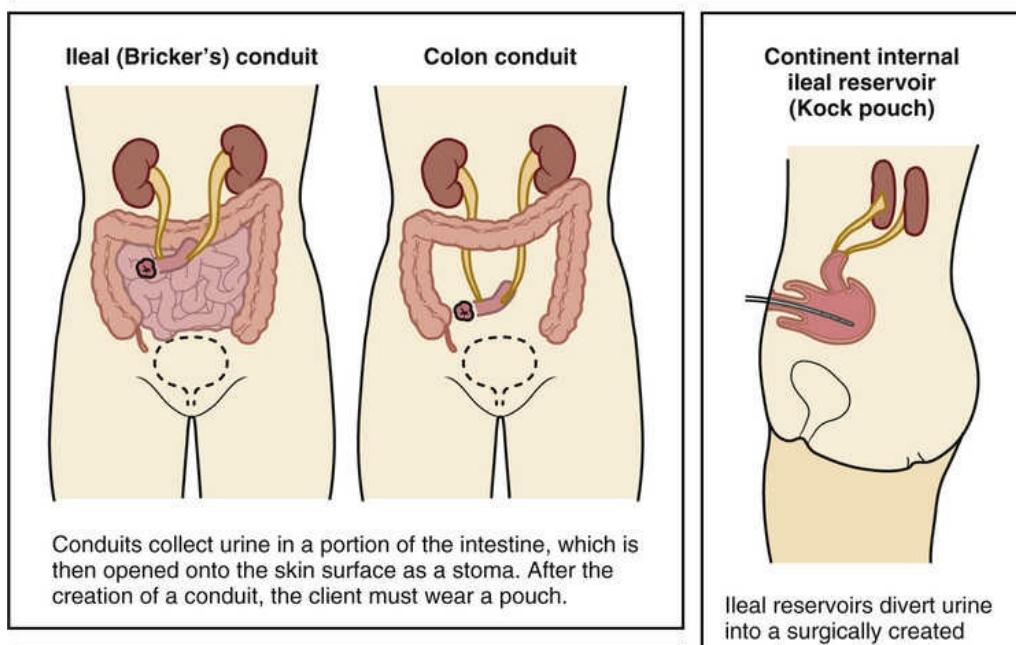

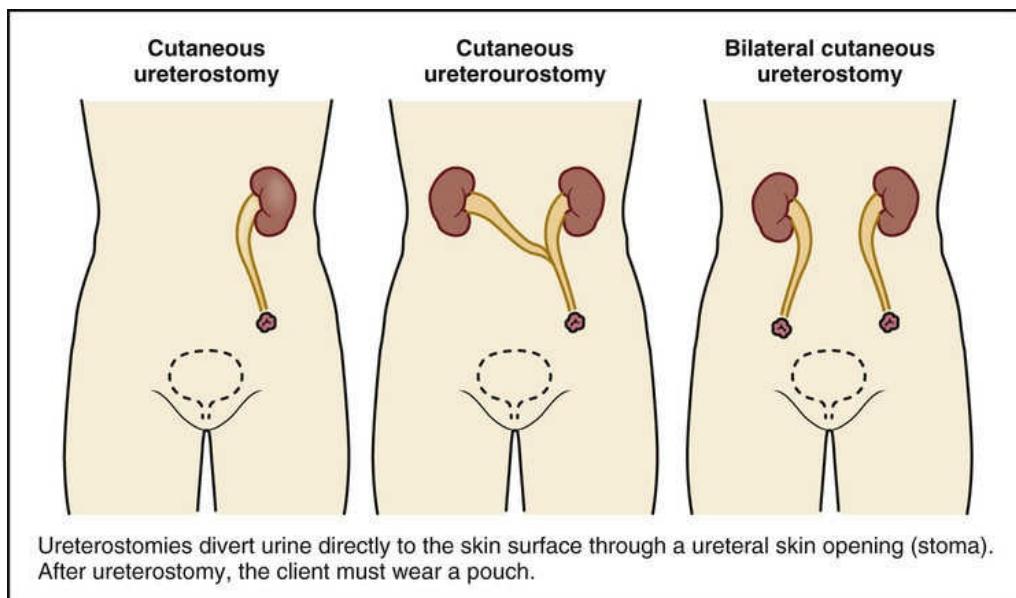

FIGURE 34-2 Surgeries for urinary diversion. (From Ignatavicius DD, Workman ML: *Medical-surgical nursing: Critical thinking for collaborative care*, ed. 7, Philadelphia, 2010, Saunders.)

Cutaneous ureterostomy and vesicotomy.

Ureterostomy is a surgical incision into the ureter that diverts the flow of urine. In a cutaneous ureterostomy, the surgeon detaches one or both ureters from the bladder and brings them to the surface of the body, usually in the region of the flank. The patient may have one or two stomas. If the patient has a cutaneous ureterostomy with two stomas (one from each ureter), the flow of urine from each stoma must be measured. Any tubing leading from the ureterostomy should be kept open so that urine can flow freely. The tube is checked frequently for signs of obstruction by mucus or blood clots. A vesicotomy is an incision into the bladder just above the pubic area. After incising the bladder, the surgeon moves it forward and sutures the cut edges to the skin, forming a stoma.

Ileal conduit.

An ileal conduit is also called *urinary ileostomy and ileal loop* or a *Bricker procedure*. A portion of the ileum is used as a tube or conduit through which urine flows to the outside. The section of ileum is separated from the intestinal tract. Urine does **not** flow through it to the intestines, as when the ureters are sutured to the sigmoid. The two open ends of the intestines where the section of ileum was removed are rejoined by anastomosis (operative union of structures). The surgeon cuts out a portion of the ileum, leaving nerve and blood supply intact so that it remains a viable tissue. The “borrowed” section of ileum is sutured together at one end to form a pouch, and the other end is brought outside to form a stoma. The ureters are attached to the ileal conduit so that urine can flow through the conduit to the outside.

Ureterosigmoidostomy or sigmoid conduit.

A sigmoid or colonic conduit is similar to an ileal conduit, except that a portion of the sigmoid colon is used to form the conduit. The ureters are implanted in the conduit.

Continent diversion (Indiana pouch).

Typically either ileum or a terminal ileum combined with ascending colon is used for continent urinary diversion. These segments are detubularized and then refashioned into a spherical shape to prevent problems such as high pressure reflux and eventual renal failure. The spherical shape has an increased capacity and decreases luminal pressure greatly ([Costa, 2013](#)) and is used as a reservoir. A one-way valve mechanism is created at the insertion site that then leads into an external stoma through which the internal pouch can be irrigated with normal saline. There is no external storage system.

Noncontinent diversion.

Noncontinent diversion is considered the standard for urinary diversion because it has the fewest postoperative complications. Ileum (15 to 25 cm) and possible jejunum segments are used to anastomose the ureters at the proximal end and create a stoma on the abdominal wall at the distal end to attach to an external storage system. The urine flows in a peristaltic manner through the bowel segment ([Costa, 2013](#)).

Clinical Cues

There are significant differences in the irrigation of tubes, drains, and stomas for the urinary system, so make sure to **clarify orders**. For example, the Indiana pouch may be irrigated one to four times a day with 30 to 60 mL of normal saline (size and maturity of the pouch will vary) ([UOAA, 2015](#)), whereas ureteral stents or ureteral catheters are usually not irrigated. If the provider does order irrigation of a stent or ureteral catheter, the amounts of sterile normal saline are much smaller (3 to 10 mL).

Orthotic bladder substitutes.

Bladder substitutes or neobladders can be created using a portion of the patient's own intestine; they are more commonly used for male patients with cancer of the bladder, when the sphincter is

intact and there is no cancer in the urethra or bladder neck. The advantage is normal micturition. Examples include hemi-Kock, Studer, and ileal W-neobladder.

Nursing Management

Postoperative nursing care.

After surgery, observe for pain, abdominal rigidity, fever, and bleeding. Assess the amount and characteristics of the urine and mucus and record accurate output of urine every hour for the first 24 hours and then every 4 to 8 hours. **Regardless of which surgical procedure the patient has had, the urine should never stop flowing.**

The urine should initially be light red or pink and progress to clear within 3 days or less. Bright red bleeding or clots should be reported immediately. The stoma should be pink or red. A pale, dark, or dusky stoma suggests decreased blood flow, which should be reported immediately. Skin irritation and breakdown can be a problem, and every effort is made to keep urine from touching the skin when the patient has an external stoma. A well-fitted and properly adhering collection appliance is essential. A thin gauze roll or tampon is placed into the stoma during appliance changing and cleaning to prevent leakage of urine onto the skin. For a permanent ostomy, the bag can be used for 3 to 7 days. The bag should be emptied when it becomes one third to half full, to prevent the weight of the urine from pulling the bag loose. At night the bag can be connected to a larger urine container. The bag should be changed in the morning when there is less urine flow. The area around the stoma is washed with a solution of 1 : 1 vinegar and warm water to remove any crystals. If no crystals are present, warm, soapy water may be used. The area is thoroughly rinsed and patted dry with a towel before a new bag is attached, because any remaining moisture may interfere with the seal of the new appliance. A bath or shower may be taken with the bag on or off.

Most appliances contain an odor barrier; however, odor may be a problem because of poor hygiene; alkaline urine; normal breakdown of urine when it is exposed to air; and the ingestion of certain foods, such as asparagus. Dilute urine is also less odorous and can be accomplished by increasing fluid intake. Reusable appliances must be washed with soap and water and soaked in a dilute white vinegar solution or a commercial deodorizing product for 20 to 30 minutes. The pouch is then rinsed and allowed to dry. Deodorant tablets may be placed in the appliance to decrease odor.

Complementary and Alternative Therapies

Reduce Odor of Urine

For patients with a urinary diversion, a diet that includes whole grains, nuts, plums, prunes, and cranberry juice will help to acidify the urine and decrease odors.

Psychological care of a patient facing malignancy and an operation that will radically change his body image should be a primary nursing concern, and there are always sexual concerns when a urinary diversion is performed. Some of the more radical procedures will produce impotence in the male. Encourage the patient and spouse to talk about fears and concerns, and provide emotional support. Help the patient and family to identify appropriate community resources, and make referrals as needed for specialized counseling.

Cancer of the Kidney

Etiology and Pathophysiology

Cancer of the kidney, known as renal cancer, is relatively uncommon; however, these tumors are extremely difficult to treat in the later stages. Neoplasms of the kidney occur in men (ages 50 to 70 years) twice as often as in women. Risk factors include smoking and exposure to lead or phosphate.

The tumors usually begin growing in the renal cortex. They can become very large, but they are well defined and press into the renal structures rather than invade the tissue. The blood vessels also can become constricted by the tumor growth.

Signs, Symptoms, and Diagnosis

The principal symptoms of malignant tumors of the kidney are hematuria, palpable abdominal or flank mass, and flank pain (although pain and a mass may not be present in the early stages). Other symptoms that may occur are fever, fatigue, weight loss, decreased appetite, and hypertension. Renal angiogram, arteriogram, CT, MRI, or ultrasound may be performed to determine whether the symptoms are being caused by a cyst (nonmalignant) or by a tumor.

Treatment and Nursing Management

The only treatment that has any success is surgical removal of the affected kidney (nephrectomy) before metastasis takes place. Unfortunately, the patient usually does not have severe symptoms until metastases have occurred. Chemotherapy with a variety of drug regimens is used for metastatic cancer (see [Chapter 8](#)). Immunotherapy may be used for recurrent tumors.

Interleukin 2 (IL-2), an immunotherapy, is the only therapy that has a long-lasting response ([ACS, 2014](#)). However, it can cause serious side effects, so it is reserved for those with advanced cancer who are strong enough to withstand this treatment or do not respond to targeted drugs. Sunitinib (Sutent), sorafenib tosylate (Nexavar), temsirolimus (Torisel), everolimus (Afinitor), bevacizumab (Avastin), pazopanib (Votrient), and axitinib (Inlyta) are targeted drugs for advanced kidney cancer. They act to deprive the tumor cells of blood and nutrients. Temsirolimus and everolimus inhibit tumor cell growth and proliferation; these drugs are available to patients who failed to respond to sunitinib or sorafenib. Pazopanib interferes with the growth of new blood vessels that would supply the tumor.

Chemotherapy is not a standard treatment for renal cancer, because kidney cancer cells are usually resistant. Chemotherapy is only attempted after immunotherapy and targeted therapy have failed. Drugs used in this case are vinblastine, floxuridine, 5-fluorouracil (5-FU), capecitabine, and gemcitabine.

Nursing care of patients with renal cancer after nephrectomy is the same as that for other cancer patients after nephrectomy (see [Chapter 8](#) for care of patients with cancer).

Renal Failure

Renal failure is the inability of the kidneys to maintain normal function. Renal failure is classified as acute or chronic. The final stage of chronic and irreversible renal failure is called **end-stage renal disease (ESRD)**.

Acute Renal Failure

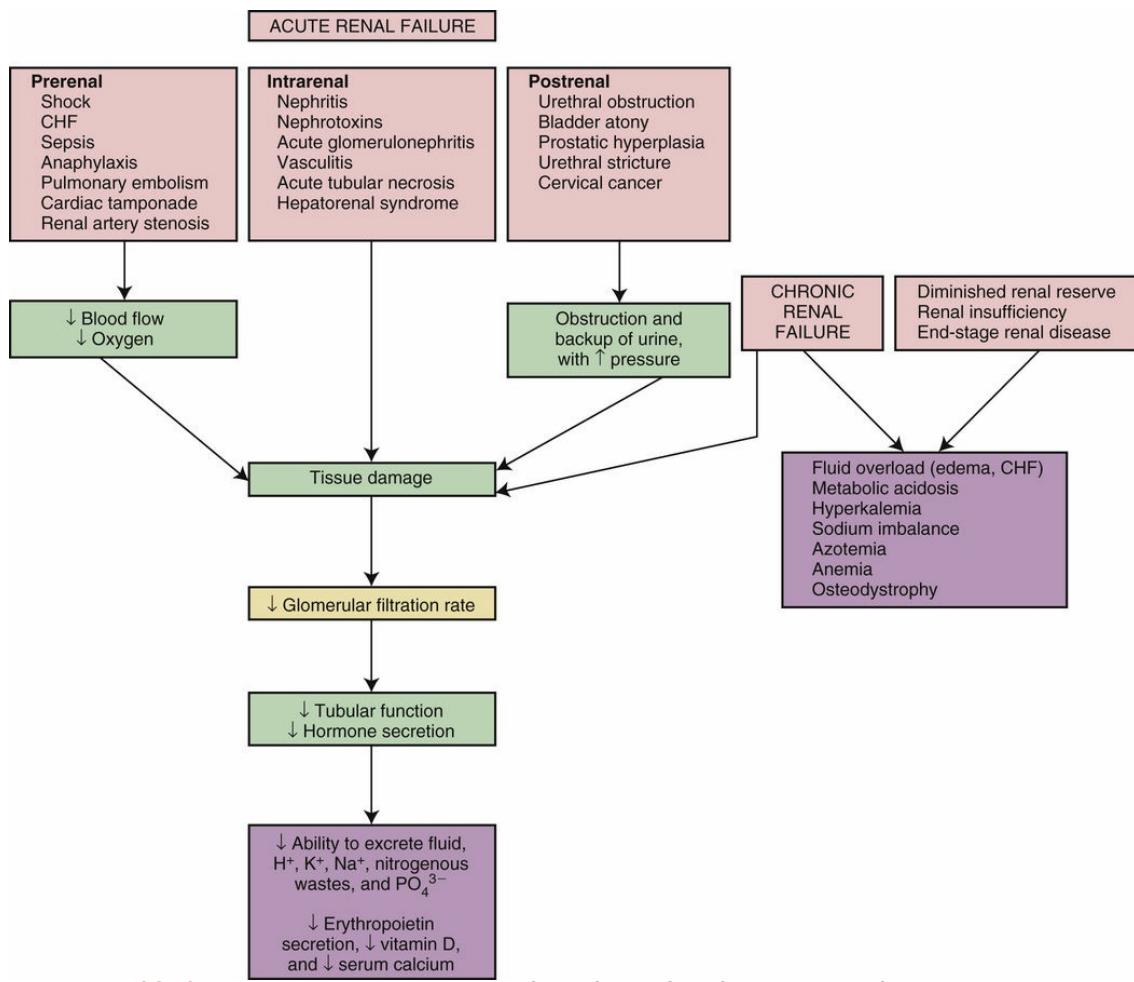

Etiology

Acute renal failure (ARF) occurs suddenly as a result of physical injury, infection, inflammation, or damage from toxic chemicals. Nephrotoxic agents are those that are poisonous to kidney cells and include many drugs, iodine substances used as radiographic contrast media, heavy metals, snake venom, or exposure to industrial chemicals. These toxins may inflict damage on the renal tubules, causing acute tubular necrosis (ATN) and loss of function. They can also indirectly harm the tubules by causing severe constriction of blood vessels that serve the kidney, producing renal ischemia. ATN is responsible for 90% of acute renal failure. Other causes of renal ischemia include circulatory collapse, severe dehydration, and prolonged hypotension in compromised surgical or trauma patients.

Pathophysiology

The pathophysiology of ARF is not well understood. One theory is that cellular or protein debris in the tubules blocks the flow of urine and filtration stops. Another theory is that decreased blood flow results in oxygen deprivation, which causes cellular death and tubular necrosis.

There are three types of acute renal failure, depending on the cause. **Prerenal ARF** is caused by decreased blood flow, such as in hypovolemic shock, or decreased cardiac output, as in cardiogenic shock. **Intrarenal ARF** occurs from glomerular damage, ATN caused by ischemia or toxins, or vascular disease that affects the vessels in the kidney. **Postrenal ARF** is caused by obstruction in the ureters, bladder, or urethra—for example, an enlarged prostate—that causes eventual backup of urine into the kidney, which in turn leads to tissue damage. ARF is potentially reversible, especially if identified early; patients often regain kidney function. [Concept Map 34-1](#) shows the pathophysiology of renal failure.

Think Critically

During your clinical experience, which of your patients may have been at risk for ARF? What factors placed these patients at risk?

The course of acute tubular necrosis is divided into three phases: oliguric/nonoliguric, diuretic, and recovery phases. In the oliguric/nonoliguric phase, the patient puts out either a great deal of or very little urine. Oliguria is a urine output of 100 to 400 mL in 24 hours. This phase usually occurs immediately or within 1 week after an ischemic event and lasts for an average of 10 to 14 days; however, it can go on for weeks to months, and prolonged oliguria worsens the prognosis. BUN and creatinine levels rise. When this occurs, there may be volume overload, which can precipitate heart failure, multiple electrolyte imbalances, metabolic acidosis, catabolism (destructive breakdown of body tissue), and end-stage renal disease (ESRD); dialysis is needed.

Older Adult Care Points

Because of the overall decreased kidney function related to aging, older adult patients may experience oliguria even though urine volumes are as high as 600 to 700 mL/day.

Nonoliguric ATN is often caused by nephrotoxic agents. Urine output is greater, but the kidneys cannot eliminate waste products efficiently; BUN and creatinine levels rise, and electrolyte imbalances occur. Dialysis is needed less often or for shorter periods, and the prognosis is better than for oliguric failure.

The diuretic phase only occurs if dialysis has not been started early and extracellular fluid

volume has built up. In this phase, the kidney is unable to concentrate urine, and output can be between 1000 and 2000 mL/day. With this increased output, there is a danger of dehydration, hyponatremia, and hypokalemia. Approximately 25% of deaths related to ARF occur during this phase.

The recovery phase begins as the kidney function begins to normalize. The concentration of urine, urine output, and electrolyte balance begin to recover. There are 1 to 2 weeks of rapid improvement and then a period of slower recovery lasting between 3 and 12 months. About one third of ARF patients are left with residual renal insufficiency, and about 5% must continue dialysis.

Signs and Symptoms

Renal failure will have an effect on the entire body, and the signs and symptoms will vary according to the phase and response to treatment. Carefully observe for any of the following:

- Changes in urine output and urine results (e.g., specific gravity, proteinuria)
- Electrolyte imbalances (e.g., hyponatremia, hyperkalemia, hypocalcemia)
- Fluid imbalance (e.g., hypotension, hypertension, edema, pulmonary edema)
- Acid-base imbalance (e.g., metabolic acidosis)
- Gastrointestinal effects (e.g., nausea, vomiting, anorexia, constipation)
- Mental status changes (e.g., lethargy, memory impairment)
- Anemia and platelet dysfunction (e.g., fatigue, bleeding signs, bruising)
- Impaired wound healing and susceptibility to infection (e.g., elevated WBC)

Diagnosis

Diagnostic testing includes urinalysis, creatinine, BUN, CBC, electrolytes, and arterial blood gases. In addition, radiologic studies (such as ultrasound, IVP, CT, or MRI) can be performed if an obstruction is suspected. A renal biopsy may be obtained to assist in determining the cause or to evaluate the extent of kidney damage.

Treatment

Treatment of ARF is aimed toward correcting the underlying cause and preventing or controlling complications and maintaining a tolerable internal environment until the kidneys are able to recover and resume their normal functions. Symptomatic treatment includes correction of fluid and electrolyte balances, management of anemia and hypertension, and cleansing the blood and tissues of waste products with **hemodialysis** (filtration of blood across a semipermeable membrane) or **peritoneal dialysis** (filtration of blood across the peritoneal membrane). Volume overload is treated with diuretics and sometimes low-dose dopamine to promote better kidney perfusion. Dialysis is also used to reduce volume overload if it cannot be reduced with drugs. Electrolyte imbalances (hyperkalemia, hypocalcemia, hyperphosphatemia, and mild hypermagnesemia) are monitored and treated. Metabolic acidosis, if severe, is treated with IV sodium bicarbonate. Dialysis with buffer in the dialysate may be used.

Other problems include malnutrition, anemia, and potential for infection. The catabolic state is treated with nutritional management through total parenteral nutrition (TPN). Potassium, phosphate, and magnesium are omitted from the solution while the patient is oliguric. Anemia occurs because the kidney cannot produce normal amounts of erythropoietin. The life span of red blood cells is shortened because of both the toxic wastes circulating in the blood and the hemodilution from fluid overload. To treat this anemia, the provider may order epoetin alfa (Epogen), a synthetic substance that stimulates red blood cell production. Infection is common with ARF and is the leading cause of death in these patients. Nurses must be vigilant in monitoring for signs of infection that could be associated with IV access sites, drains and tubes, and a lowered immunity state.

Continuous renal replacement therapies (continuous hemofiltration).

Continuous renal replacement therapies (CRRTs) can be used for patients in the intensive care unit (ICU) who have ARF and multisystem organ involvement or for those who are hemodynamically unstable. A double-lumen catheter is typically inserted into the subclavian or internal jugular vein. The blood is removed from the arterial lumen of the catheter and passed through a semipermeable

membrane and returned to the venous lumen of the catheter (Dirkes and Hodge, 2008). This method filters out wastes much more slowly than hemodialysis but does not cause such rapid fluid and electrolyte shifts. Continuous arteriovenous hemofiltration (CAVH) uses the patient's own blood pressure to pump the blood. Continuous arteriovenous hemodialysis (CAVHD) combines hemodialysis and hemofiltration, thus removing waste and fluid. Continuous venovenous hemofiltration (CVVH) and continuous venovenous hemodiafiltration (CVVHDF) are both controlled by a pump (Clin-eGuide, 2009). Slow continuous ultrafiltration (SCUF) is primarily used for fluid removal, such as for patients with pulmonary edema (Dirkes and Hodge, 2008).

❖Nursing Management

■ Assessment (Data Collection)

When taking a patient's history, include questions that relate to fluid imbalance (e.g., changes in voiding patterns, weight gain, muscle cramps, cardiac arrhythmia or palpitations, vomiting, or edema) and potential risk factors (e.g., patient or family history of renal disease or hypertension; recent surgery, trauma, or anesthesia; and exposure to nephrotoxic substances or any medications). The patient should also be encouraged to describe specific symptoms (e.g., fatigue, lethargy, weakness, or pain).

All patients need a complete head-to-toe assessment and complete vital signs at the beginning of every shift. Acutely ill patients who are at risk for ARF need frequent reassessment for signs of fluid retention (e.g., skin turgor, edema, lungs sounds, weight, and strict I&O monitoring) and for imbalances in electrolytes (e.g., change of mental status or cardiac dysrhythmias).

■ Nursing Diagnosis and Planning

Examples of problem statements frequently associated with ARF include:

- Fluid volume excess due to decreased kidney function.
- Altered nutrition due to nausea and loss of appetite.
- Altered activity tolerance due to metabolic changes.
- Potential for infection due to indwelling urinary catheter.

Specific nursing diagnoses can be chosen from the NANDA-I list (see inside back cover).

Examples of expected outcomes include:

- Patient will have no signs of fluid overload (e.g., weight gain, edema, crackles in lungs, decreased urinary output) for the next 2 hours.
- Patient will metabolize sufficient calories (based on dietitian's calculation) to prevent catabolism (destructive breakdown of body tissue) during this shift.
- Patient will maintain bed rest and participate in activities of daily living (ADLs) as much as possible (e.g., brushes own teeth) during this shift.
- Patient will not have any signs or symptoms of infection (e.g., fever, cloudy urine) during hospitalization.

■ Implementation

Carefully monitor for signs of fluid imbalance. This includes physical assessment of edema, daily weights, and lung sounds. Strict measurement of I&O is essential. In the acute phase, hourly measurements of urine output are necessary.

Equipment, such as IV control pumps, should be used for accurate and safe delivery of IV fluids. In intensive care settings, arterial or central venous monitoring provides additional information about fluid status. Electrolytes should be monitored and may manifest as changes in the patient's mental status or cardiac dysrhythmias. The patient may be too ill to eat and may require TPN or enteral feedings. Even if the patient is unable to eat, make efforts to reduce noxious stimuli that exacerbate nausea, and administer antiemetics. Provide assistance with ADLs as needed during the acute phase, and progressively provide opportunities for the patient to participate once fatigue resolves. To prevent infection, be vigilant for signs and symptoms of infection. Perform hand hygiene frequently and encourage others to do so. Surgical aseptic technique should be used for procedures such as Foley catheter insertion and central line dressing changes. Help the patient and the family cope with the stress of this serious condition by allowing them to express concerns and

fears, by providing accurate information about ARF, and by making appropriate referrals.

Evaluation

Evaluation of outcomes for acutely ill patients must occur often, because the plan of care may need frequent revision. For example, **if there are sudden changes or if the hourly urine output drops below 30 mL/hr, the provider must be immediately notified.** The patient should be assessed for signs of worsening, such as shortness of breath and lung crackles associated with pulmonary edema, or decreased cardiac output associated with heart failure. The patient must be transferred from a general medical-surgical unit to the ICU if the condition becomes unstable.

Chronic Renal Failure

Etiology

Chronic renal failure (CRF) is a progressive loss of kidney function that develops over the course of many months or years. CRF is caused by destruction of the nephrons. All of the factors that can cause ARF may also cause CRF. Hypertension, diabetes mellitus, sickle cell disease, glomerulonephritis, nephrotic syndrome, lupus erythematosus, heart failure, and cirrhosis of the liver may also contribute to CRF.

The most common causes of CRF are glomerulonephritis and nephrosclerosis. **The primary causes of nephrosclerosis are hypertension and atherosclerotic disease of the small arteries in the kidneys.** As the blood supply decreases, the kidney cells degenerate and lose their ability to function, resulting in ESRD.

Health Promotion

Diabetes Mellitus

Diabetic nephropathy (kidney disease and dysfunction secondary to diabetes mellitus) is the most common cause of death in patients with diabetes mellitus. In keeping with the *Healthy People 2020* goal “to reduce kidney failure due to diabetes,” help your patients to understand the interrelationship between diabetes and kidney health. For example, you could say, “Mr. Smith, with your hypertension, when your blood sugar goes up, protein starts to leak into your urine. This causes an increased pressure in the kidney vessels, which eventually leads to kidney damage.”

Nephrosclerosis is classified as benign or malignant, depending on the severity of the disease and the speed with which hypertensive and atherosclerotic changes occur. The symptoms of nephrosclerosis are similar to those of chronic glomerulonephritis and renal failure. Treatment is the control of hypertension.

Pathophysiology

In the early stages of the disease, renal function can be adequate, but the waste products will begin to accumulate in the plasma. The patient does not experience symptoms until about 65% of the kidney tissue is damaged. As the disease progresses, nitrogenous waste products, such as urea nitrogen and creatinine, build up to higher levels in the blood. In the final or end stage of renal failure, 90% or more of kidney function is lost. **Azotemia** is the accumulation of nitrogenous products, which is signaled by an increase in BUN and serum creatinine. The patient may experience nausea and vomiting and changes in mental awareness and levels of consciousness. **The kidney is not able to excrete potassium; therefore be alert for high levels of serum potassium (5 to 7 mEq/L), which can adversely affect the heart, causing dysrhythmia and cardiac arrest.**

There are three stages of CRF. In stage 1 there is diminished renal reserve but no accumulation of metabolic wastes. The healthier kidney works harder. Urine concentration is decreased, and polyuria and nocturia occur. Stage 2 is renal insufficiency and is signaled by a rise in circulating metabolic wastes; therefore BUN and serum creatinine levels begin to rise. The glomerular filtration rate falls, and oliguria and edema occur. Stage 3 is ESRD. Circulating metabolic wastes accumulate in the blood, homeostasis cannot be maintained, electrolyte and fluid imbalances are serious, and dialysis or kidney transplant is necessary to maintain life.

Signs and Symptoms

The symptoms of CRF do not appear early in the disease. A high-normal elevation of BUN is an early warning sign, and the patient is likely to be asymptomatic. **One of the earliest signs of renal impairment is the inability of the kidneys to concentrate urine. This produces polyuria and very dilute urine, and the patient may report nocturia.** Renal insufficiency, which occurs before renal failure, can produce occasional headaches and fatigue, but these symptoms usually either go unnoticed or unreported by the patient. At this point, the kidney function is about 20% to 40% of normal. When symptoms do become apparent, kidney function can be as little as 5% to 10% of normal. As renal insufficiency progresses, the kidneys may not be able to produce much urine at all. This causes oliguria and eventually anuria.

Uremia or **uremic syndrome** includes the clinical signs and symptoms that affect the entire body during ESRD. Uremia signs generally appear when BUN concentration passes 100 mg/dL. The presence of uremic signs is the absolute indicator for initiating dialysis, and the goal is to maintain BUN below 100 mg/dL and to keep creatinine below 8 mg/dL.

The skin becomes dry, scaly, and a pallid yellowish gray. Pruritus (severe itching) occurs. Uremic frost (a late sign) appears as evaporated sweat leaves urea crystals on the eyebrows, face, axilla, and groin. Calcium is not absorbed from the intestinal tract, and this leads to the loss of calcium from the body and a corresponding drop in serum calcium. If the hypocalcemia is not corrected, the patient will eventually suffer from muscle cramps, twitching, and possibly seizures. As kidney cells cease to function, they are progressively less able to secrete phosphorus in the urine. An elevated serum phosphate level (hyperphosphatemia) serves to exaggerate the problem of inadequate calcium absorption; phosphate binds with calcium, decreasing its absorption from the intestinal tract. The patient is hypertensive from fluid overload, and body weight increases. Pulmonary edema and heart failure may occur. Metabolic changes occur, including triglyceride elevation and carbohydrate intolerance. Dietary protein is restricted in an attempt to decrease the waste products that the kidney can no longer handle; therefore serum protein decreases. Anemia is present because of decreased production of erythropoietin. Anorexia, nausea, and vomiting occur because of gastrointestinal mucosa irritation from waste products circulating in the blood. Constipation from drug therapy and fluid restriction is common. Patients may complain about restless leg syndrome, and the leg discomfort may interfere with sleep. When circulating wastes are increased, the nervous system cells become irritated, and the patient can become irritable and short-tempered. [Figure 34-3](#) shows the manifestations of uremia.

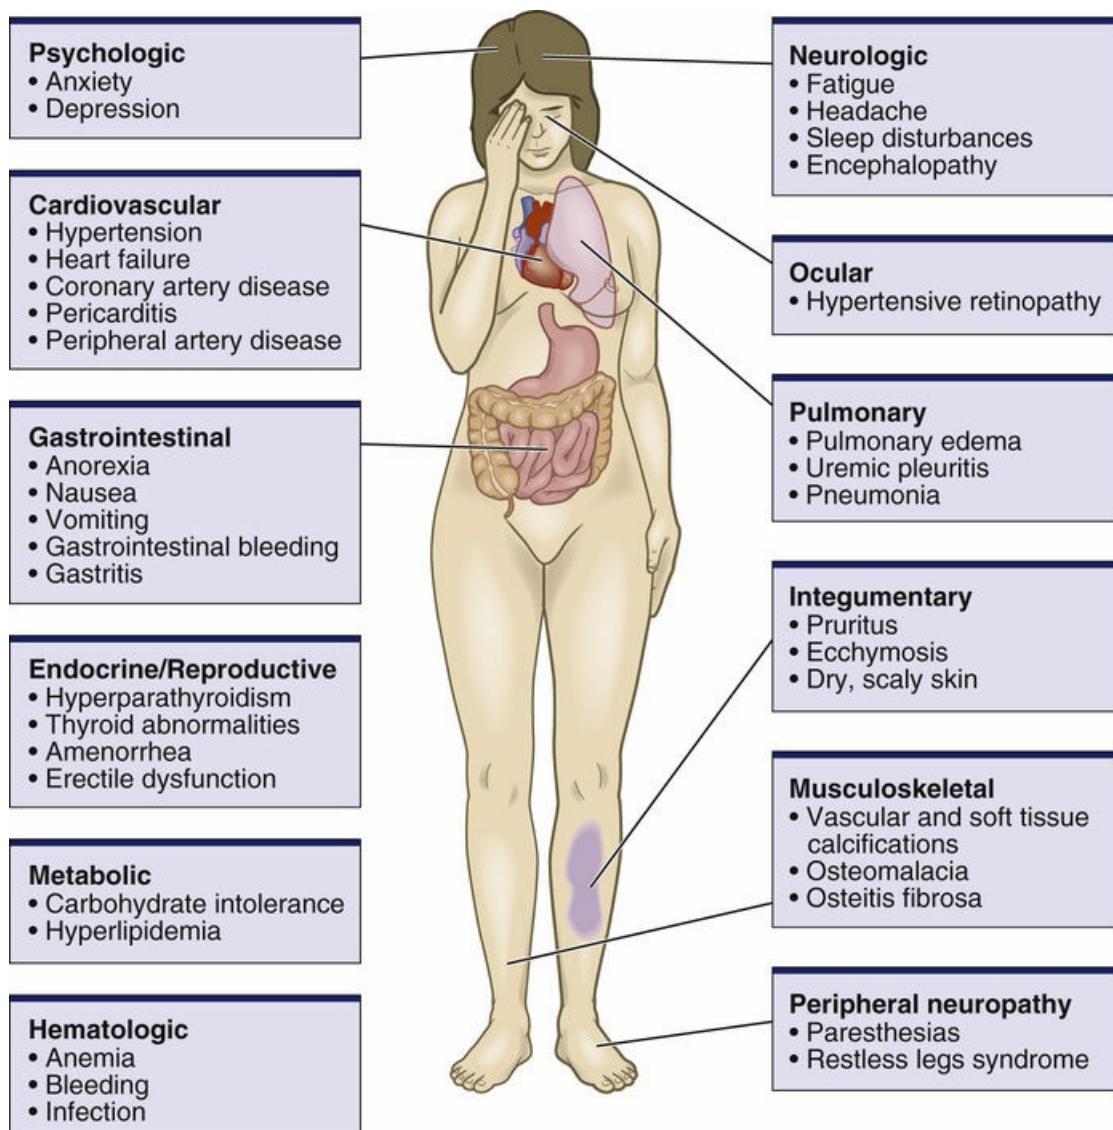

FIGURE 34-3 Systemic effects of uremia. (From Lewis SL, Dirksen SR, Heitkemper MM, et al: *Medical-surgical nursing: Assessment and management of clinical problems*, ed. 9, St. Louis, 2014, Mosby.)

Diagnosis

Creatinine is a stable by-product of skeletal muscle activity that is excreted completely by the kidneys; therefore creatinine clearance (CC) is a good measure of GFR. CC depends on the amount of blood passing through the kidney; narrowing of the renal arterioles, shock, or dehydration decreases the volume that is available to the kidney for filtration. CC is also affected by the functional abilities of the glomeruli. Urine is collected for a 24-hour period. Urinalysis with culture and sensitivity, hematocrit, and hemoglobin provide additional information. A renal ultrasound, renal scan, CT scan, and renal biopsy are additional diagnostic tests.

Treatment and Nursing Management

Medical treatment and nursing intervention include measures to correct fluid and electrolyte imbalance and acid-base imbalance. Decreasing protein in the diet of patients with beginning renal insufficiency may help slow the disease process. A variety of drugs, such as antacids, antihypertensives, antilipemics, epoetin alfa therapy, and vitamin and mineral supplements, are used to counteract the fluid and electrolyte imbalances, treat metabolic acidosis, and control the complications (Table 34-4). Diuretics are used while there is some remaining kidney function (renal insufficiency) but are not useful during ESRD. Inotropic agents, such as digitalis or dobutamine, are used in severe cases of heart failure. Antiseizure medications, such as phenytoin (Dilantin) or

diazepam (Valium), also may be needed, because uremic toxins can irritate the nervous system. Dialysis and kidney transplant are two major alternatives that offer hope for patients with ESRD. The Chronic Renal Insufficiency Cohort Study (CRIC) was initiated in 2001 to further the understanding of kidney disease and has published many discoveries ([National Institute of Diabetes, 2014](#)).

 **Table 34-4**

Common Drugs Used to Treat Chronic Renal Failure

CLASSIFICATION	ACTION	NURSING IMPLICATIONS	PATIENT TEACHING
Diuretics			
Furosemide (Lasix)	Promotes urine flow; rids body of excess fluid; used in early stages of chronic renal failure (CRF)	Potentially nephrotoxic and ototoxic. Strict I&O recording is necessary. Monitor laboratory values for blood dyscrasias. Side effects: vomiting, headache, constipation, and dizziness.	Report fever, sore throat, bleeding, bruising, difficulty swallowing, rash, or change in hearing.
Antihypertensives			
ACE inhibitors Enalapril (Vasotec)	Reduces angiotensin II and aldosterone, which decreases peripheral resistance and sodium reabsorption	Monitor for hypotension, blood dyscrasias, signs of infection, or bruising. African Americans have a higher incidence of angioedema (facial swelling, hoarseness), which can be fatal.	Immediately report cough, difficulty breathing, rash, tremors, blood in stool, or bleeding after brushing teeth. Report persistent dizziness or numbness and tingling.
Vitamins			
Calcitriol (Rocaltrol)	Active form of vitamin D	Monitor serum calcium; normal level 8.4–10.6 mEq/L. Monitor for hypocalcemia.	Report signs of hypocalcemia (e.g., twitching of mouth, numbness of fingers, laryngeal spasm, carpopedal spasm).
Folic acid and vitamin B ₁₂	For red blood cell formation	Give with food to promote absorption. Side effects not expected.	Store in dry, light-protected container.
Minerals			
Iron (ferrous sulfate)	Used to treat anemia	Give with water or juice to promote absorption. Do not give with milk products.	Take with food if gastric distress occurs. Sit upright for 30 min after taking. <i>Stool may turn black; this is a harmless side effect.</i>
Ferumoxytol (Feraheme)	Treats iron deficiency anemia of CRF	Administer by IV injection.	The most common adverse reactions include diarrhea, nausea, dizziness, hypotension, constipation, and peripheral edema.
Calcium Supplements			
Calcium carbonate	Prevents problems of calcium loss	Monitor serum calcium.	Constipation is a common side effect.
Calcium acetate (also binds phosphate)	Give with meals to bind phosphate	Monitor ECG changes for potential dysrhythmias.	Nausea, vomiting, drowsiness, or headache may occur.
Hematopoietic Growth Factors			
Epoetin alfa (EpoGen) Darbepoetin (Aranesp)	Treatment of anemia; promotes red blood cell formation	Can cause hypertension; monitor blood pressure. May need increased doses of heparin. Subcutaneous route is preferred.	Report nausea, vomiting, edema, fatigue, or chest pain.
Resins			
Sodium polystyrene (Kayexalate)	Treatment of hyperkalemia	Can be given mixed with food or in an enema. Monitor electrolytes. Side effects: nausea, vomiting, constipation, and anorexia.	Report any muscle weakness, irregular heartbeat, or stomach pain.

ACE, Angiotensin-converting enzyme; ECG, electrocardiogram; I&O, intake and output.

Renal dialysis.

Dialysis is indicated for acute renal failure or for renal insufficiency when diet, medications, and fluid restriction have failed. It may also be used for patients with ESRD, drug overdose, hyperkalemia, fluid overload, or metabolic acidosis ([Neligan, 2010](#)). Hemodialysis and peritoneal dialysis rely on diffusion to remove waste elements normally excreted in the urine. The principle of **diffusion** states that solute molecules that are in constant motion tend to pass through a semipermeable membrane from the side of higher concentration to the side of lower concentration.

Hemodialysis.

During hemodialysis, blood moves from the arterial circulation through a dialysate bath and back to the venous circulation. A dialysis membrane separates the blood from the dialyzing solution. The molecules of waste pass through this membrane out of the blood and into the dialyzing solution until the two solutions are equal in concentration ([Figure 34-4](#)).

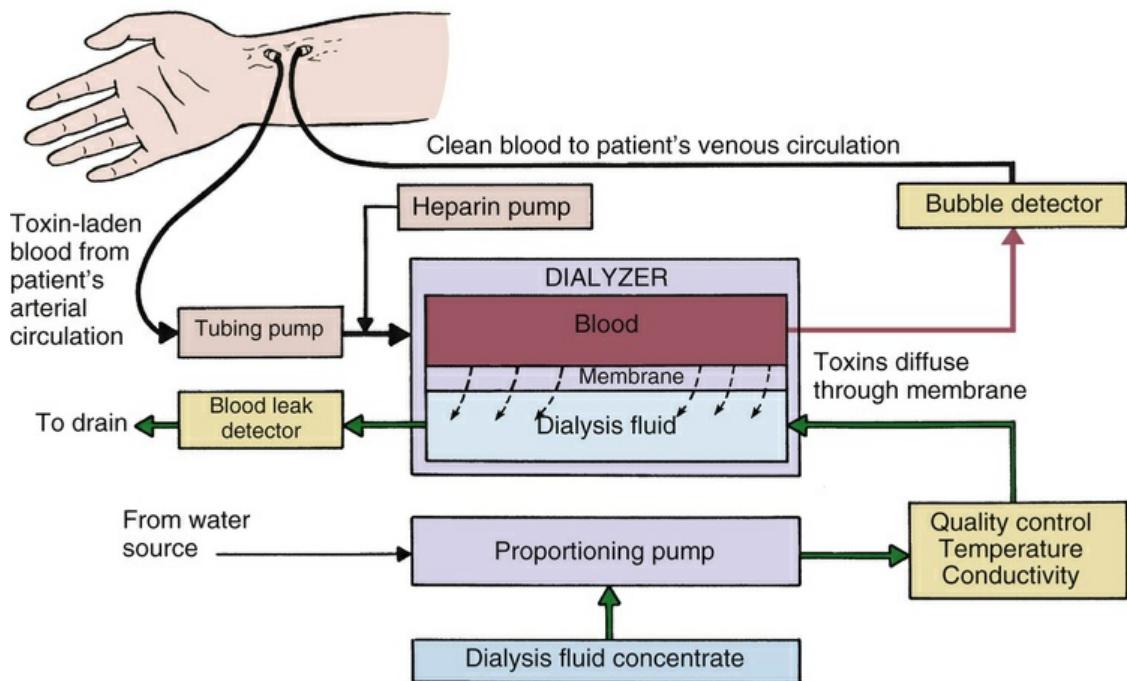

FIGURE 34-4 Hemodialysis. (From Black JM, Hawks JH: *Medical-surgical nursing: Clinical management for positive outcomes*, ed. 8, Philadelphia, 2009, Saunders.)

A temporary access for hemodialysis can be achieved by inserting a jugular or femoral vein dialysis catheter. The jugular site has a low incidence of thrombosis; it can be used for 1 to 3 weeks and is preferred over the femoral site. Only trained dialysis staff should use these temporary access sites for medication administration or blood draws.

Two kinds of internal access are used for ongoing hemodialysis. An arteriovenous fistula (AVF) is formed by joining an artery and a vein together (Figure 34-5, A). The vein is made into a large superficial vein with an arterial supply that is easily accessible by venipuncture. Typically the radial or brachial artery is joined to the cephalic vein in the arm. A period of 6 to 8 weeks after surgery is needed for the vessel walls to become thickened and usable for the repeated insertion of the hemodialysis needles. Although the AVF has fewer complications and better patency, it requires relatively healthy blood vessels; therefore patients with diabetes, prolonged IV drug use, or peripheral vascular disease may need an alternative access site.

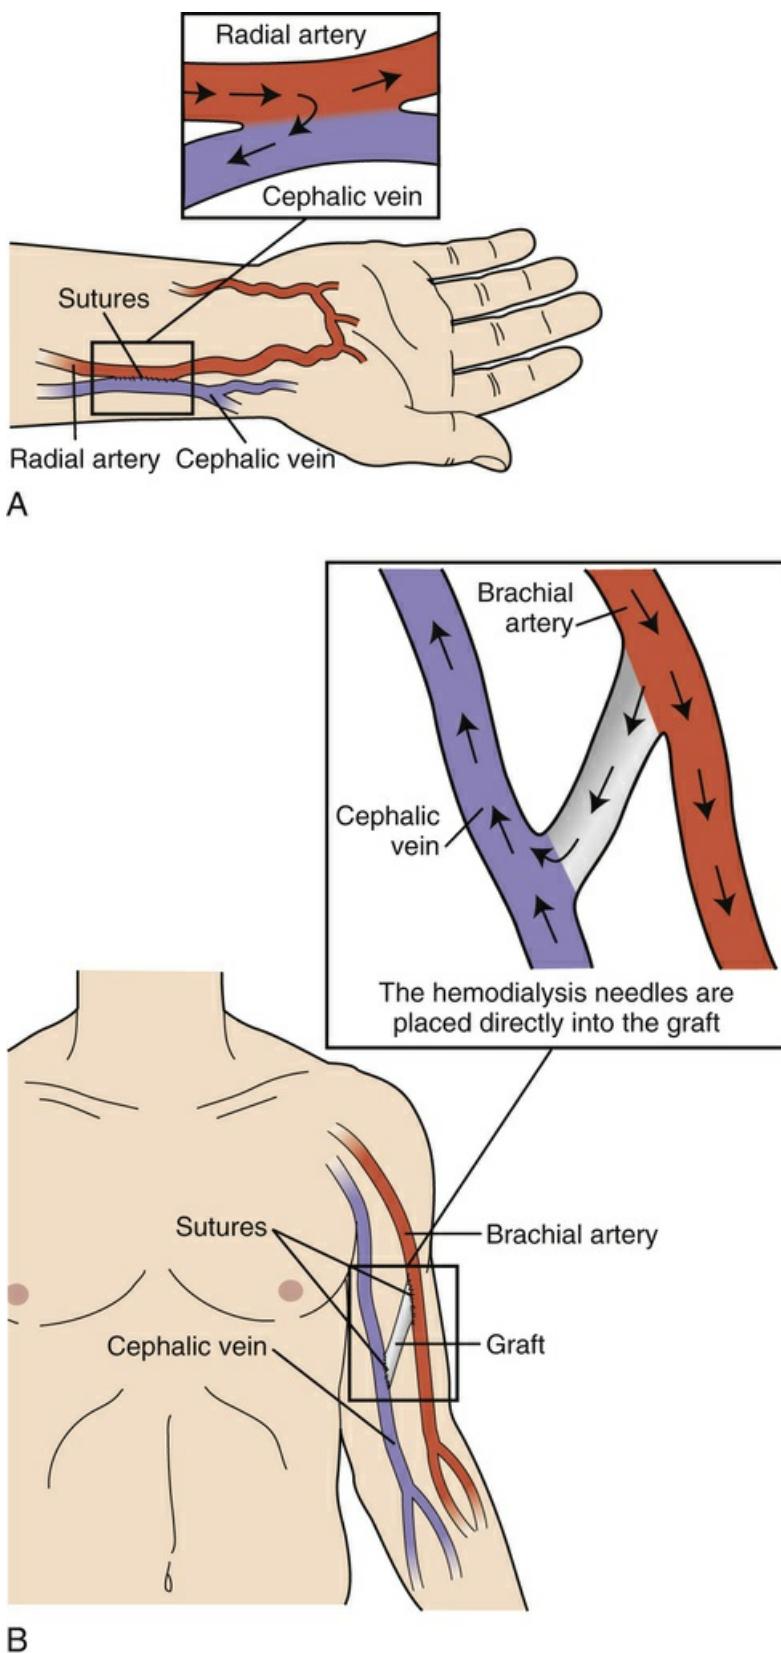

FIGURE 34-5 **A**, Arteriovenous fistula. **B**, Vascular graft access for long-term hemodialysis. (From Ignatavicius DD, Workman ML: *Medical-surgical nursing: Critical thinking for collaborative care*, ed. 7, Philadelphia, 2010, Saunders.)

The arteriovenous (AV) access is accomplished by connecting an artery and a vein with a graft of a piece of synthetic material. The hemodialysis needles are then placed directly into the graft (see Figure 34-5, B).

Clinical Cues

To assess for a bruit, gently auscultate the shunt with your stethoscope. You should hear an intermittent soft swishing sound that will correlate with the rhythm of the patient's pulse.

Medications commonly prescribed for patients undergoing dialysis include multivitamins, antacids, iron and calcium supplements, antihypertensives (especially angiotensin-converting enzyme [ACE] inhibitors), epoetin alfa, phosphate binders, and possibly anticonvulsants. Darbepoetin (Aranesp) is a newer and longer-acting form of erythropoietin therapy (see [Table 34-4](#)).

Complications.

A patient on hemodialysis may experience fluid overload, electrolyte imbalance, alterations in blood components leading to anemia, and platelet abnormalities that produce bleeding tendencies. Patients also may develop dialysis disequilibrium syndrome. This may occur because of a rapid decrease in fluid volume and is more likely after the first several treatments. Observe the patient for changes in mental status, headache, vomiting, or seizures. Be alert for cardiac dysrhythmias, signs of air emboli, or hemorrhage. Other major problems are systemic infections or localized infections at the access site.

Hepatitis C and acquired immunodeficiency syndrome (AIDS) are dangers because of blood access and risk of contamination. Patients who had multiple blood transfusions during the early to mid-1980s may have been exposed to the human immunodeficiency virus (HIV). (Hepatitis B is also possible but is less of a concern thanks to vaccination, antibody testing, and strict body fluid precautions. Patients and dialysis staff should receive hepatitis B vaccine.)

Nursing management.

When caring for a hospitalized patient who has an arteriovenous graft or an AVF, it is important to check the site and protect it from injury. The site should be observed at least four times a day for signs indicating clotting or infection, and the peripheral circulation distal to the graft should also be checked (capillary refill and color of nail beds). Palpate for a thrill (vibration in the vessel) by gently laying your fingers on the enlarged vessel. You should be able to feel a buzz or vibration. A **bruit** (soft swishing sound) should be clearly heard on auscultation, and the rhythm of the sound should coincide with the patient's pulse. When a graft has been inserted, the extremity is elevated postoperatively and kept at a level above the heart for 24 to 72 hours. Thereafter, the patient should sleep with that extremity free (i.e., not on the side with the arm tucked underneath the body). Care is taken never to compress the extremity containing the vascular access.

Clinical Cues

The arm or leg in which the arteriovenous shunt has been created should never be used for checking blood pressure or performing venipuncture (peripheral IV lines or blood draws). Post a sign above the bed to alert other members of the health care team.

Antihypertensive drugs are not given the morning of dialysis, because they can cause severe hypotension during the treatment. Nitroglycerin (NTG) patches, digitalis, and anticoagulants also are held. Consult with the dialysis nurse to coordinate the timing of medications. Before the patient goes to dialysis, do a physical assessment, check for bruit and thrill at the access site, and obtain a complete set of vital signs and a weight. These measurements will be compared with post-treatment results.

Patients undergoing hemodialysis will have considerable fluid volume shifts that affect homeostasis. Plan to assess these patient more frequently in the hours after dialysis treatment is completed. Postdialysis nursing care includes monitoring the access site for bleeding for 1 hour after the treatment. Assess the patient for signs of confusion or disorientation, hypotension, nausea or vomiting, headache, dizziness, or muscle cramps. Monitor and compare vital signs to pretreatment values and continue assessment of the access site for patency and signs of infection. **Invasive procedures are postponed for 4 to 6 hours after dialysis, because the clotting time is extended from the heparin used during dialysis, and prolonged bleeding could occur.**

The scheduling of hemodialysis sessions varies from patient to patient, but treatments usually are

done two or three times a week. Stable patients can be treated on an outpatient basis at a dialysis center.

Peritoneal dialysis.

Peritoneal dialysis is an alternative procedure that can be used instead of hemodialysis to remove waste products or toxins that have accumulated as a result of ARF or CRF. During peritoneal dialysis, dialyzing fluid that is equal in osmolality and similar in composition to normal body fluid is introduced into the peritoneal cavity via a Tenckhoff catheter by gravity or pump (Figure 34-6). Medications such as heparin, insulin, potassium, or antibiotics may be added to the solution. The solution is left in the peritoneal cavity for a specified time (dwell time) until the concentration of the solutions on either side of the peritoneal membrane is equalized.

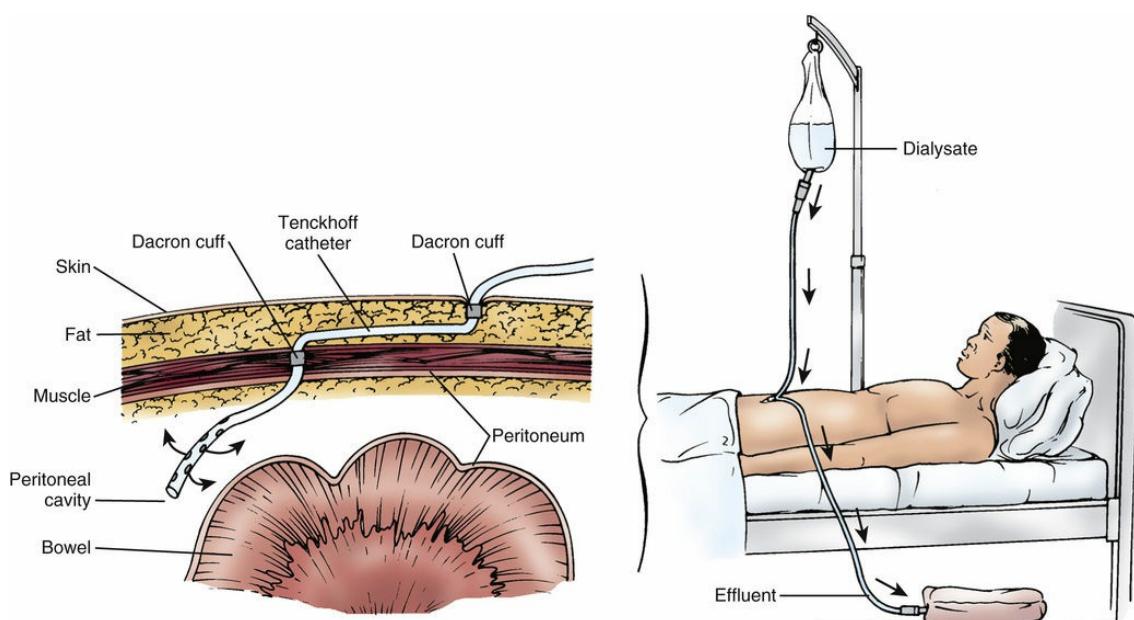

FIGURE 34-6 Peritoneal dialysis through an abdominal catheter. (From Ignatavicius DD, Workman ML: *Medical-surgical nursing: Critical thinking for collaborative care*, ed. 7, Philadelphia, 2010, Saunders.)

After the fluid is infused, the patient can move about during the dwell time. At the end of the dwell time, the dialysate solution containing waste products is drained from the abdominal cavity. The drainage should be colorless or straw-colored unless the catheter was recently inserted (the drainage may be bloody for the first several treatments).

Peritoneal dialysis has several advantages: (1) treatment can be started more quickly than hemodialysis, (2) anticoagulants are not necessary, (3) maturation of the access site and canalization of blood vessels is not required, (4) there is less stress on the cardiovascular system because fluid exchanges occur more slowly, and (5) some patients with renal failure fare better on a gentler therapy. Peritoneal dialysis cannot be done when there is severe trauma to the abdomen; after multiple abdominal surgeries; if there are adhesions in the abdominal cavity; or if the patient has a severe coagulation defect, paralytic ileus, or diffuse peritonitis.

There are several types of peritoneal dialysis. The basic principles are the same, but the dwell times, schedule of frequency, and use of a control pump versus gravity flow will vary. The first type is **continuous ambulatory peritoneal dialysis (CAPD)**. The CAPD process goes on 24 hours a day, 7 days a week. As a self-dialysis method, CAPD may be the easiest for the patient, and it requires no machinery. For CAPD, the bag of dialyzing solution is suspended above the level of the abdomen, and tubing is attached to the permanently implanted peritoneal dialysis catheter. The clamp on the CAPD tubing is opened and the dialysate solution is allowed to run into the abdomen by gravity flow. After the dwell time (4 to 8 hours), the fluid is drained. A second type is **nocturnal intermittent dialysis**, which is accomplished either with or without use of a control pump and is performed three to five times per week for 10 to 12 hours at night. This allows the patient to be free between treatment times. A third type, **continuous cycling peritoneal dialysis**, combines CAPD

with nocturnal intermittent dialysis for home use. An automated cycling machine allows the patient to do three exchanges at night while sleeping, then during the day there is one exchange, but the dwell time lasts all day long. The last type, **automated peritoneal dialysis**, is regulated by machinery and can be used in acute care settings, in clinics, and at home during the night.

Complications.

Potential complications of peritoneal dialysis include peritonitis, leakage, obstruction or other problems with the catheter, respiratory problems, and fluid overload or hypertriglyceridemia (disturbance of lipid metabolism).

Think Critically

What signs and symptoms might indicate that a patient undergoing peritoneal dialysis has peritonitis?

Nursing management.

Nursing care for a patient undergoing peritoneal dialysis includes obtaining the patient's weight before and after the treatment; maintaining careful I&O records; maintaining strict aseptic technique in handling the dialysate bags, peritoneal catheter, and all equipment; monitoring vital signs; observing for complications such as peritonitis; and keeping the patient as comfortable as possible. The dialysate solution should be at room temperature and must be instilled slowly. In accordance with National Patient Safety Goals, the patient and family are taught all the steps of the procedure before discharge, to ensure safety and prevent infection.

Kidney transplant.

An alternative to dialysis is to transplant a kidney from a blood relative of the patient, another tissue-compatible donor, or from a cadaver whose kidney tissue is compatible with that of the recipient.

Tissue typing to determine donor-recipient compatibility is performed, along with extensive psychological assessment and counseling for both the live donor and the recipient. Transplant candidates must be free from medical problems that might increase the risks of the procedure or jeopardize the success of the transplant. Malignancy, IV drug abuse, severe obesity, active vasculitis, and severe psychosocial problems eliminate some candidates.

Legal and Ethical Considerations

Organ Donation

There are 58 organ procurement organizations in the United States (HHS, 2015). Medicare, Medicaid, and The Joint Commission mandate that the local organ procurement organization (OPO) must be notified about brain death of a patient so that a well-trained representative of the OPO can evaluate the suitability of the potential donor and approach the family in a timely manner. Currently, research on increasing donation is being promoted, and grants are available ([U.S. Department of Health and Human Services, 2014](#)).

A significant factor in transplant therapy is the shortage of organs. In the United States more than 100,000 people are on the waiting list at any moment in time. Stable patients who are waiting for a transplant must live close to a transplant center and be ready immediately when an organ becomes available. Hypertension is brought under the best possible control, any infection is treated, and the patient is dialyzed immediately before transplantation. One of the *Healthy People 2020* goals is to increase the proportion of patients who receive a kidney transplant within 3 years after being put on the waiting list.

There are three types of immunosuppressive drugs to prevent organ rejection: (1) cytokine inhibitors (e.g., cyclosporine [Sandimmune], tacrolimus [Prograf]); (2) antiproliferative agents (e.g., azathioprine [Imuran]); and (3) antibodies (e.g., muromonab-CD3 [Orthoclone OKT3]). A recently approved drug is everolimus (Zortress), which inhibits the growth of cells that would ordinarily

contribute to rejection of the transplanted kidney (Clin-eGuide, 2010). Long-term problems for transplant patients are increased susceptibility to infection and a higher risk of malignancy.

Renal transplant patients are transferred to critical care or specialty units after surgery, where they are closely monitored for signs of rejection: fever, increased blood pressure, and pain over the iliac fossa where the new kidney was placed (Figure 34-7). Ongoing assessment includes watching for the signs of renal failure, particularly oliguria, anuria, and rising BUN levels and serum creatinine. Protection from sources of infection is a top priority. Once the new kidney is functioning properly, the primary provider may lift any previous dietary restrictions.

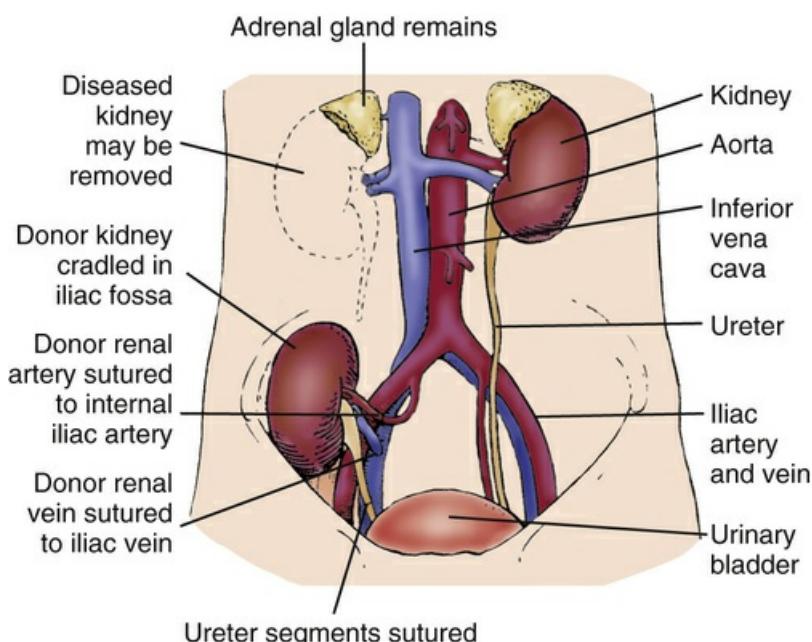

FIGURE 34-7 Placement of transplanted kidney. (From Black JM, Hawks JH: *Medical-surgical nursing: Clinical management for positive outcomes*, ed. 8, Philadelphia, 2009, Saunders.)

Renal failure and dialysis are very expensive for the patient and family. However, lack of funds does not exclude anyone from needed care. Since July 1973, an amendment to the Social Security Act allows Medicare to pay for most of the cost of treating ESRD, including dialysis and renal transplant. Medical expenses continue after transplant, because the drugs needed to prevent rejection are very expensive.

❖Nursing Management

■ Assessment (Data Collection)

The assessment findings will vary because of the slow but progressive development of kidney failure and the effect that kidney disease has on other body systems. Take a past medical history that includes medication, previous illness and surgeries, family history of illness, and a report of current complaints and concerns.

Perform a general head-to-toe assessment including complete vital signs and a baseline weight. Observe for changes and symptoms that include:

- Neurologic changes (e.g., lethargy or irritability)
- Cardiovascular abnormalities (e.g., dysrhythmias or hypertension)
- Respiratory abnormalities (e.g., shortness of breath or fluid in lungs)
- Gastrointestinal distress (e.g., nausea, vomiting, or constipation)
- Musculoskeletal discomfort (e.g., muscle cramps, twitching, or restless legs syndrome)
- Skin changes (e.g., itching or uremic frost)

Monitor BUN, serum creatinine, electrolytes, and urinalysis. As the disease progresses, assess for impaired urine concentration, decreased output, and anemia.

Clinical Cues

Although it is common to weigh patients in the morning with the same scale and the same amount of clothing, use your clinical judgment to initiate weights more frequently than once per day if needed. Watch for signs of fluid overload (e.g., facial or peripheral edema, shortness of breath, or crackles in lungs). One kilogram, or 2.2 lb, of weight gain is equal to approximately 1 L of fluid.

In addition, assess patients for sexual difficulties or concerns. Patients may experience medication side effects, such as impotence. Weight gain, peripheral edema, or presence of a shunt may alter body image or feelings of attractiveness. Fatigue caused by anemia or hormonal imbalance can result in decreased libido (sexual desire). Partners may fear that the patient is too ill to participate in sex or that the hemodialysis shunt will be damaged.

Clinical Cues

Help your patient to verbalize concerns about sexual problems by using a matter-of-fact approach (e.g., "Mr. Smith, have you or your partner noticed any changes in your sexual relations since you started your new medication?"). It is possible that you may not be able to directly solve the problem, but giving the patient the opportunity to talk about it is helpful. In addition, once you have assessed the problem, you can refer the patient to the appropriate resource if the problem is beyond your expertise (e.g., the provider may be able to change medication or the family may need psychological counseling).

Nursing Diagnosis

Patients with renal disease will have problems related to anemia, bleeding tendency, susceptibility to infection, nausea, vomiting, anorexia, gastrointestinal bleeding, and fluid overload that exacerbates conditions such as congestive heart failure. Examples of problem statements commonly associated with chronic renal disease and dialysis include:

- Altered nutrition due to dietary restrictions and loss of appetite.
- Fatigue due to anemia.
- Potential for infection from invasive procedures (e.g., dialysis shunt).
- Acute confusion due to accumulation of toxins.
- Altered sexual function due to stress and medication side effects.

Specific NANDA-I diagnoses can be chosen from the NANDA-I list (see inside back cover).

Examples of expected outcomes include:

- Patient will eat at least 50% of all meals during this shift.
- Patient will have adequate energy to independently perform ADLs before discharge.
- Patient will not have any signs or symptoms of infection (e.g., fever, redness, or swelling at shunt site) during hospitalization.
- Patient will demonstrate ability to make safe judgments (e.g., calls for help as needed) and orientation to person, place, and time before discharge.
- Patient will verbalize concerns or fears about sexual dysfunction.

Planning

In planning care for a patient with chronic renal disease, consider the stress of prolonged intensive treatment, the frustrations of dealing with an incurable illness, rigid dietary restrictions, fatigue, malaise, occasional limited mobility, and possibly sexual difficulties, all of which take their toll on both the patient and family. Consider the family's needs as well as the patient's when planning nursing intervention.

General nursing goals for care of patients with chronic renal disease include:

- Positive adaptation to therapeutic regimen (i.e., dietary and fluid modifications, dialysis)
- Maintaining fluid and electrolyte balance
- Prevention of complications
- Ensuring knowledge for appropriate self-care

- Assisting with resolution of body image disturbance
- Prevention of caregiver role strain and family dysfunction related to chronic illness

Think Critically

What kinds of behaviors would suggest caregiver role strain for the spouse of a patient who has CRF?

Implementation

Daily weight, measurement of I&O, determining the pattern of urination, and restricting fluid as ordered by the provider (generally calculated as intake of 500 to 700 mL plus the amount of output from previous 24 hours) are essential to the well-being of a patient with renal damage. In addition to these basic procedures, there should be ongoing monitoring of electrolytes, BUN, and creatinine. Hyperkalemia and a sodium imbalance will occur, as will hypocalcemia and hyperphosphatemia (see Chapter 3).

Because of the buildup of nitrogenous wastes from protein metabolism, restriction of protein intake is necessary; only high-quality protein foods (e.g., meat and eggs) are encouraged (Figure 34-8). Potassium is also restricted. Sodium intake often is restricted, especially if the patient is hypertensive. Previously, aluminum carbonate (Basaljel) was used as a phosphate binder; however, concern over elevated aluminum levels has prompted the use of calcium carbonate, which acts as a phosphate binder and a calcium supplement. The complexity of diet restrictions and modifications makes understanding and compliance very difficult for the patient and the family (Table 34-5).

THERE ARE TWO DIFFERENT TYPES OF PROTEIN		THE HEMODIALYSIS AND THE PERITONEAL MEMBRANE ARE NOT SELECTIVE, WHICH MEANS THAT VITAL AMINO ACIDS AND VITAMINS AS WELL AS UNWANTED WASTES ARE REMOVED			
One is called animal or high-biological protein, which contains ALL essential amino acids	The other type is vegetable or low-biological protein, which contains SOME amino acids	If you are on HEMODIALYSIS, you should aim for 1.2 g of protein per kg of body weight; e.g., if you weigh 65 kg (143 lb), your protein intake should be about 78 g/day	If you are on PERITONEAL DIALYSIS, you should aim for 1.3 g of protein per kg of body weight; e.g., if you weigh 70 kg (154 lb), your protein intake should be about 91 g/day		
EXAMPLES OF PROTEIN SOURCES					
3.5 oz of extra-lean ground beef has 24 g of protein, whereas ribeye has 28 g of protein	Half of a chicken breast (3.5 oz) has 29 g of protein, turkey white meat (3.5 oz) has 30 g of protein	One can of Ensure has 13 g of protein, whereas 1 scoop of Promod has 5 g, and one egg has 6 g of protein	15 large cooked shrimp have 17 g of protein; a 3 oz can of white tuna in water has 22 g of protein	One cup of milk has 8 g of protein, whereas 1/2 cup of regular tofu has 10 g, and one slice of white bread has 2 g of protein	One cup of cooked corn, peas, potato, pasta, or rice has about 4 g of protein

FIGURE 34-8 Tips for protein intake. (From Black JM, Hawks JH: *Medical-surgical nursing: Clinical management for positive outcomes*, ed. 8, Philadelphia, 2009, Saunders. Modified from Darlene Michl, Victoria, BC, Canada, www.personalhealthcoaching.ca.)

Table 34-5

Dietary Restrictions for a Patient With Renal Failure

DIETARY COMPONENT	WITH CHRONIC UREMIA	WITH HEMODIALYSIS	WITH PERITONEAL DIALYSIS
Protein	0.55-0.60 g/kg/day	1-1.5 g/kg/day	1.2-1.5 g/kg/day
Fluid	Depends on urinary output, but may be as high as 1500-3000 mL/day	500-700 mL/day plus amount of urinary output	Restriction based on fluid weight gain and blood pressure
Potassium	60-70 mEq/day	70 mEq/day	Usually no restriction
Sodium	1-3 g/day	2-4 g/day	Restriction based on fluid weight gain and blood pressure
Phosphorus	700 mg/day	700 mg/day	800 mg/day

Assess the patient's health status and learning needs throughout the illness and provide information to manage symptoms and prevent further damage whenever possible. The expertise of other professionals, especially nutritionists, is needed to help accomplish the goals of (1) minimizing uremic toxicity; (2) maintaining acceptable electrolyte levels; (3) controlling hypertension; (4) providing sufficient calories; and (5) maintaining good nutritional status.

Encourage communication between patient and spouse to elicit feelings about changes in sexual activity, role reversal, and family responsibilities. Patients with kidney failure commonly have self-care deficits that affect self-esteem and create an increased caregiver burden. Encourage the family to achieve a balance between supporting the patient and allowing as much independence as possible.

Communication

Noncompliant Hemodialysis Patient

John is a 48-year-old man who has end-stage renal disease and is on hemodialysis twice a week. He has not been compliant with his diet and fluid restrictions and has been increased to three dialysis treatments a week. He gained 5 lb over the weekend.

Nurse: "John, I see that you gained five pounds since Friday. Tell me about your weekend."

John: "I never have any fun or do normal things with my friends, so I went fishing with some buddies and we drank a lot of beer. We barbecued fish and some sausage. It was a real feast!"

Nurse: "How are you feeling today?"

John: "I feel rotten. I don't have any energy, and my thinking is slow. My legs are really swollen, and I'm having trouble breathing."

Nurse: "Do you think that might have something to do with the beer and food?"

John: "I suppose it does, but can't a guy have a little fun?"

Nurse: "John, I am concerned. You know that fluid and waste overload puts your whole body out of balance and causes damage in other organs. It's especially hard on the heart."

John: "Yeah, I know you've told me. It's just so hard. You don't understand what it is like."

Nurse: "You are right. I don't have kidney disease or the strict diet and fluid restrictions. I think it would be very difficult, but I would want to take care of myself for my family and friends."

John: "Well, you know that my wife left me and I don't see much of the kids, but I sure do enjoy my granddaughter. I really enjoy my times with the guys at the Lodge, too."

Nurse: "Do you have any friends who are in a similar situation who you can talk to?"

John: "No, none of my friends has kidney disease."

Nurse: "There is a young man who comes here for dialysis treatments who is always talking about fishing. Maybe the two of you could give each other some encouragement and support."

John: "Well, I don't know. I don't make new friends very easily."

Nurse: "He will be here on Wednesday. How about if we schedule your treatment for the same time? Perhaps you could get acquainted."

John: "O.K. That seems fine."

Nurse: "Next week we can talk again to see how you are doing with your diet, fluid restrictions, and medication schedule."

John: "Thanks. I will try to do better this week."

Clinical Cues

If a patient is somewhat resistant to listening to the nutritionist, support the diet teaching by showing enthusiasm and providing openings for the nutritionist to give the information. For example, the nurse says, "I'd be interested in hearing about the list of quality protein foods. This sample menu looks pretty good. Do you have more examples we could look at?"

Evaluation

For chronic renal failure, perform and compare data for daily physical assessments, weights, I&O, and laboratory reports. Monitor trends over a period of days to determine clinical improvement or the presence of problems. Daily fluctuations in subjective symptoms, such as fatigue or discomfort, along with ambivalent feelings toward the therapeutic regimen, are expected; however, if symptoms are prolonged or ongoing, the care plan should be revised. [Nursing Care Plan 34-1](#) includes problem statements/nursing diagnoses, interventions, and outcomes that are commonly used for patients with renal insufficiency and failure.

Think Critically

Your patient with CRF is withdrawn and sullen at times and is sharp and demanding at other times. How will you respond to this? How will you help the family deal with this behavior?

Nursing Care Plan 34-1

Care of a Patient With Chronic Renal Failure

Scenario

Mrs. Stevens, age 54 years, has had hypertension since her early 20s. She was diagnosed with chronic renal failure several years ago. Now she reports headaches, fatigue, and nausea. She states, "I have to sleep with three pillows and I am just exhausted." She feels that "her doctor is keeping something from her" and she is withdrawn and sullen. Tearfully, she reports, "The renal diet is so complex and my husband and son cannot manage the cooking and shopping." Her nephrologist conducted a series of diagnostic tests and recommended hemodialysis and eventual kidney transplant when an organ is available. Laboratory results include hematocrit 25%, hemoglobin 9 g/100 mL, BUN 48 mg/dL, and creatinine 3 mg/dL; admission weight: 137 lb ("normal weight around 130 lb"); 3+ pitting edema, bilateral feet and ankles.

Problem Statement/Nursing Diagnosis

Altered activity tolerance/*Activity intolerance related to anemia.*

Supporting Assessment Data

Subjective: "I am just exhausted."

Objective: Hematocrit 25%; hemoglobin 9 g/100 mL, appears tired.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will identify her activity limits for this shift.	Monitor for signs of weakness or increasing fatigue.	These signs and symptoms can signal a potential decreased RBC count and impaired oxygen-carrying capacity.	Able to independently perform basic hygienic needs this morning.
	Check vital signs for changes when activities appear stressful or overtaxing.	Marked increase in pulse or respiratory rate during routine ADLs suggests activity intolerance.	Reported feelings of fatigue and mild dyspnea after walking to the nurses' station. Vital signs at that time were BP 145/90, P 120, R 32/min. Repeat vitals after 30 min of rest: BP 140/80, P 85, R 20/min.
	Have patient use rating scale (scale 1/10) for different types of activities, such as walking to the bathroom or climbing the stairs.	The exertional scale (1/10) allows the patient (and the nurse) to rate and monitor performance and alter activities accordingly.	Ambulating in the hall was "too much"; reported an exertion level of 6/10.

	Adjust activities to allow for periods of rest.	Adequate rest facilitates recovery; activities can be increased or decreased according to the patient's level of tolerance.	Patient was assisted back to her room. Rested for 3 hr.
	Help visitors and patient to discuss what time of day and type of activities will fit the patient's current energy level (e.g., son could visit on Saturday morning and read a book with the patient).	Visitors need specific instructions to prevent overstimulating (or avoiding) the patient.	Patient's family agrees to come in midmorning hours and limit stay to 1 hr.
By discharge, patient will be able to perform ADLs independently without distress.	Assist with ADLs as required and keep personal articles within reach.	Patient's ability to do ADLs will wax and wane. Items close by and assistance as needed will help to conserve energy.	Able to independently comb hair and apply makeup when personal items are within easy reach.
Patient will demonstrate increased hematocrit value of 30% and increased hemoglobin of 11 g/100 mL.	Monitor for decreased hematocrit and hemoglobin values.	Normal range for hematocrit is 37%-47% (female). Normal range for hemoglobin is 12-16 g/dL (female).	7:00 A.M. Hematocrit: 24%; hemoglobin: 9 g/100 mL.
	Give epoetin and monitor for side effects (e.g., increased BP, dyspnea, chest pain, seizures, headaches, calf pain). Give iron, multivitamins, and folic acid as prescribed. Instruct about foods that supply iron (e.g., lean meat and vegetables) and folic acid (e.g., whole wheat bread).	Nutritional supplements and epoetin are given to help the body with RBC production.	Epoetin given subcutaneously, as prescribed. No adverse effects noted.
	Monitor infusions of packed RBCs, as ordered.	Transfusions may be needed if anemia is severe.	No transfusion ordered at this time. Outcomes partially met. Continue plan.

Problem Statement/Nursing Diagnosis

Loss of power/*Powerlessness related to perceived lack of information and stress of chronic illness.*

Supporting Assessment Data

Subjective: "Doctor is keeping something from me."

Objective: Appears withdrawn, sullen, and tearful.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will express feelings associated with chronic illness during this shift.	Encourage expression of feelings (e.g., frustration, anger).	Expression of feelings and beliefs allows the patient and the nurse to clarify how the situation affects behavior and decision making. Taking the time to listen also builds trust and rapport.	Patient stated that she was discouraged and depressed about her illness. Expresses anger toward her provider, because she thinks, "he is not telling the whole story."
	Encourage expression of beliefs about illness and outcomes.	Patient may experience strong feelings and may or may not be able to identify the source. The nurse may not be able to correct all situations, but just talking about the frustration will help some patients.	She "hates the idea of dialysis" and feels like it is "controlling her life."
	Observe for factors contributing to feelings (e.g., lack of information, loss of social roles) and correct if possible. Assist patient to identify factors that can and cannot be controlled.	Identifying factors that cannot be controlled allows the patient to realistically work on achievable goals.	Patient identified that knowing more about dialysis would be helpful.
Patient will participate in planning care and daily goals within 2-3 days.	Provide opportunities for patient to participate in activities that will increase sense of accomplishment (e.g., phoning for an appointment with social services).	A sense of accomplishment empowers the patient to act positively on own behalf.	Assisted patient in making a list of questions for her provider (e.g., "What are the steps for starting hemodialysis? How long can I live on dialysis?").
	Assist patient to identify small, achievable goals and to make realistic plans.	Small goals are more readily accomplished, and a feeling of success provides motivation to attempt larger goals.	Patient requested some written information about kidney transplantation and asked to speak to the transplant coordinator.
Patient will state hopes and plans for the future before discharge.	Emphasize that quality of life can be good for patients on dialysis (e.g., extends time to spend with friends and family).	Emphasizing positive outcomes can create a sense of hope and optimism.	She says that she is not optimistic about getting a donated kidney, but would still like to have the information and the hope that it could happen for her.
	Give positive reinforcement for statements of hope and future planning.	Positive reinforcement encourages repetition of a desirable behavior.	At the end of the shift, patient stated that making the list of questions and talking about her frustrations had helped. Outcomes partially met. Continue with plan.

Problem Statement/Nursing Diagnosis

Insufficient knowledge/*Deficient knowledge related to diet and nutrition.*

Supporting Assessment Data

Subjective: "The renal diet is so complex and my husband and son cannot manage the cooking and shopping."

Objective: Appears overwhelmed at the amount of information and seems unsure how to use it effectively.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will state willingness to learn about prescribed diet during this shift.	Assess readiness to learn, preferred learning styles, and barriers to learning.	Possible barriers for the patient include being upset, tired, uncomfortable, or anxious about her condition. Learning new information will be difficult under these conditions.	The patient identifies need for herself and her family to learn about her dietary restrictions. Patient also shows interest in attending a group class that will be conducted next month.
	Perform teaching in short sessions.	Complex information is best delivered in manageable pieces.	Limited teaching session to 10 min because of fatigue.
	Use language and terms that patient is able to understand.	Medical jargon and technical terms will not help the patient understand the basic dietary information.	Verbalized understanding of terminology related to health teaching (e.g., restricted protein).

With help, the patient will create a sample diet that is within renal diet parameters within 2-3 days.	Obtain a dietary consultation and reinforce information provided by the nutritional expert.	A renal nutritionist must be consulted to create an individual diet plan based on laboratory values, nutritional requirements, and patient's eating preferences.	Nutritionist came to see the patient and discussed overall nutritional goals and plan. Arrangements have been made with the nutritionist to meet with the family next week.
Patient will apply knowledge about diet and nutrition to reduce nitrogenous waste by-products and solute overload by next outpatient dialysis appointment.	Ensure that the patient has verbal and written instructions. Encourage expression of concerns (e.g., cost, preparation, availability of seasonal foods).	Written material can be reviewed at a later date and shared with family. Food commonly has a sociocultural base.	Written information was provided about diet and renal disease. Patient is concerned that family will need guidance in shopping.
	Invite the family (especially the person most likely to cook and shop) to attend the teaching sessions.	Costs, food preferences, and family participation should be considered to increase the likelihood of success.	Family will attend teaching session next week.
	Help patient review specific information about high-quality proteins (e.g., meat, eggs) and hidden sodium sources (e.g., canned food).	Reviewing information increases retention of new information.	The patient was able to identify high-quality protein foods but continues to be confused about how sodium, phosphorus, and calcium are affecting her kidney function. Follow-up teaching sessions will be arranged this week to address the topic. Outcomes partially met. Continue with plan.

Problem Statement/Nursing Diagnosis

Fluid volume excess/*Excess fluid volume related to retention of sodium and water from inadequate kidney function.*

Supporting Assessment Data

Subjective: "Sleeps with three pillows."

Objective: Admission weight: 137 lb (normal weight around 130 lb), 3+ pitting edema, bilateral feet and ankles.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will have restricted fluid intake (500-700 mL plus output from previous 24 hr) during this shift.	Strict I&O.	Discrepancies in I&O suggest fluid retention and overload.	Fluid intake 1000 mL, output 600 mL.
	Fluid restrictions, as ordered. Assist to establish acceptable schedule for restricted fluids.	Kidneys may produce a small but inadequate output of urine. Limiting fluid prevents overload, whereas spacing fluid throughout the day helps to relieve subjective feelings of thirst.	Patient is aware of and compliant with fluid restrictions.
	Assist with good oral care and discourage mouth breathing; rinse mouth frequently; space fluids throughout the day.	Patient's subjective feeling of moist oral mucous membranes will increase compliance with fluid restrictions.	Subjective relief obtained from frequent, small quantities of ice chips and periodic mouth care.
	Instruct patient and visitors about fluid restriction.	Visitors may unintentionally offer fluid as a comfort measure if they are uninformed about therapeutic goals.	Patient actively reminds all visitors and staff "not to tempt me."
	Post a sign over the bed to alert visitors and health care team members about fluid restrictions.	Many persons can pass through a patient's room, and all should be aware of precautions to prevent inadvertently offering restricted foods and fluids.	Sign placed above bed for fluid restrictions.
Patient will demonstrate signs of decreased fluid load (e.g., lungs will be clear to auscultation, foot and ankle edema will decrease) within 24-48 hr.	Check for signs of fluid overload: edema, crackles in lungs, orthopnea, and changes in mental status.	Peripheral fluid is observed in extremities and face. Edema within body organs (e.g., lungs or brain) manifests as functional impairment.	Fine crackles noted in base of posterior lung fields bilaterally. Reports some mild shortness of breath, especially with exertion or if lying flat in bed. Subjectively feels breathing is okay "when sitting in a chair." Resting pulse oximetry 94%. 3+ pitting edema noted bilaterally in feet.
Patient's weight will return to previous level within 10 days.	Weigh daily (or more frequently if needed) and monitor trends.	An increase in weight is one of the key indicators of fluid imbalance. 1 kg, or 2.2 lb, of weight gain is equal to excess of 1 L of fluid.	Patient's A.M. weight: 137.5 lb.
Patient will demonstrate minimal peripheral edema within 7-10 days.	Administer diuretic (e.g., hydrochlorothiazide) as prescribed.	Diuretics can be given in chronic renal function to reduce hypertension and edema; usually discontinued after dialysis is initiated.	Given: hydrochlorothiazide 100 mg. No adverse side effects noted.
	Restrict sodium to 2 g/day, as ordered.	Decreasing solute load decreases fluid retention.	Compliant with 2-g sodium diet. Outcomes partially met. Continue with plan.

Critical Thinking Questions

- What diagnostic tests do you think the nephrologist would have ordered for Mrs. Stevens?
- Why might Mrs. Stevens's renal disease not have been diagnosed earlier?
- If Mrs. Stevens does not agree to hemodialysis, what other alternatives are available to her?
- What concerns do you anticipate that Mr. Stevens and their son would have?

ADLs, Activities of daily living; *BP*, blood pressure; *I&O*, Intake and output; *P*, pulse; *R*, respirations; *RBC*, red blood cell.

Community Care

A major function of nurses in the community is to assist patients who have hypertension or diabetes patients to achieve good control of their disease to help prevent damage to the kidneys. One of the *Healthy People 2020* goals is to reduce the rate^② of new cases of ESRD. All nurses can promote healthy kidney function by encouraging the intake of more water and prompt recognition and treatment of urinary tract infections. In addition, nurses can participate in community education to increase awareness of organ donation programs.

Nurses in outpatient clinics assist with urologic procedures, such as cystoscopy and removal or destruction of renal stones. Clinic nurses will also have opportunities to teach patients how to manage problems of incontinence.

Home care nurses are constantly on the alert for signs of ARF or CRF among their patients. Many illnesses and the variety of drugs that these patients receive may cause kidney damage. Many home care patients have indwelling catheters that must be periodically replaced with new ones. Home health nurses also identify problems of incontinence and have the advantage of being able to see the environmental and social factors that must be addressed.

Nurses in long-term care facilities deal with a variety of urinary problems. Bladder training for incontinence is a prime consideration. Monitoring for drug toxicities in this population is imperative, because drugs are not excreted quickly, and polypharmacy can have additive effects. Keeping residents dry and odor free is very important for physical and psychological reasons. Monitoring for urinary retention or obstruction to the flow of urine is another priority in the older adult population.

Nurses who work in dialysis centers are typically the primary nurses for patients in renal failure. These nurses must constantly assess patients for complications, watch for medication-related problems, and continue to reinforce diet and lifestyle modifications. Considerable psychosocial support and counseling may be necessary, because patients undergoing dialysis commonly experience depression, hopelessness, sexual problems, role changes, and relationship problems.

Get Ready for the NCLEX® Examination!

Key Points

- Teach prevention of infectious disorders, such as cystitis and urethritis (e.g., good hygiene, drinking plenty of water, and seeking prompt treatment for genital discharge or dysuria).
- Symptoms of pyelonephritis include fever, chills, headache, malaise, nausea and vomiting, and pain in the flank radiating to the thigh and genitalia.
- Acute glomerulonephritis is characterized by fever, chills, flank pain, widespread edema, visual disturbances, and significant hypertension. Nursing implications include encouraging bed rest; low-protein and low-sodium diet; and administering antihypertensives, corticosteroids, and diuretics as prescribed.
- Symptoms of chronic glomerulonephritis include edema, dyspnea, and headache associated with hypertension.
- In hydronephrosis flow of urine from the kidney is obstructed; the kidney dilates and fills with fluid.
- In renal stenosis the renal artery becomes blocked or narrowed because of atherosclerosis.
- Renal stones are associated with frequent urinary infections, inadequate fluid intake and concentrated urine, urinary stasis, and urate in the urine.
- Symptoms of trauma to the kidneys, ureters, and bladder may include gross hematuria, pain, or an enlarged mass in the renal or bladder area.
- Risk factors for cancer of the bladder include male gender, smoking, and exposure to industrial toxins.
- Major symptoms of cancer of the kidney include hematuria and enlargement of affected kidney.
- Prerenal ARF is caused by decreased blood flow; intrarenal ARF occurs from damage in the kidney; and postrenal ARF is caused by obstruction that causes backup of urine into the kidney.
- ATN can be caused by decreased oxygenation or blood flow or nephrotoxic substances.
- The three phases of ARF are oliguric/nonoliguric, diuretic, and recovery.
- Nephrosclerosis (hardening of renal arterioles), glomerulonephritis, and diabetic nephropathy are the most common causes of CRF.
- Treatment of CRF includes diet management, fluid and electrolyte management, hemodialysis, or peritoneal dialysis and kidney transplant.
- Hemodialysis is the use of diffusion to remove waste products normally excreted by the kidneys. Complications include fluid overload, electrolyte imbalance, anemia, platelet abnormalities, and infection.
- Nursing implications for peritoneal dialysis are to weigh the patient and take vital signs before and after treatment, measure I&O, use strict aseptic technique, and monitor for infection.
- Kidney transplant is another treatment for kidney failure. Signs of organ rejection include elevated blood pressure, fever, pain over the transplant area, fatigue, oliguria, and increased BUN and serum creatinine.

Review Questions for the NCLEX® Examination

1. Which patient statement indicates that she needs additional teaching regarding the discharge instructions for urinary tract infection?

1. "I will always wipe from back to front after a bowel movement."
2. "I should avoid wearing tight slacks."
3. "I won't wash my underclothing with strong detergents."
4. "I will take a shower instead of a tub bath."

NCLEX Client Need: Health Promotion and Maintenance

2. A patient with a history of throat infection becomes suddenly ill with fever, chills, flank pain, widespread edema, puffiness around the eyes, visual disturbances, and marked hypertension. The nurse would anticipate which diagnostic test?

1. Urinalysis
2. Intravenous pyelogram
3. Serum amylase
4. Prothrombin time

NCLEX Client Need: Physiological Integrity: Basic Care and Comfort

3. A patient with nephrotic syndrome is admitted with severe generalized edema, ascites, and cloudy urine. The patient is irritable and tired. What is the priority nursing problem?

1. Potential for infection
2. Fluid volume excess
3. Pain
4. Fatigue

NCLEX Client Need: Physiological Integrity: Basic Comfort and Care

4. A 45-year-old man has a history of calcium oxalate stones which can result in further renal calculi. What should you include about diet in this patient's education?

1. He should increase his protein intake, but restrict dietary calcium and sodium.

2. He should increase intake of spinach and nuts.
3. He should increase fluids and dietary calcium.
4. He should increase sodium, but decrease protein intake.

NCLEX Client Need: Health Promotion and Maintenance

5. While caring for a patient who has received ESWL (lithotripsy) for renal calculi, the nurse would anticipate what possible actions that may be taken to help the patient increase the rate of stone passage? (*Select all that apply.*)

1. Performance of PDI therapy
2. Administration of corticosteroids and calcium channel blockers and alpha antagonists, as prescribed
3. Administration of Vicodin for pain
4. Cystoscopy to retrieve the stones

NCLEX Client Need: Physiological Integrity: Basic Care and Comfort; Pharmacological Therapies

6. A nurse is assisting in administering BCG intravesically to a patient with bladder cancer. Place the steps in the correct order to accomplish this procedure.

1. Clamp the urethral catheter for 2 hours.
2. Change position every 15 to 30 minutes.
3. Aseptically insert a urinary catheter.
4. Drain urinary bladder.
5. Instill the BCG fluid.

NCLEX Client Need: Safe and Effective Care Environment

7. A patient with CRF has a BUN of 120 mg/dL. What is the primary significance of this laboratory value?

1. It is an expected laboratory result for a patient with CRF.
2. The value signifies renal insufficiency.

3. The result in conjunction with uremic signs indicates need for dialysis.
4. The patient should be referred as a good candidate for peritoneal dialysis.

NCLEX Client Need: Physiological Integrity: Basic Comfort and Care

8. What is included in the nursing care of a patient undergoing peritoneal dialysis? (*Select all that apply.*)

1. Maintain aseptic technique when accessing a peritoneal catheter.
2. Instruct the patient to remain supine until the dialysate is drained.
3. Weigh the patient before and after dialysis.
4. Monitor vital signs.
5. Check color and volume of effluent.

NCLEX Client Need: Safe and Effective Care Environment

9. A nurse is sending a patient to the dialysis clinic. What predialysis nursing intervention should be included? (*Select all that apply.*)

1. Withholding anticoagulants
2. Administering antihypertensive
3. Assessing dialysis access site
4. Checking vital signs
5. Monitoring laboratory values

NCLEX Client Need: Safe and Effective Care Environment

10. A patient with CRF is on dialysis and waiting for a kidney transplant. The patient says, "I am never going to be at the top of the list for a kidney. I wish I could just die and get it over with." What is the most therapeutic response?

1. "I am sure you are going to get a kidney. A lot of people donate these days."

2. "Are you thinking about hurting or killing yourself?"
3. "I would be discouraged too, but I have never been very good at waiting."
4. "You seem really down today. What's going on?"

NCLEX Client Need: Psychological Integrity

Critical Thinking Questions

Scenario A

Mr. Jakes, 25 years old, complains of sudden onset of fever and chills, flank pain, and "feeling full all over and peeing dark smoke-colored urine." He tells you he had strep throat 2 weeks ago, but is otherwise healthy.

1. Based on Mr. Jakes's history and complaints, what physical assessments should you perform?
2. Why is the history of strep throat 2 weeks ago significant?
3. The provider informs Mr. Jakes that he has glomerulonephritis and prescribes complete bed rest. How long must bed rest continue?

Scenario B

Mr. Mell, a 43-year-old interstate truck driver, complains of severe right lower back pain with nausea, vomiting, and pink-tinged urine. He relates a history of stones and reports, "It always feels like this until the kidney stone passes." The provider orders IV normal saline, morphine, routine laboratory tests to include BUN and creatinine, and an IVP.

1. What are three or four risk factors for kidney stones that might apply to Mr. Mell?
2. His BUN result is 17 mg/dL. What does this result indicate? What is your responsibility in reporting this data?
3. What is the care for Mr. Mell after a lithotripsy?

Scenario C

Mrs. Diaz, 35 years old, has had a nephrostomy for treatment of hydronephrosis caused by a renal stone in the pelvis of the kidney. She returns from the surgical unit with a nephrostomy tube, a urethral catheter, and a rubber Penrose drain in place.

1. Explain the purpose of the nephrostomy tube.
2. What is the specific care for these drains and tubes?

UNIT XII

Endocrine System

OUTLINE

Chapter 35 The Endocrine System

Chapter 36 Care of Patients With Pituitary, Thyroid, Parathyroid, and Adrenal Disorders

Chapter 37 Care of Patients With Diabetes and Hypoglycemia

CHAPTER 35

The Endocrine System

Objectives

Theory

1. Identify the location of each endocrine gland.
2. Diagram the principal actions and target tissues for hormones of the hypothalamus and pituitary, parathyroid, adrenal, and pancreas glands.
3. Summarize the effects of the thyroid hormones.
4. Compare care for common diagnostic tests for the endocrine system.

Clinical Practice

5. Assess for specific age-related changes of the endocrine system in an older adult.
6. Teach patients about the diagnostic tests that might be performed for symptoms of endocrine disorders.
7. Perform a focused assessment on a patient who may have an endocrine disorder.
8. Distinguish appropriate problem statements/nursing diagnoses and interventions for problems common to patients with endocrine disorders.

KEY TERMS

adenohypophysis (ă-DEN-o-hī-POF-ă-sis, p. 821)
adrenocorticotropic hormone (ă-DREN-o-KOR-ti-kō-TRŌ-pik HŌR-mōn, p. 826)
endocrine (EN-do-krin, p. 826)
exocrine (Ek-so-krin, p. 826)
fructosamine assay (FRÜK-tōs-ăm-ēn ĂS-sā, p. 832)
glucocorticoids (glü-kō-KOR-ti-koydz, p. 825)
glucose tolerance test (GLŪ-cōs TÖL-ĕr-ĕns, p. 831)
hemoglobin A_{1c} (A_{1c}) (HĒ-mō-glō-bin, p. 831)
hormones (HOR-mōnz, p. 822)
hypersecretion (hī-per-SE-KRĒ-shun, p. 827)
hyposecretion (hī-pō-SE-KRĒ-shun, p. 827)
insulin (IN-sū-lin, p. 826)
mineralocorticoids (min-er-ăl-ō-KOR-ti-koydz, p. 825)
negative feedback (p. 827)
parathormone (pär-ă-THOR-mōn, p. 824)
pressor (PRĒS-sör, p. 825)
target cells (p. 827)
target tissues (p. 827)
thyrocalcitonin (thī-rō-KÄL-si-TŌ-nin, p. 824)

thyroid panel (THĪ-royd, p. 828)

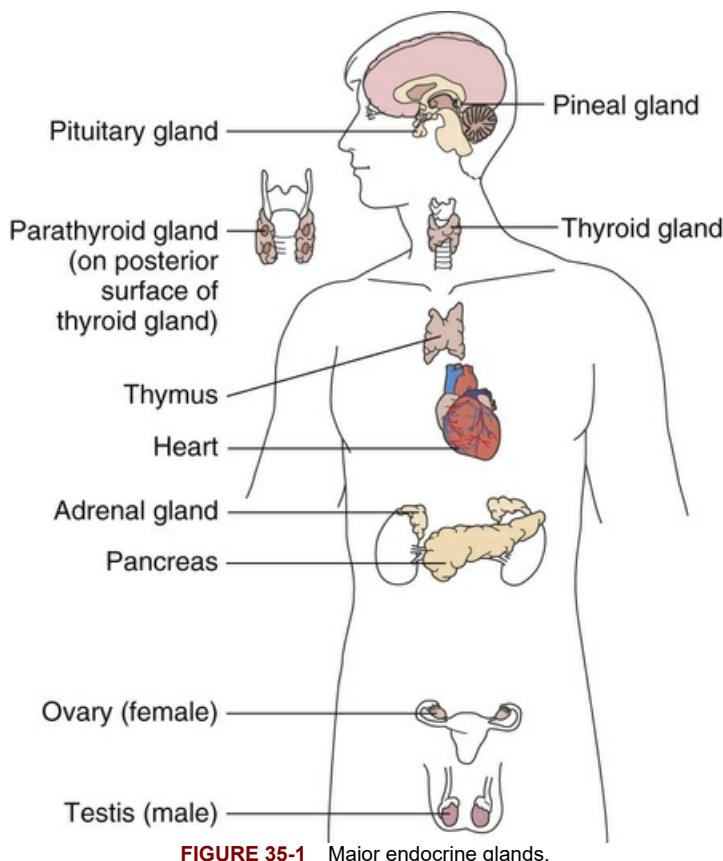

thyroxine (THĪ-rok-sin, p. 824)

triiodothyronine (trī-ī-dō-THĪ-rō-nen, p. 824)

Anatomy and Physiology of the Endocrine System

Organs and Structures of the Endocrine System (Figure 35-1)

- The pituitary gland connects to the hypothalamus via the hypophyseal stalk. The pituitary gland has two parts: the anterior pituitary (**adenohypophysis**) and the posterior pituitary (neurohypophysis).
- The thyroid gland has two lobes and lies below the larynx over the thyroid cartilage, in front of and on either side of the trachea.
- The parathyroid glands are four to six small glands that are located on the posterior surface of the thyroid gland.
- The adrenal glands are located on the anterior upper surface of each kidney; each is composed of the cortex and medulla.
- The pancreas sits in the upper left aspect of the abdominal cavity. Beta cells, which secrete the hormone insulin, and alpha cells, which secrete the hormone glucagon, are both found in the islets of Langerhans.
- The ovaries are located in the pelvic cavity in females.
- The testes hang suspended in the scrotum in males.
- The pineal gland is in the midbrain, in the cranial vault.
- The thymus gland lies at the base of the neck, in the front of the thoracic cavity.

Functions of the Endocrine System

- When the muscle is stretched the heart secretes hormones with a diuretic effect.
- The endocrine system alters chemical reactions and controls the rate at which chemical activities take place within cells.
- The hormones secreted change the permeability of cell membranes and select the substances that can be transported across cell membranes.
- The endocrine hormones activate a particular mechanism in a cell, such as the system that controls cellular growth and reproduction. The **hormones** produced by the endocrine system, the target organs on which they act, and the principal actions of each hormone are presented in [Table 35-1](#).

Table 35-1
The Principal Endocrine Glands and Their Hormones

Gland	Hormone	Target Tissue	Principal Actions
Hypothalamus	Releasing and inhibiting hormones	Anterior lobe of pituitary gland	Stimulates or inhibits secretion of specific hormones
Anterior lobe of pituitary	Growth hormone (GH)	Most tissues in the body	Stimulates growth by promoting protein synthesis
	Thyroid-stimulating hormone (TSH)	Thyroid gland	Increases secretion of thyroid hormone; increases the size of the thyroid gland
	Adrenocorticotrophic hormone (ACTH)	Adrenal cortex	Increases secretion of adrenocortical hormones, especially glucocorticoids, such as cortisol
	Follicle-stimulating hormone (FSH)	Ovarian follicles in females; seminiferous tubules in males	Follicle maturation and estrogen secretion in females; spermatogenesis in males
	Luteinizing hormone (LH); called interstitial cell-stimulating hormone (ICSH) in males	Ovary in females, testis in males	Ovulation, progesterone production in females; testosterone production in males
Prolactin		Mammary gland	Stimulates milk production
Posterior lobe of pituitary (storage only; ADH and oxytocin are synthesized in the hypothalamus)	Antidiuretic hormone (ADH)	Kidney	Increases water reabsorption (decreases water lost in urine)
	Oxytocin	Uterus; mammary gland	Increases uterine contractions; stimulates ejection of milk from mammary gland
Thyroid gland	Thyroxine and triiodothyronine	Most body cells	Increases metabolic rate; essential for normal growth and development
	Calcitonin	Primarily bone	Decreases blood calcium by inhibiting bone breakdown and release of calcium; antagonistic to parathyroid hormone
Parathyroid gland	Parathyroid hormone (PTH) or parathormone	Bone, kidney, digestive tract	Increases blood calcium by stimulating bone breakdown and release of calcium; increases calcium absorption in the digestive tract; decreases calcium lost in urine
Adrenal cortex	Mineralocorticoids (aldosterone)	Kidney	Increases sodium reabsorption and potassium excretion in kidney tubules; increases water retention
	Glucocorticoids (cortisol)	Most body tissues	Increases blood glucose levels; inhibits inflammation and immune response
	Androgens and estrogens	Most body tissues	Secreted in small amounts; effect is generally masked by hormones from ovaries or testes
Adrenal medulla	Epinephrine, norepinephrine	Heart, blood vessels, liver, adipose tissue	Helps cope with stress; increases heart rate and blood pressure; increases blood flow to skeletal muscle; increases blood glucose
Pancreas (islets of Langerhans)	Glucagon	Liver	Increases breakdown of glycogen to increase blood glucose levels
	Insulin	General, but especially liver, skeletal muscle, adipose tissue	Decreases blood glucose levels by facilitating uptake and utilization of glucose by cells; stimulates glucose storage as glycogen and production of adipose tissue
Testes	Testosterone	Most body cells	Maturation and maintenance of male reproductive organs and secondary sex characteristics
Ovaries	Estrogens	Most body cells	Maturation and maintenance of female reproductive organs and secondary sex characteristics; menstrual cycle
	Progesterone	Uterus and breast	Prepares uterus for pregnancy; stimulates development of mammary gland; regulates menstrual cycle
Pineal gland	Melatonin	Hypothalamus	Inhibits gonadotropin-releasing hormone, thus inhibiting reproductive functions; regulates sleep and wakefulness
Thymus	Thymosin	Tissues involved in immune response	Immune system development and function

Effects of the Pituitary Hormones

- The effects of pituitary hormones when secreted are illustrated in [Figure 35-2](#).

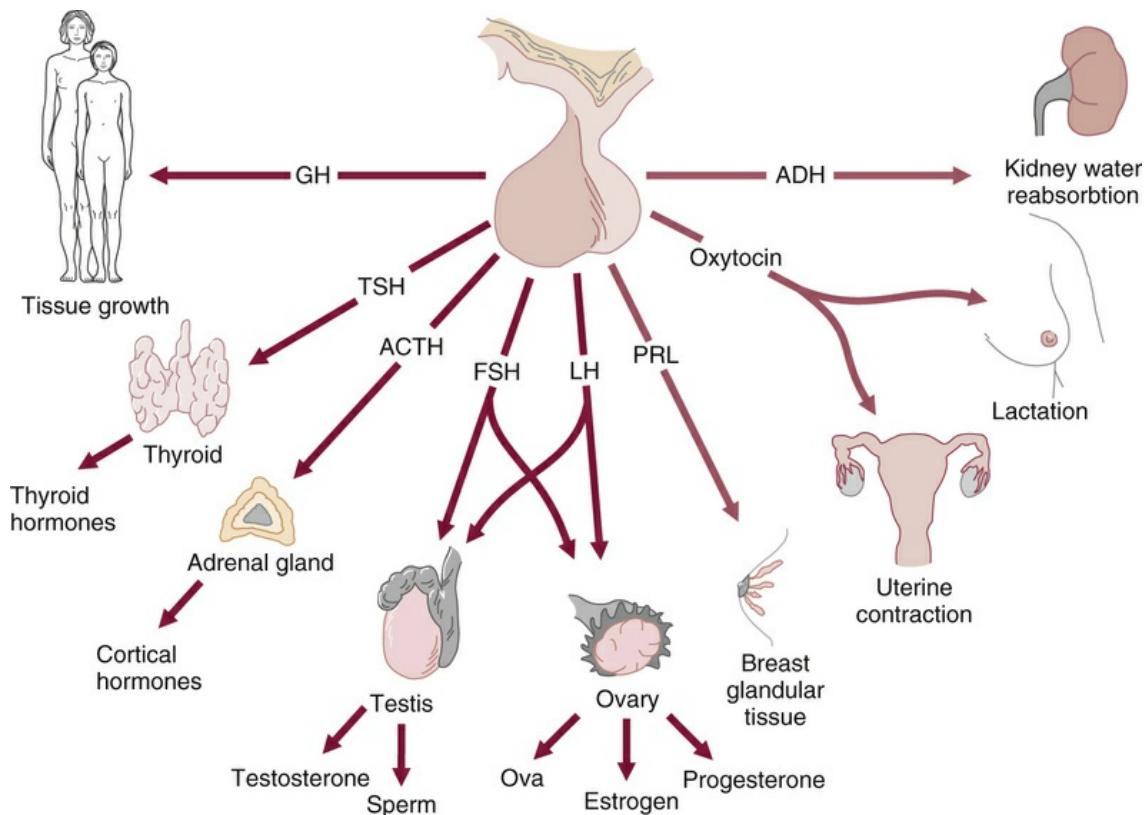

FIGURE 35-2 Effects of hormones from the pituitary gland. ACTH, Adrenocorticotrophic hormone; ADH, antidiuretic hormone; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinizing hormone; PRL, prolactin; TSH, thyroid-stimulating hormone.

- Any type of dysfunction of the pituitary gland will affect one or more of the hormones, as well as their target organs (Figure 35-3).

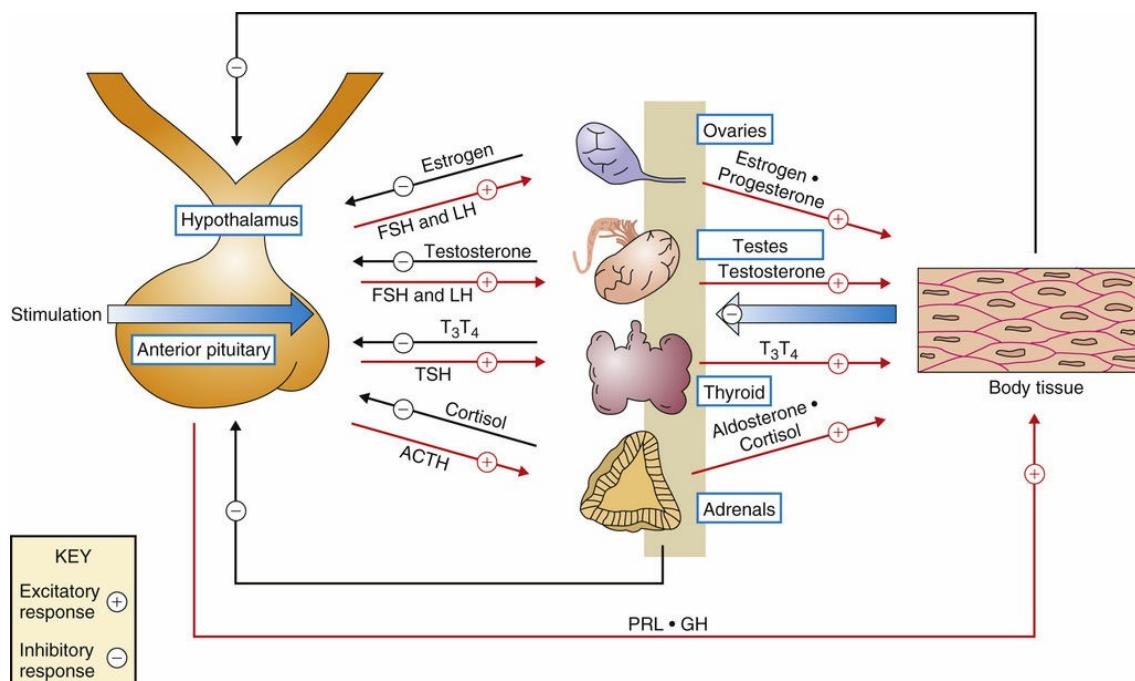

FIGURE 35-3 Feedback system of the hypothalamus, pituitary, and target glands. ACTH, Adrenocorticotrophic hormone; FSH, follicle-stimulating hormone; LH, luteinizing hormone; T_3 , triiodothyronine; T_4 , thyroxine; TSH, thyroid-stimulating hormone. (From Ignatavicius DD, Workman ML, Mishler MA: *Medical-surgical nursing: A nursing process approach*, ed. 3, Philadelphia, 1999, Saunders.)

Effects of the Thyroid Hormones

- The thyroid gland secretes the hormones **thyroxine** (T_4), **triiodothyronine** (T_3), and **thyrocalcitonin**. The 3 and the 4 indicate how many iodine atoms are attached.
- T_3 is the more potent form of thyroid hormone. T_4 is converted to T_3 by removing an iodine from the T_4 molecule.
- Intake of protein and iodine is needed to synthesize both thyroid hormones.
- Thyroid hormones activate the cellular production of heat; stimulate protein and lipid synthesis, mobilization, and degradation (breakdown); and stimulate the manufacture of coenzymes from vitamins.
- Thyroid hormones regulate many aspects of carbohydrate metabolism and affect tissue response to epinephrine and norepinephrine.

Functions of the Parathyroid Glands

- Parathormone**, or **parathyroid hormone**, is produced and secreted by the parathyroid glands.
- A low calcium level will stimulate release of parathormone, which increases the plasma level of calcium. A high calcium level will inhibit the release of parathormone.
- Parathormone acts on the renal tubules to increase the excretion of phosphorus in the urine and to stimulate the reabsorption of calcium. It also stimulates the production of the active form of vitamin D, which enhances calcium absorption in the small intestine. Parathormone also acts on bone, causing the release of calcium from the bone into the bloodstream.
- Calcitonin (released by the thyroid gland) is the balance to parathormone that causes calcium to go into the bones and allows for renal excretion to reduce calcium levels in the blood.

Safety Alert

Parathyroid Deficiency

A deficiency of parathyroid hormone produces muscle cramps, twitching of the muscles, and, in some cases, severe convulsions because of hypocalcemia.

Functions of the Adrenal Gland Hormones

- The adrenal medulla (middle portion) secretes two hormones, epinephrine and norepinephrine (called catecholamines), in response to stimulation from the sympathetic nervous system.
- Epinephrine prepares the body to meet stress or emergency situations and prevents hypoglycemia (Figure 35-4). Norepinephrine functions as a **pressor** (causing blood vessel constriction) to maintain blood pressure.

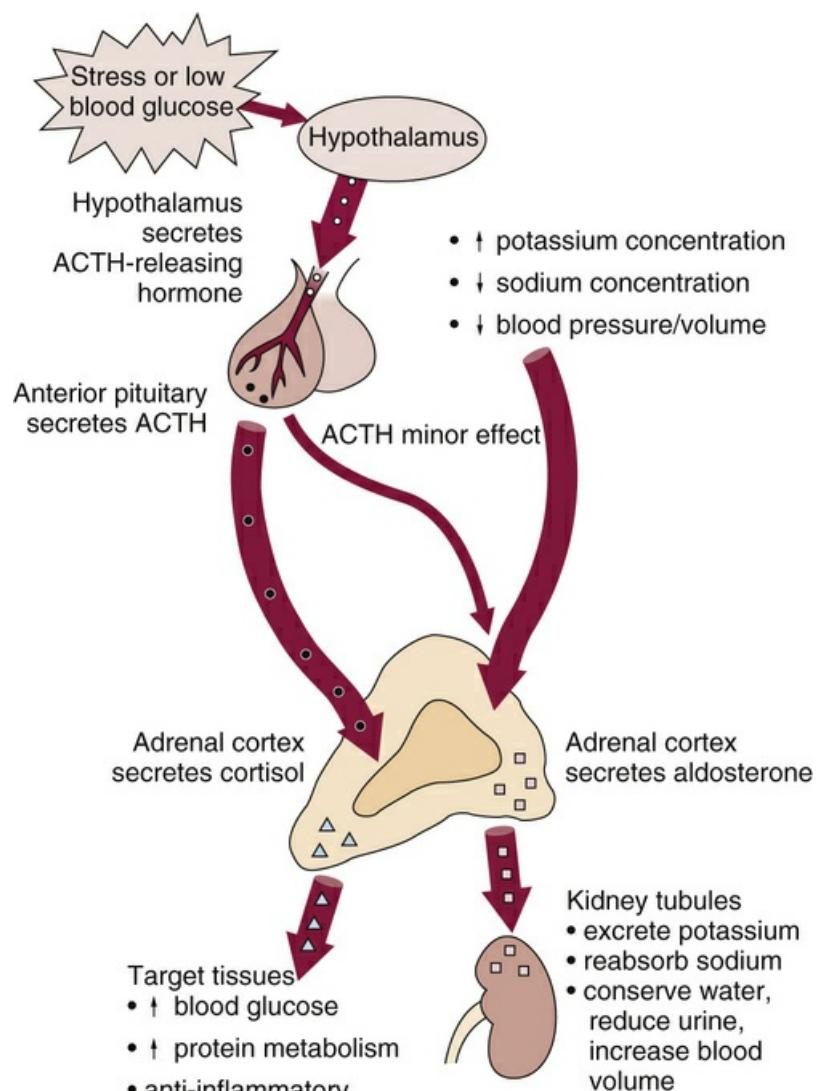

FIGURE 35-4 Effects of epinephrine and control of its secretion. (From Applegate E: *The anatomy and physiology learning system*, ed. 4, Philadelphia, 2011, Saunders.)

- The hormones secreted by the adrenal cortex are called *adrenal corticosteroids*. (The word *steroid* is sometimes used to designate an adrenal corticosteroid or a synthetic compound with similar properties.)
- The two major types of hormones secreted by the adrenal cortex are the mineralocorticoids and the glucocorticoids ([Figure 35-5](#)).

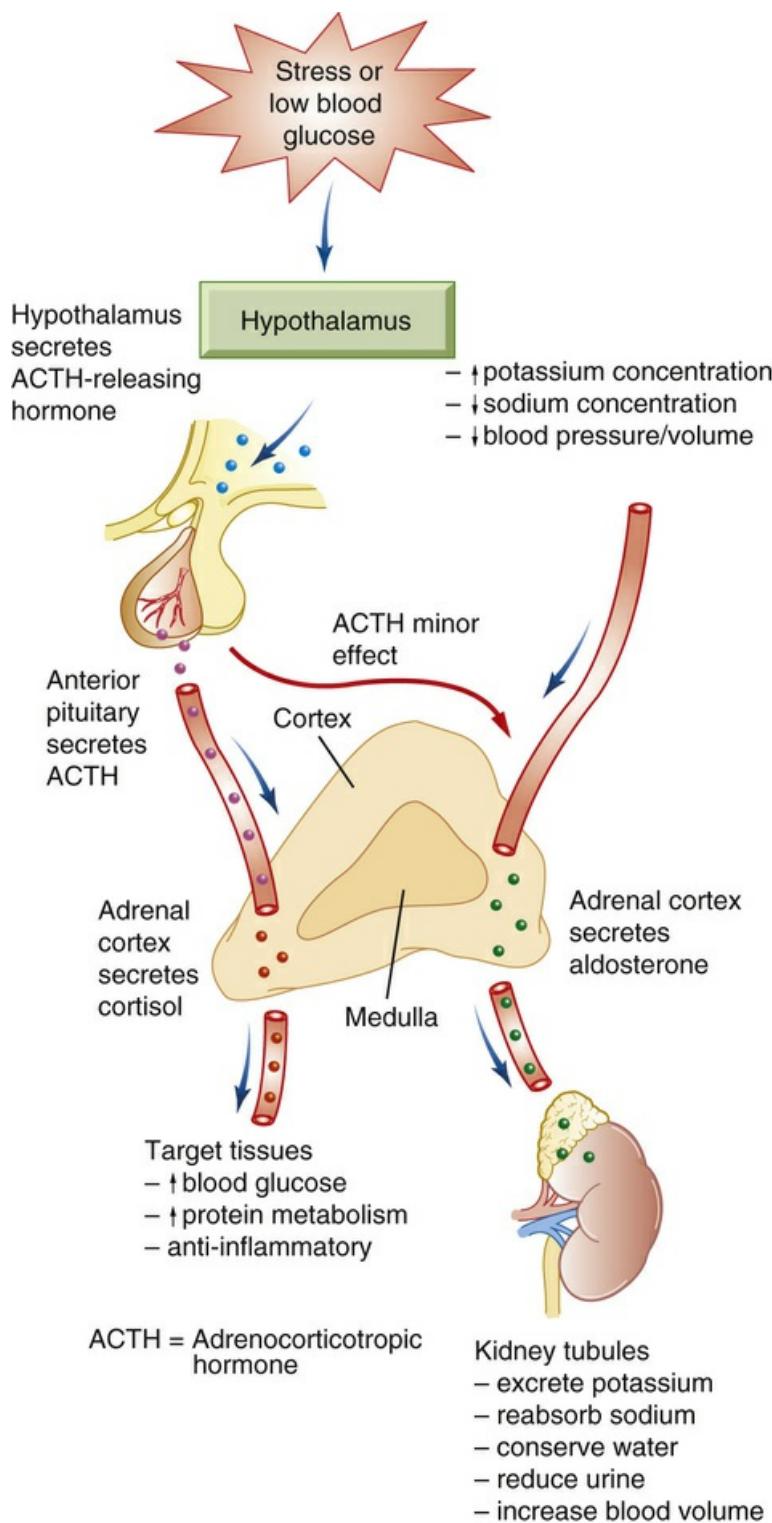

FIGURE 35-5 Regulation of aldosterone and cortisol secretion. ACTH, Adrenocorticotrophic hormone. (From Applegate E: *The anatomy and physiology learning system*, ed. 2, Philadelphia, 2000, Saunders.)

- The adrenal glands also secrete small amounts of androgenic hormones, which have effects similar to those of the male and female sex hormones.
- The **mineralocorticoids** affect the electrolytes, particularly sodium, potassium, and chloride. The primary mineralocorticoid is aldosterone, which promotes conservation of water by acting on the kidney to retain sodium in exchange for potassium. Water stays with sodium, and potassium is excreted in the urine.
- Without the mineralocorticoids, a person would die within 3 to 7 days, because these hormones

directly control fluid balance, blood volume, cardiac output, exchange of nutrients, and wastes in each cell; mineralocorticoids affect all chemical processes and glandular functions within the body.

- The **glucocorticoids** are essential to the metabolic systems for proper utilization of carbohydrates, proteins, and fats.
- The primary glucocorticoid is cortisol, or hydrocortisone. Cortisol acts to increase glucose levels in the blood. Cortisol also helps counteract the inflammatory response.
- Both aldosterone and cortisol are controlled by **adrenocorticotrophic hormone** (ACTH)–releasing hormone from the hypothalamus and ACTH secreted by the anterior pituitary (see [Figure 35-3](#)).

Hormonal Function of the Pancreas

- The pancreas is both an **endocrine** (secretes into the bloodstream) and **exocrine** (secretes through a duct to the target tissues) gland. Its endocrine function is to produce the hormones insulin and glucagon.
- The beta cells are responsible for producing and secreting insulin. **Insulin** is needed for the cells of the body to be able to use glucose as fuel. The alpha cells release glucagon, which stimulates the liver to change glycogen to glucose ([Figure 35-6](#)).

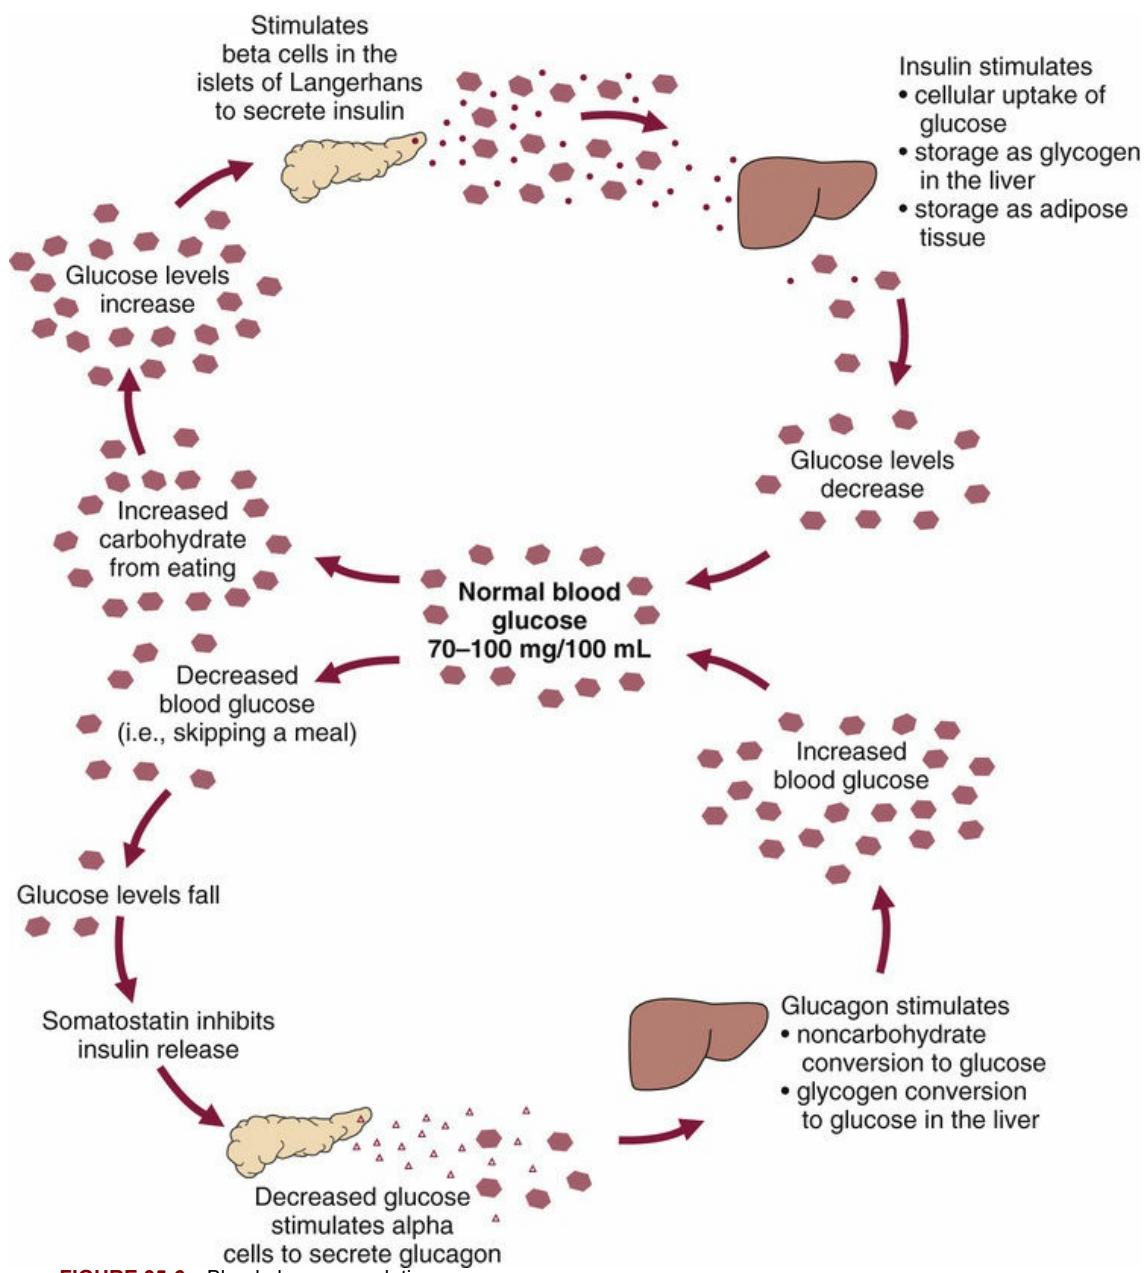

FIGURE 35-6 Blood glucose regulation. (Adapted from Applegate E: *The anatomy and physiology learning system*, ed. 2, Philadelphia, 2000, Saunders.)

Effects of Aging on the Endocrine System

- The pituitary gland becomes smaller.
- The thyroid becomes more lumpy or nodular; beginning around age 20 years, metabolism gradually declines.
- Hormones that usually decrease with older age include aldosterone, renin, calcitonin, and growth hormone; specific hormones decrease in older women (estrogen and prolactin) and older men (testosterone).
- Hormones that may increase with older age include follicle-stimulating hormone (FSH), luteinizing hormone (LH), norepinephrine, and antidiuretic hormone (ADH).
- Hormones that remain unchanged or are only slightly decreased with age include thyroid hormones (T_3 and T_4), cortisol, insulin, epinephrine, parathyroid hormone, and 25-hydroxyvitamin D.
- Blood glucose levels rise with older age, with fasting levels climbing about 1 mg/dL for each

decade after the age of 50 years and postprandial levels increasing 6 to 13 mg/dL.

- Although insulin levels remain unchanged with age, decreased glucose tolerance may occur because of changes in the cell receptor sites; older adults experience hypoglycemia more quickly than younger people and may progress to dangerously low levels of blood glucose before signs and symptoms are obvious. This decreased glucose tolerance because of cell receptor change can place older adults at risk for hyperglycemia and the onset of type 2 diabetes.
- Although thyroid hormone levels may decrease with aging, the body makes up for it by decreasing the rate at which thyroid hormone is broken down; therefore resting levels of thyroid hormone are usually normal in older adults. Thyroid disorders are, however, twice as common in older adults. Hypothyroidism is the most common thyroid disorder, especially in older women.
- The amount of hormones secreted by older adults changes, decreasing the individual's ability to adapt to stress and respond to environmental changes.
- Because of decreasing liver and kidney function in older adults, hormone replacement therapy must be done very cautiously to prevent hormone overdosage.

The Endocrine System

The endocrine system regulates metabolism, growth and development, sexual function, and reproductive processes. A primary function of the endocrine system is to synthesize and release hormones directly into the bloodstream and the body fluids. The cells and tissues that are affected by a specific hormone are called its **target cells** or **target tissues**.

Some of the endocrine hormones, such as the thyroid hormones, affect practically every cell in the body. Others, such as the sex hormones, exert their special effects on only one organ system. Moreover, hormones from one endocrine gland can affect another endocrine gland. The pituitary gland, for example, secretes several different kinds of hormones that affect other endocrine glands. For this reason, the pituitary gland is often referred to as the “master gland” of the body.

The endocrine system and the nervous system are the two major control systems of the body, and their regulatory functions are interrelated. However, the endocrine system typically controls body processes that occur slowly, such as cell growth, whereas the nervous system controls body processes that occur more rapidly, such as breathing and body movement.

The secretion of a particular hormone normally depends on the need. If an endocrine gland receives a message that its particular hormone is in short supply, it will synthesize and release more of that hormone. If, on the other hand, the hormonal need of a target tissue is being satisfied, production or secretion of the hormone will be inhibited—a concept known as **negative feedback**.

Some glands, such as the adrenal medulla and posterior pituitary, receive their information about hormone levels in the body **directly** and respond only to stimulation of nerve endings within the glands themselves. However, the posterior pituitary gland **indirectly** receives notice to either release or inhibit hormones: stimulation comes by way of the hypothalamus and the anterior lobe of the pituitary (the adenohypophysis). The hypothalamus contains special nerve endings that produce releasing and inhibiting hormones; these hormones are then absorbed into capillaries of a portal system, which transports the hormones to the adenohypophysis (the anterior lobe of the pituitary). Thus the hypothalamus controls the secretion of hormones from the pituitary. The pituitary, in turn, controls the release or inhibition of hormones from other glands. Many of the hormones of the anterior pituitary are “tropic” hormones; that is, they tend to cause a change in the endocrine gland that is the target of the specific pituitary hormone. An example is ACTH, which acts on the adrenal cortex. (If you break down this term, you can easily see that the components of *adrenal–cortex–tropic* tell you exactly where or what type of hormone this is and where it comes from.) The major endocrine glands are shown in [Figure 35-1](#); see [Table 35-1](#) for the various tropic hormones and target tissues.

Endocrine System Disorders

Causes

Endocrine disorders are caused by an imbalance in the production of hormone or by an alteration in the body's ability to use the hormones produced. Dysfunction can occur at any point in the production-secretion-feedback regulation cycle.

Primary endocrine dysfunction means that an endocrine gland is either oversecreting or undersecreting hormone(s)—situations referred to as **hypersecretion** and **hyposecretion**, respectively. Tumor or hyperplasia of the endocrine gland may lead to hypersecretion. Hyposecretion is usually the result of destruction of endocrine glandular tissue by an inflammatory process or other destructive mechanism that interferes with normal endocrine function. Infection, mechanical damage, or an autoimmune response may cause such an inflammatory response in a gland.

Secondary endocrine dysfunction occurs from factors outside the gland itself. Medications, trauma, hormone therapy, and other factors may cause secondary dysfunction. Such dysfunction may be temporary or permanent; endocrine function often returns to normal if the cause is corrected (e.g., the medication is discontinued).

Prevention

Preventing most endocrine disorders is not possible by lifestyle changes; however, there are some dietary considerations regarding the thyroid gland that may be beneficial.

Health Promotion

Preventing Goiter

Goiter, an overgrowth of the thyroid, may be prevented by sufficient intake of iodine. Iodine is available in foods grown near the ocean and in seafood. Iodized salt is the major source for most people.

Think Critically

Why might a person with an endocrine disorder delay seeking medical care?

Diagnostic Tests and Procedures

Tests of the endocrine system are performed on blood samples; on urine samples; or by scans, ultrasounds, radiographs, or magnetic resonance imaging (MRI). [Table 35-2](#) presents the various tests and procedures and their nursing implications.

Clinical Cues

Thyroid test results are altered by iodine-based contrast media for radiologic studies. Furosemide, phenytoin, heparin, aspirin, and other drugs may affect thyroid tests ([Pagana and Pagana, 2014](#)).

Table 35-2

Diagnostic Tests and Procedures of the Endocrine System

Test	Purpose	Description	Nursing Implications
Blood Tests			
Pituitary hormone levels: LH, FSH, GH, ACTH, TSH, prolactin <i>Normal value:</i> 4.5–11.5 mcg/dL	To detect oversecretion or deficiency of pituitary hormones	Sample of venous blood is drawn; requires at least 1 mL for immunoassay test; check laboratory procedure manual.	Monitor venipuncture site for bleeding; apply bandage or dressing.
Serum T ₄ (total thyroxine) <i>Normal value:</i> 4.5–11.5 mcg/dL	To assess thyroxine in blood to evaluate thyroid function	Requires a venous blood sample of at least 1 mL.	Aspirin, iodine-containing medications, contrast media, and other drugs may affect result; check with laboratory.
Serum T ₃ (total triiodothyronine) <i>Normal value:</i> 70–190 ng/dL	Used with T ₄ to evaluate thyroid function	Requires a venous blood sample of at least 1 mL.	Same as for serum T ₄ .
TSH <i>Normal value:</i> 1–10 mCU/mL	To differentiate between pituitary dysfunction and primary thyroid dysfunction; assists with diagnosis of hypothyroidism	Requires a venous blood sample of at least 1 mL.	Same as for serum T ₄ .
Antithyroid antibody titer <i>Normal value:</i> <1 : 100	To detect the presence of thyroid antibodies and distinguish between autoimmune disorders and toxic thyroid adenoma	Requires a venous blood sample.	Radioactive iodine will interfere if given within 24 hr of drawing the blood sample.
Calcitonin <i>Normal value:</i> <100 pg/mL	Used for differential diagnosis of cancer of the thyroid	Requires a venous blood sample.	If base level is within normal, the pentagastrin stimulation test may be administered by injection to test for calcitonin secretion. Blood samples are then drawn 1½ and 5 min after injection.
Cortisol <i>Normal value:</i> 8 A.M., 6–23 mcg/dL; 4 P.M., 3–15 mcg/dL; 10 P.M., <50% of 8 A.M. value	To assess cortisol production by adrenal glands	Requires sample of venous blood.	Explain that a specimen may be collected two or three times in 24 hr to evaluate circadian effects on cortisol secretion. Keep stress to a minimum. Note time collected on laboratory slip.
Adrenocorticotropic hormone (ACTH) <i>Normal value:</i> A.M., 20–100 pg/mL; P.M., 10–40 pg/mL	To assess ACTH production from pituitary gland	Requires venous blood sample. Place specimen in ice water immediately after drawing.	Prepare ice bath before venipuncture. Note collection time on laboratory slip. Single specimen is best collected in morning.
ACTH stimulation test <i>Normal value:</i> after ACTH, serum cortisol >20 mcg/dL	To assess adrenal response to ACTH To detect adrenal cortical insufficiency (Addison disease)	Baseline venous sample taken for cortisol determination. ACTH is administered IV or IM. Blood sample is withdrawn at 30 and 60 min for further cortisol determinations.	Note time ACTH is administered; note time each specimen is drawn. Instruct patient to avoid strenuous activity on the day before the test. Check with laboratory regarding food restrictions.
Dexamethasone suppression test <i>Normal value:</i> after dexamethasone, serum cortisol <5 mcg/dL	To diagnose Cushing syndrome To assess response to dexamethasone	Morning baseline serum cortisol levels are measured. Oral dexamethasone is administered at bedtime. Blood sample is collected the next morning to measure cortisol levels if an overnight test is ordered. A 24-hr urine collection is done at the same time. A 3-day test may be done which requires additional doses of dexamethasone and collection of all urine.	Explain the procedure to the patient. Check orders for drugs to be withheld. Both cortisol levels must be drawn at the same time each day. Note time specimens were drawn and patient medications on laboratory slips. Instruct patient to avoid strenuous activity the day before the test. No fasting is necessary. Collected urine should be kept cool.
CRH stimulation test	To identify if an abnormality exists in the pituitary glands, hypothalamus, or the adrenal glands. All of these play a role in cortisol secretion and this test helps pinpoint the source.	Baseline serum cortisol levels are measured. An injection of synthetic CRH is given IV. Blood samples are taken at 30, 60, 90, and 120 min after administration of the CRH.	Explain the procedure to the patient. The test may take up to 3 hr to complete. The patient should have nothing by mouth for 4 hr before the start of the test.
Thyroid Scans			
Radioactive iodine uptake (RAIU) <i>Normal values:</i> <6% uptake in 2 hr; 2%–25% in 6 hr; 15%–45% in 24 hr; 24-hr urine: 40%–80% radioactive iodine excreted in 24 hr	To assess function of thyroid gland To measure the rate of iodine uptake by the thyroid	Trace dose of radioactive iodine (RAI) is given orally. A gamma counter or scintillation counter is placed over the gland to measure the amount of RAI absorbed. Concurrent 24-hr urine specimen may be collected to assess iodine secretion.	Test must not be performed during pregnancy or lactation. Explain that the amount of radioactive iodine used is small and will not make the patient “radioactive.” Explain the procedure and the time it will take. Instruct how to collect 24-hr urine.

			specimen if required.
Thyroid scan	To determine size, shape, and activity of the thyroid gland To detect hyperactive "hot" spots and hypoactive "cold" spots	After administering RAI, a scintillation camera moves back and forth across the gland to obtain an image of iodine concentration and distribution in the thyroid gland. A computer may provide a three-dimensional image. Often done in conjunction with RAIU.	Same implications as for RAIU. Patient must lie perfectly still during the scanning. Scan takes about 20 min. Rescanning is performed at intervals of 6 and 24 hr after RAI is administered.
Urine Tests			
17-Hydroxycorticosteroids (17-OHCS) <i>Normal values:</i> females, 2-8 mg/24 hr; males, 3-9 mg/24 hr	To determine levels of glucocorticoid metabolites	Collect a 24-hr urine specimen in a container with preservative. Medications may interfere; consult with provider and laboratory about medications patient is taking.	Instruct patient in collection procedure. Note start and end time of collection on laboratory slip. Note medications patient is taking on laboratory slip.
17-Ketosteroids (17-KS) <i>Normal values:</i> females, 6-15 mg/24 hr; males, 8-22 mg/24 hr; older than age 65, 4-8 mg/24 hr	To determine amount of androgen metabolites in the urine	Collect 24-hr urine specimen. Check with laboratory regarding need to keep specimen chilled.	Same as for 17-OHCS test.
Aldosterone <i>Normal values:</i> 3-20 mcg/24 hr	To determine urinary aldosterone levels to assist in diagnosis of aldosteronism	Requires 24-hr urine specimen with preservative; specimen must be kept chilled.	Instruct in dietary and medication restrictions. Record diet and medications on laboratory slip.
Fluid deprivation test	To detect diabetes insipidus	While patient is NPO, hourly urine output, specific gravity, and osmolality are measured along with body weight and vital signs. Vasopressin is given subcutaneously; hourly measurements are continued for several hours.	Explain the procedure to the patient. Provide urine collection containers. Remind patient to void hourly.
Hypertonic saline test	To stimulate release of ADH to evaluate ADH secretion and detect diabetes insipidus	The patient is loaded with water. An infusion of hypertonic saline is administered. Urine output and urine specific gravity are measured hourly.	Tell patient to produce a urine specimen in the marked container every hour.

ADH, Antidiuretic hormone; *FSH*, follicle-stimulating hormone; *GH*, growth hormone; *IM*, intramuscularly; *IV*, intravenously; *LH*, luteinizing hormone; *NPO*, nothing by mouth; *TSH*, thyroid-stimulating hormone.

Abnormalities in thyroid gland activity are among the most common endocrine disorders. To detect abnormalities, a group of tests—called a **thyroid panel**—is performed. A thyroid panel measures TSH, T_4 , T_3 , thyroid antibodies, calcitonin, and thyroglobulin. These tests may also be ordered individually.

Laboratory testing for serum calcium and phosphate levels is usually performed to assess parathyroid function. Adrenal gland function is evaluated by laboratory testing, including electrolyte panels, glucose levels, and hormone levels; a 12-lead electrocardiogram (ECG) may be performed if cardiac dysrhythmias are suspected.

Think Critically

The provider has ordered laboratory tests to determine whether the patient has an endocrine disorder. The patient wants you to tell her the results of the tests. What will you do?

Diagnostic tests for detecting diabetes can be found in **Table 35-3**. According to the 2014 American Diabetes Association guidelines ([American Diabetes Association, 2014](#)), diagnosis of diabetes mellitus is based on one of four abnormalities:

1. Symptoms of diabetes mellitus (see [Chapter 37](#)) plus a random glucose level greater than or equal to 200 mg/dL
2. A fasting glucose level greater than or equal to 126 mg/dL
3. An A_{1c} hemoglobin level greater than 6.5%
4. A glucose tolerance test revealing a postprandial glucose greater than or equal to 200 mg/dL, 2 hours after 75 g of glucose is administered

Table 35-3
Diagnostic Tests for Detecting and Monitoring Diabetes Mellitus

Test	Purpose	Description	Nursing Implications
Serum Tests			
Fasting blood glucose <i>Normal value:</i> 70-100 mg/dL; older adult: rises 1 mg/dL per decade of age	To determine level of circulating glucose; to detect hyperglycemia or hypoglycemia	Requires a fasting venous blood sample.	Explain importance of fasting state to the patient.
2-hr postprandial blood glucose <i>Normal value:</i> <126 mg/dL; older adult: rises 5-10 mg/dL with older age	To determine need for glucose tolerance test; to determine need for change in diabetes therapy	Venous blood sample drawn 2 hr after a meal.	Explain the importance of arriving for blood sampling exactly 2 hr after finishing a meal.
Glucose tolerance test <i>Normal values:</i> Fasting <126 mg/dL; 2 hr, <200 mg/dL	To detect abnormal glucose metabolism; to assist in diagnosis of diabetes mellitus	A venous blood sample is drawn after a 10-12 hr fast; patient is given a glucose "load," usually a prepared liquid drink of 300 mL, that contains a specified amount of glucose.	Instruct patient to eat a balanced diet with at least 150 g of carbohydrate for 3 days before the test and maintain a normal level of physical activity. Instruct patient to fast for 10-12 hr before beginning the test.

		Venous blood samples are drawn at 30-min intervals for 2 hr. Phenytoin (Dilantin), birth control pills, diuretics, and glucocorticoids will adversely affect results; consult provider regarding these medications.	Explain that during the test the patient cannot eat, drink, or smoke, and must stay at rest for 2 hr. During the test, instruct patient to report feelings of weakness, dizziness, nervousness, and confusion.
Hemoglobin A _{1c} (A _{1c}) <i>Normal value: 4%-5.6% (of total hemoglobin)</i>	To determine degree of diabetic control of blood sugar over the preceding 2-3 months. 6-8 wk	A sample of venous blood is required. Fasting is not necessary.	Explain to the patient the need for this test to be done periodically to monitor effectiveness of diabetic therapy and determine degree of control over the disease process.
Fructosamine assay <i>Normal value: 1.5-2.7 mmol/L</i>	To determine degree of diabetic control of blood sugar over preceding 2-3 wk	A sample of venous blood is required. Fasting is not necessary.	Less influenced by age than A _{1c} .
C-peptide <i>Normal value: 0.78-1.89 ng/mL</i>	To evaluate endogenous secretion of insulin when the presence of insulin antibodies interferes with direct assay of insulin	A fasting sample of 1 mL of venous blood is used.	Caution the patient to fast for 8-12 hr before the test. Water is permitted.
Urine Tests			
Ketone bodies	To determine presence of ketones in the urine, which indicates a state of ketoacidosis	A fresh urine sample is tested with a dipstick. Follow instructions on bottle of test material.	Instruct diabetic patient that ketone testing should be done whenever illness has interfered with normal eating and activity for more than 24 hr and whenever signs of hyperglycemia are present.

In a **glucose tolerance test**, the patient is given a set amount of glucose to evaluate insulin secretion and ability to metabolize glucose.

The **hemoglobin A_{1c} (A_{1c})** test (formerly called the *glycosylated hemoglobin test*) measures blood glucose over a period of many weeks (Table 35-4). Glucose in the bloodstream attaches itself to the hemoglobin A (red blood cell) molecule and remains there for the life span of the red blood cell. Providers use A_{1c} test results to prescribe adjustments to a patient's treatment program for managing diabetes. One of the *Healthy People 2020* objectives is to increase the proportion of adults with diabetes who have an A_{1c} test at least twice a year. Fructosamine assay is another test to monitor control of glucose over time. The **fructosamine assay** monitors blood glucose over a shorter time frame than the A_{1c} test, because the assay measures sugar attached to the protein albumin, which has a shorter life span than hemoglobin.

Table 35-4
Average of Blood Glucose Based on Hemoglobin A_{1c} Levels

A _{1c} Level	Average Blood glucose
4%	68 mg/dL
5%	97 mg/dL
5.7%-6.4%	Prediabetes
6%	126 mg/dL
Greater than 6.5%	Type 2 diabetes
7%	154 mg/dL

❖Nursing Management

■ Assessment (Data Collection)

A full physical assessment and history are needed to evaluate a patient who is possibly experiencing an endocrine disorder. The patient's perception of the function of various body systems affected by the endocrine glands is essential.

❑ Think Critically

Why would it be important to assess the patient's past and current emotional status if you suspect an endocrine disorder?

■ Nursing Diagnosis

Table 35-5 presents the most common patient problems, expected outcomes, and nursing interventions for patients with endocrine problems. Additional problem statements/nursing diagnoses are included in [Nursing Care Plans 36-1, 36-2, and 37-1](#).

☒ Focused Assessment

Data Collection for the Endocrine System

Ask the following questions:

- Have you gained or lost weight over the past 6 months?

- Has your appetite increased or decreased?
- Have you noticed any changes in thinking? Any difficulty concentrating? Any difficulty with memory?
- Have you become more anxious or nervous? Do you cry a lot?
- Has your personality changed?
- Has your energy level changed?
- Have you experienced muscle cramping or numbness or tingling in your hands and legs?
- Have you been experiencing diarrhea or constipation?
- Have you had more gas or abdominal bloating?
- Have you noticed any facial or ankle swelling?
- Has your voice become huskier?
- Have you been thirstier than usual? Do you urinate more now?
- Have you had heart palpitations? Has your pulse rate changed?
- Has your sleep pattern changed? Do you need more sleep? Are you finding it difficult to sleep?
- *For women:* Have your menstrual periods altered?
- Is there any history in your family of thyroid, pituitary, or adrenal disease, or diabetes?
- Have you noticed a difference in the way you react to the environmental temperature? Are you cold or hot when others are comfortable?
- Have you noticed any changes in the texture or thickness of your hair or eyebrows? What about your fingernails? Are they brittle?
- Has your skin become dry and rough?
- Have you ever had radiation treatments to the head or neck?

Table 35-5

Common Problem Statements, Goals/Expected Outcomes, and Nursing Interventions for Patients With Endocrine Disorders

Problem Statement	Goals/Expected Outcomes	Nursing Interventions
Altered fluid volume due to increased urine output (DI, HyperT, AD).	Patient will display balance between intake and output.	Monitor for dehydration and signs of decreased cardiac output. Measure and record intake and output q2h; maintain ordered IV fluid rate; encourage oral fluid intake.
Constipation due to loss of fluid from intestine, slowed intestinal peristalsis (DI, HypoT, AD).	Patient will display normal bowel pattern within 2 wk.	Provide high-bulk diet; encourage fluid intake; administer stool softener or laxatives as prescribed. Encourage exercise to promote better bowel function.
Altered body image due to changes in physical appearance (PT, HyperT).	Patient will verbalize acceptance of alteration in body appearance within 2 mo.	Allow time for verbalizing feelings. Assist to identify strengths and positive aspects of self and life. Focus on strengths and positive aspects. Give sincere compliments.
Altered sexual function due to decreased libido, amenorrhea, or impotence (PT, HyperT).	Patient will acknowledge need for patience until therapy improves the symptoms.	Help patient understand how therapy might help the problem. Assist patient to recognize and maintain personal worth as an individual. Assist to maintain roles within family or living unit. Help significant others understand patient's illness.
Insufficient knowledge due to illness and treatment (all endocrine disorders).	Patient will verbalize beginning understanding of concepts taught at end of 2 wk.	Teach patient and significant others about the disease and each aspect of treatment. Provide written instructions regarding medications, their side effects, and what should be reported to the provider. Provide instructions for "sick" days. Alert to signs and symptoms of too much or too little medication. Emphasize the importance of follow-up care. Stress the need for medical-alert tag or bracelet and

		wallet card.
Altered due to anorexia, constipation, increased metabolic rate (PT, HyperT).	Patient will regain and maintain weight within normal limits within 6 mo.	Weigh twice a week. Alter diet as needed to increase fiber and carbohydrate content. Provide small, frequent meals of preferred foods. Provide patient teaching about nutritional requirements.
Fatigue due to weakness, somnolence, lethargy (PT, DI, HypoT, CS).	Patient will verbalize decrease in weakness and fatigue within 1 mo; patient will demonstrate improved energy within 3 mo.	Provide periods of rest. Assist with ADLs as needed. Set slower pace for activities. Give patient time to respond to verbal communications. Encourage physical activity to highest level of tolerance.
Potential for injury due to possible increased intracranial pressure (PT), inability to think clearly (HyperT, HypoT), mental and physical sluggishness (HypoT).	Patient will not experience damage from increased intracranial pressure.	Conduct regular checks of neurologic status. Monitor for signs of increased intracranial pressure. Continue hormone replacement therapy as needed to decrease symptoms from tumor or hypofunction.
Disrupted sleep pattern due to insomnia, hypermetabolic state (HyperT, CS).	Patient will use relaxation methods to induce sleep.	Assist with rest periods during the day if fatigue is severe. Instruct in relaxation methods to help induce sleep. Provide noise-free, sleep-inducing environment.
Limited coping ability due to emotional lability (HyperT, AD, CS).	Patient will devise plan to cope with mood swings until they resolve.	Encourage verbalization of feelings and concerns. Assure patient that as disease is controlled, moods will be more stable. Help patient identify strengths and focus on them. Teach relaxation techniques to handle stressful times. Explain physiologic causes of changes in mood.
Altered cardiac output due to fluid depletion (DI, AD), hypometabolic state (HypoT), hypermetabolic state (HyperT).	Patient will maintain adequate blood pressure.	Explain to patient how disease process is affecting heart function. Monitor for signs of dysrhythmia and hypotension. Assure that treatment of underlying disease should alleviate heart symptoms.
Potential for infection due to surgical incision (PT, HyperT), anti-inflammatory effect of excess cortisol (CS).	Patient will not develop infection as evidenced by normal temperature, WBC count within normal range, and absence of visible signs of wound infection.	Maintain strict asepsis for invasive procedures and dressing changes. Monitor temperature, WBC, and subtle signs of infection; steroids can suppress usual signs. Advise to stay away from individuals who have colds or other infections.
Altered nutrition: due to altered glucose metabolism (CS), hypometabolic state (HypoT).	Patient will regain and maintain weight within normal limits within 3 mo of beginning therapy.	Teach signs and symptoms of hyperglycemia and how to administer prescribed insulin; teach regarding correct diet for condition. Assist in designing diet according to food preferences. Teach to balance diet and exercise.

AD, Addison disease; ADLs, activities of daily living; CS, Cushing syndrome; DI, diabetes insipidus; HyperT, hyperthyroidism; HypoT, hypothyroidism; IV, intravenous; PT, pituitary tumors and hypopituitary syndrome; WBC, white blood cell.

Endocrine disorders to which these problem statements apply are in parentheses.

■ Planning

Planning care for a patient with an endocrine disorder will depend on the type of disorder the patient has. Stress has a direct effect on endocrine function. Therefore measures to help the patient decrease stress should be planned. General nursing goals for patients with an endocrine disorder are:

- Prevention of injury
- Maintenance of fluid and electrolyte balance
- Early identification of hormone imbalance
- Reduction of stress
- Use of effective coping mechanisms
- Knowledge of self-care
- Tolerance for physical activity
- Promotion of normal bowel function
- Improvement of mental-emotional status
- Integration of body image

■ Implementation

Interventions vary depending on the type of endocrine problem and are discussed with specific disorders in [Chapters 36](#) and [37](#) (see [Table 35-5](#)).

■ Evaluation

Evaluation is accomplished by determining whether symptoms are resolving and by laboratory testing to determine whether treatment of the endocrine problem is effective. Many of the symptoms of endocrine disorders are subjective, and you must collect reliable data from the patient about symptoms, such as levels of fatigue, feeling cold or hot, and paresthesias. Each patient is questioned about the symptoms and their improvement during the evaluation of care and treatment. In an effort to better evaluate changes in condition, several rating scales are available for fatigue and paresthesias, much like the pain rating scale.

Community Care

Many patients with endocrine disorders are cared for in outpatient settings. Home care nurses frequently find that patients with heart disease, neurologic problems, diabetes, or respiratory problems also have a thyroid problem. Careful assessment by a clinic nurse may uncover a developing endocrine problem.

Get Ready for the NCLEX® Examination!

Key Points

- The endocrine system is made up of glands and hormones that regulate metabolism, growth and development, and sexual and reproductive processes.
- The primary regulatory activities of the endocrine system include altering chemical reactions, changing the permeability of the cell membrane, and activating a particular cell mechanism. The secretion of a particular hormone normally depends on the physiologic need for it.
- Any type of dysfunction of the pituitary gland will affect one or more of its numerous hormones, as well as the target organ for that hormone.
- Age-related changes of the endocrine system include decreased size of the pituitary gland, decreased metabolic rate, decreases in some hormone levels, increases in others, and only slight changes in still others.
- Endocrine disorders are caused by an imbalance in the production of hormone or by an alteration in the body's ability to use the hormones produced. Primary endocrine dysfunction consists of either hypersecretion or hyposecretion; secondary endocrine dysfunction occurs from factors outside the gland.
- Endocrine system tests include examination of blood or urine, radiographs, ultrasound, and MRI scans.
- A thyroid panel may be ordered to evaluate thyroid function. Patients with primary hypothyroidism will have low levels of T_3 and T_4 and high levels of TSH.
- A full physical assessment and history are needed to evaluate the patient with a possible endocrine disorder.
- General goals for the patient with an endocrine disorder include prevention of injury, maintenance of fluid and electrolyte balance, maintenance of hormone balance, reduction of stress, and use of effective coping mechanisms.

Review Questions for the NCLEX® Examination

1. A patient is scheduled to have a RAIU thyroid scan. What important teaching points should be covered? (*Select all that apply.*)

1. Thyroid medications should not be taken before the test.
2. The radioactive iodine tracer will be given orally several hours before the actual imaging.
3. The scanner may be donut shaped, and some patients experience claustrophobia.
4. Diet intake has no effect on the test results.

NCLEX Client Need: Reduction of Risk Potential

2. A patient complains of muscle cramping and twitching. Based on knowledge of the endocrine system, which hormonal deficiency should be evaluated?

1. Aldosterone
2. Parathyroid hormone
3. Estrogen
4. Melatonin

NCLEX Client Need: Reduction of Risk Potential

3. The nurse is taking care of a patient with hyperparathyroidism. Which laboratory results would confirm the diagnosis?

1. Elevated serum calcium
2. Increased bone density
3. Elevated serum phosphate
4. Increased serum potassium

NCLEX Client Need: Physiological Adaptation

4. A nurse is caring for several patients who have endocrine problems. For which patient is the nurse most likely to perform a urine dipstick for ketone bodies?

1. A patient with abnormal thyroid gland activity
2. A patient with diabetes mellitus
3. A patient with adrenal cortical insufficiency
4. A patient with Cushing syndrome

NCLEX Client Need: Physiological Adaptation

5. A patient is on corticosteroid therapy for an acute exacerbation of a respiratory disease. The initial assessment confirms a patient problem of *fluid volume excess*. The underlying cause for this problem would be:

1. suppression of normal corticosteroid secretion.

2. artificial increase in corticosteroids.
3. increased adrenocorticotropic hormone.
4. mineralocorticoid insufficiency.

NCLEX Client Need: Pharmacological Therapies

6. A nurse formulates a care plan for a postmenopausal woman who is admitted for hip fracture. Nursing assessments support the patient problem of *Potential for injury*. The most likely cause for the diagnosis would be:

1. inadequate estrogen secretion.
2. aldosterone deficiency.
3. progesterone deficiency.
4. inadequate parathormone secretion.

NCLEX Client Need: Reduction of Risk Potential

7. Older adults can have physiologic increases in circulating ADH. Based on knowledge of the function of ADH, which condition should nurses monitor for?

1. Dehydration
2. Fluid overload
3. Increased pulse
4. Increased urine output

NCLEX Client Need: Physiological Adaptation

8. A patient is admitted with hyperthyroidism. The initial assessments suggest the patient problem of *Altered nutrition: less than body requirements*. An appropriate expected outcome would be:

1. patient will identify causes of weight loss.
2. patient will maintain weight.
3. patient will have a balanced intake and output.
4. patient will tolerate activities of daily living.

NCLEX Client Need: Basic Care and Comfort

9. A nurse is caring for a patient who had part of the thyroid gland removed. Based on knowledge of anatomy and physiology, which abnormal laboratory value is of particular concern for this patient?

1. Blood glucose of 150 mg/dL
2. Serum sodium of 149 mEq/L
3. Serum calcium of 7 mg/dL
4. Hemoglobin of 10 g/dL

NCLEX Client Need: Reduction of Risk Potential

10. A nurse is preparing a patient for a glucose tolerance test. Which instructions must be included? (*Select all that apply.*)

1. "Eat a balanced diet for 3 days prior to the test."
2. "Maintain a normal level of activity."
3. "Fast for 24 hours before the test."
4. "No eating, drinking, or smoking during the test."
5. "Report dizziness, nervousness, weakness, and confusion."

NCLEX Client Need: Reduction of Risk Potential

Critical Thinking Questions

Scenario A

Mrs. Kovash, a 64-year-old widow, comes to the endocrine clinic to be evaluated at the request of her nurse practitioner. She complains that in the past year she has "slowed down" considerably. She states, "I guess I'm just getting old." The nurse practitioner suspects that it may not be simply aging, because Mrs. Kovash has always lived a healthy and active lifestyle.

1. What type of examinations would you expect the health care provider to perform?
2. What would you teach Mrs. Kovash regarding what to expect from the laboratory blood tests?
3. What questions would you ask the patient before tests for evaluation of thyroid function?

Scenario B

The provider tells you that a patient has a new-onset deficiency of ADH. You anticipate that the patient is likely to have dehydration, urinary frequency, constipation, fatigue, and knowledge deficit.

1. Use your knowledge of the endocrine system and explain to the patient why he is dehydrated and constipated.
2. What interventions could you use to address the patient's fatigue?
3. The provider orders intravenous fluid therapy, but the patient is reluctant to get "stuck with a needle." What patient teaching can you provide to help the patient understand the need for this therapy?

CHAPTER 36

Care of Patients With Pituitary, Thyroid, Parathyroid, and Adrenal Disorders

Objectives

Theory

1. Give examples of four major problems associated with hyposecretion of pituitary hormones and identify three nursing interventions appropriate for each problem.
2. Outline three nursing interventions appropriate for each problem of hypopituitarism.
3. Plan appropriate nursing assessments and interventions for a patient who might experience complications of a thyroidectomy.
4. Compare and contrast the symptoms of hypoparathyroidism with hyperparathyroidism.
5. Identify six signs and symptoms of adrenocortical insufficiency (Addison disease).
6. Summarize four major causes of Cushing syndrome.

Clinical Practice

7. Individualize care for a patient with a pituitary disorder by choosing patient problem statements appropriate to the patient.
8. Select appropriate nursing interventions for a patient with adrenal insufficiency.
9. Implement patient teaching for a patient with hypothyroidism.
10. Plan postoperative assessment and nursing care for a patient who has had a hypophysectomy.
11. Evaluate the nursing care of a patient who has had a thyroidectomy.
12. Identify nursing problem statements and appropriate interventions for a patient with diabetes insipidus.
13. Assist with the development of a teaching plan for a patient taking a corticosteroid.

thyrotoxicosis (thī-rō-tōk-sī-KŌ-sīs, p. 844)
Trousseau sign (p. 849)

Disorders of the Pituitary Gland

The pituitary is considered the “master” gland, controlling multiple functions in the body, and many syndromes can result from pituitary disorders. Among the more common disorders of the pituitary are:

- Pituitary tumors
- Hypofunction or hyperfunction of the pituitary gland
- Diabetes insipidus (DI)
- Syndrome of inappropriate antidiuretic hormone (SIADH) secretion

Pituitary Tumors

Tumors of the pituitary gland account for about 10% to 15% of all intracranial tumors. Local symptoms are more likely to occur when the tumor is large and creates pressure within the brain. Even smaller tumors can cause various systemic symptoms and endocrine dysfunctions, depending on whether they stimulate or inhibit the secretion of particular hormones.

Etiology and Pathophysiology

A tumor of the pituitary is usually a **benign pituitary adenoma**. The etiology is not clear, but these tumors tend to affect women more than men. Some tumors do not cause symptoms and may be identified during autopsy after death from other causes. If the tumor is large enough, there is increased pressure within the **optic chiasm** (the part of the brain where the optic nerve fibers cross), which, if not relieved, will damage the optic nerve.

Signs and Symptoms

Local symptoms of pituitary adenoma include headache from the pressure of the tumor and visual disturbance—with possible blindness—from pressure within the optic chiasm. Systemic symptoms may be vague and progress very slowly. Personality changes, weakness, fatigue, and vague abdominal pain can be present for years before the condition is diagnosed correctly.

Diagnosis

Diagnosis of a pituitary tumor begins with a complete history and physical examination. Magnetic resonance imaging (MRI) and high-resolution computed tomography (CT) with contrast media may be used to identify, localize, and determine the extent of the tumor. A thorough ophthalmologic examination will be performed to evaluate pressure on the optic chiasm or optic nerves.

Treatment

In some cases the provider may choose to treat the pituitary tumor conservatively with hormone therapy designed to reduce levels of hormone production. If the tumor continues to grow or presents serious hormonal imbalances, it may be treated surgically or by irradiation. Some specialists prefer to remove the pituitary tumor surgically and then treat the site with radiation to be sure that all tumor cells have been destroyed. **Hypophysectomy**, or surgical removal of the pituitary gland, is most commonly performed microsurgically. The usual approach is transsphenoidal via the nose or at the junction of the gums and upper lip ([Figure 36-1](#)).

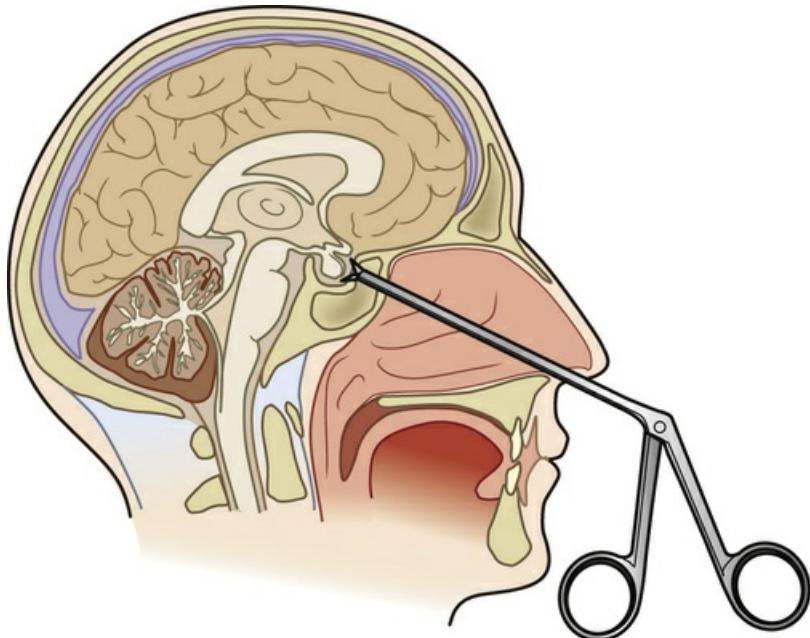

FIGURE 36-1 Transsphenoidal surgical approach for hypophysectomy. (From Ignatavicius DD, Workman ML: *Medical-surgical nursing: Critical thinking for collaborative care*, ed. 6, Philadelphia, 2010, Saunders.)

Nursing Management

After the surgery, the patient is kept in a semi-Fowler position. Closely monitor vital signs and the patient's neurologic status. It is important to note and communicate promptly any change in vision, mental status, level of consciousness, or strength. Also monitor for any complications, such as diabetes insipidus (see p. 839). A nasal drip pad is placed and is changed as needed. Expected drainage is bloody or mucuslike; clear watery drainage should be reported. Because nasal packing will be in place for 2 to 3 days, the patient must breathe through the mouth. After surgery it is important that the patient not brush his teeth, cough, sneeze, blow his nose, or bend forward, because these actions may interfere with the healing process. Assist the patient with mouth rinses and encourage hourly deep-breathing exercises to prevent pulmonary problems.

Safety Alert

Coughing

Coughing after a transsphenoidal hypophysectomy may lead to a cerebrospinal fluid leak.

Hyperfunction of the Pituitary Gland

Excessive secretion of growth hormone (GH) results in **gigantism** in children, leading to excessively tall stature, because the bone growth plates have not yet closed. In adults the result is **acromegaly**. When prolactin or gonadotropin are excessive, alteration in fertility and sexual function may occur. Adrenocorticotrophic hormone (ACTH) and thyroid-stimulating hormone (TSH) can also be secreted in excess. These are discussed in the adrenal and thyroid gland sections, respectively.

Etiology and Pathophysiology

Pituitary adenoma may increase release of hormones. Stress and pregnancy are other causes of increased hormone release. Failure of the target organ can also create high levels of hormone, because the normal feedback loop is not functional.

Signs and Symptoms

Gigantism causes the adult's facial features to change: the lips thicken, the nose enlarges, and the forehead develops a bulge (Figure 36-2). The hands and feet become enlarged in adults; the first

sign may be that the patient's shoes no longer fit. Muscle weakness may occur with acromegaly, and osteoporosis and joint pain are common. Signs of prolactin excess include amenorrhea and milk secretion in females and loss of facial hair and impotence in males.

FIGURE 36-2 The progression of acromegaly. (From Ignatavicius DD, Workman ML: *Medical-surgical nursing: Critical thinking for collaborative care*, ed. 6, Philadelphia, 2010, Saunders.)

Diagnosis

Alterations in hormone levels can be detected by laboratory testing.

Treatment

Removal of the pituitary adenoma is indicated if a tumor is the cause. Medications that block hormonal effects may be used. Slow-release formulas of somatostatin are used for acromegaly.

Nursing Management

See the previous discussion of hypophysectomy for postoperative management. Monitoring for effectiveness of medical treatment and patient teaching regarding new medications are nursing priorities.

Hypofunction of the Pituitary Gland

Hypofunction of the pituitary gland is a rare disorder characterized by a decrease in the level of one or more of the pituitary hormones.

Etiology and Pathophysiology

The most common cause of pituitary hypofunction is a tumor. Other causes include autoimmune disorders, infections, or destruction of the pituitary. A rare but serious postpartum complication, **Sheehan syndrome**, involves infarction of the gland secondary to postpartum hemorrhage.

The most common pituitary hormone deficiency involves a decrease in the amount of GH and gonadotropins. This decrease results in metabolic problems and sexual dysfunction. Decrease in GH will lead to short stature in children; in adults it leads to an increase in bone breakdown, resulting in increased bone fragility and risk for osteoporosis. The decrease in gonadotropins may lead to testicular failure in males and, ultimately, sterility. Ovarian failure, amenorrhea, and infertility occur with decreased gonadotropins in women.

Signs and Symptoms

Signs and symptoms of pituitary hypofunction depend on the cause of pituitary failure and the hormones involved. If the disorder is related to a tumor, the patient may experience headaches, visual changes, **anosmia** (loss of the sense of smell), or seizures. Other signs and symptoms depend on the hormones that are decreased and are outlined in [Table 36-1](#).

Table 36-1
Decreased Hormones in Pituitary Hypofunction and Associated Clinical Manifestations

Hormone Diminished	Associated Clinical Manifestations
Growth hormone (GH)	Decreased muscle mass, reduced strength, pathologic fractures
Follicle-stimulating hormone (FSH), luteinizing hormone (LH)	<i>Women:</i> Menstrual irregularities, diminished libido, decreased breast size <i>Men:</i> Testicular atrophy, diminished spermatogenesis, loss of libido, impotence, decreased facial hair, decreased muscle mass
Adrenocorticotrophic hormone (ACTH), cortisol	Weakness, fatigue, headache, dry/pale skin, diminished axillary and pubic hair, postural hypotension, fasting hypoglycemia, decreased tolerance for stress, susceptibility to infection
Thyroid hormone	Similar to hypothyroidism, although milder: cold intolerance, constipation, fatigue, lethargy, weight gain

Adapted from Lewis SL, Dirksen SR, Heitkemper MM, Bucher L, et al: *Medical-surgical nursing: Assessment and management of clinical problems*, ed. 9, St. Louis, 2014, Mosby.

Diagnosis

Diagnosis of pituitary gland hypofunction is made by history, physical examination, and diagnostic studies. Laboratory blood tests are performed to measure levels of pituitary hormones. MRI and CT are used to determine the presence or absence of a pituitary tumor.

Treatment and Nursing Management

The mainstay of treatment for hypofunction of the pituitary gland is lifelong replacement of the affected hormones. Somatropin, via subcutaneous injection, is used to replace GH. The patient experiences a feeling of increased energy and well-being, although there are side effects, such as edema, joint pain, and headache. Gonadal hormone therapy is usually offered, including testosterone for men and estrogen or progesterone for women, although associated risks may outweigh the benefits for some patients. If the disorder is caused by a tumor, surgery or radiation for tumor removal is usually performed, followed by hormone therapy.

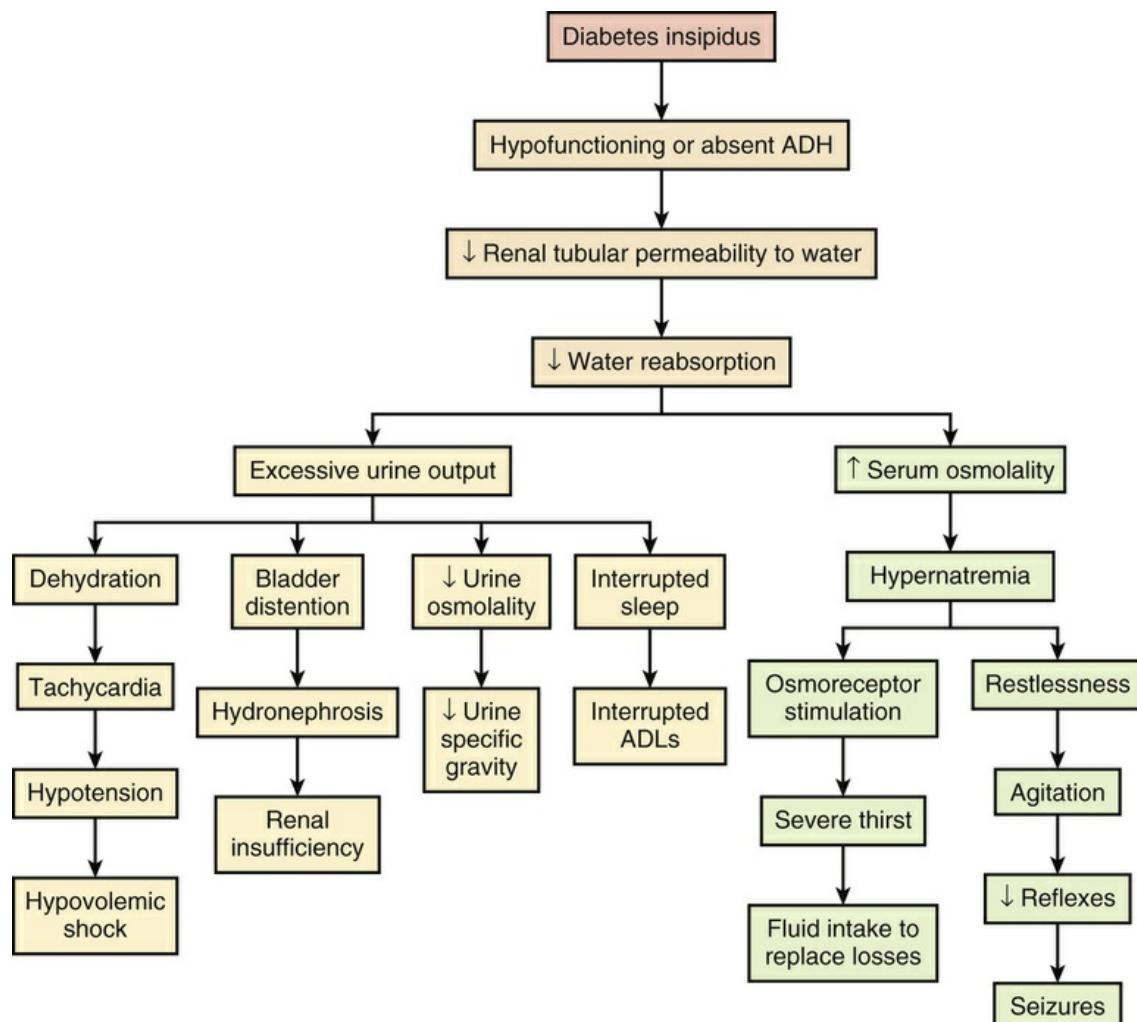

Nursing management involves recognizing the signs and symptoms of hypofunction of the pituitary. Teach the patient about lifelong hormone replacement therapy, including the method and frequency of hormone replacements, side effects, and follow-up.

Diabetes Insipidus

Etiology and Pathophysiology

Diabetes insipidus (DI) is characterized by the production of copious amounts of dilute urine. DI results from decreased production of antidiuretic hormone (ADH), which regulates reabsorption of water in the kidney tubules. When ADH is not present in a sufficient amount, the water is not reabsorbed from the tubule and is excreted as urine ([Concept Map 36-1](#)). The most common forms

of DI are central and nephrogenic. Central DI most commonly occurs after trauma or surgery in the area of the pituitary or hypothalamus and may be temporary or permanent. Nephrogenic DI results from hypercalcemia or lithium toxicity, causing the kidney to be resistant to the effects of ADH. Two less common types of DI are gestational and primary polydipsia (dipsogenic DI).

CONCEPT MAP 36-1 Pathophysiology of diabetes insipidus. ADH, Antidiuretic hormone; ADLs, activities of daily living.

Signs and Symptoms

The patient experiences profound **diuresis** (production of a large amount of urine), often as much as 3 to 20 L in every 24-hour period. Other signs and symptoms include thirst, weakness, and fatigue, often from **nocturia** (urination at night). The patient will exhibit signs of deficient fluid volume, such as tachycardia, hypotension, weight loss, constipation, and poor skin turgor. If untreated, the patient will demonstrate signs of shock and central nervous system manifestations progressing from irritability to eventual coma from hypernatremia and severe dehydration.

Diagnosis

To diagnose DI a complete history is obtained, and a physical examination and laboratory tests are performed, including urine and plasma osmolality and urine specific gravity. A water deprivation test is performed to confirm a suspected case of central DI.

Treatment and Nursing Management

Replacement of fluid and electrolytes, along with hormone therapy, represents the basis of

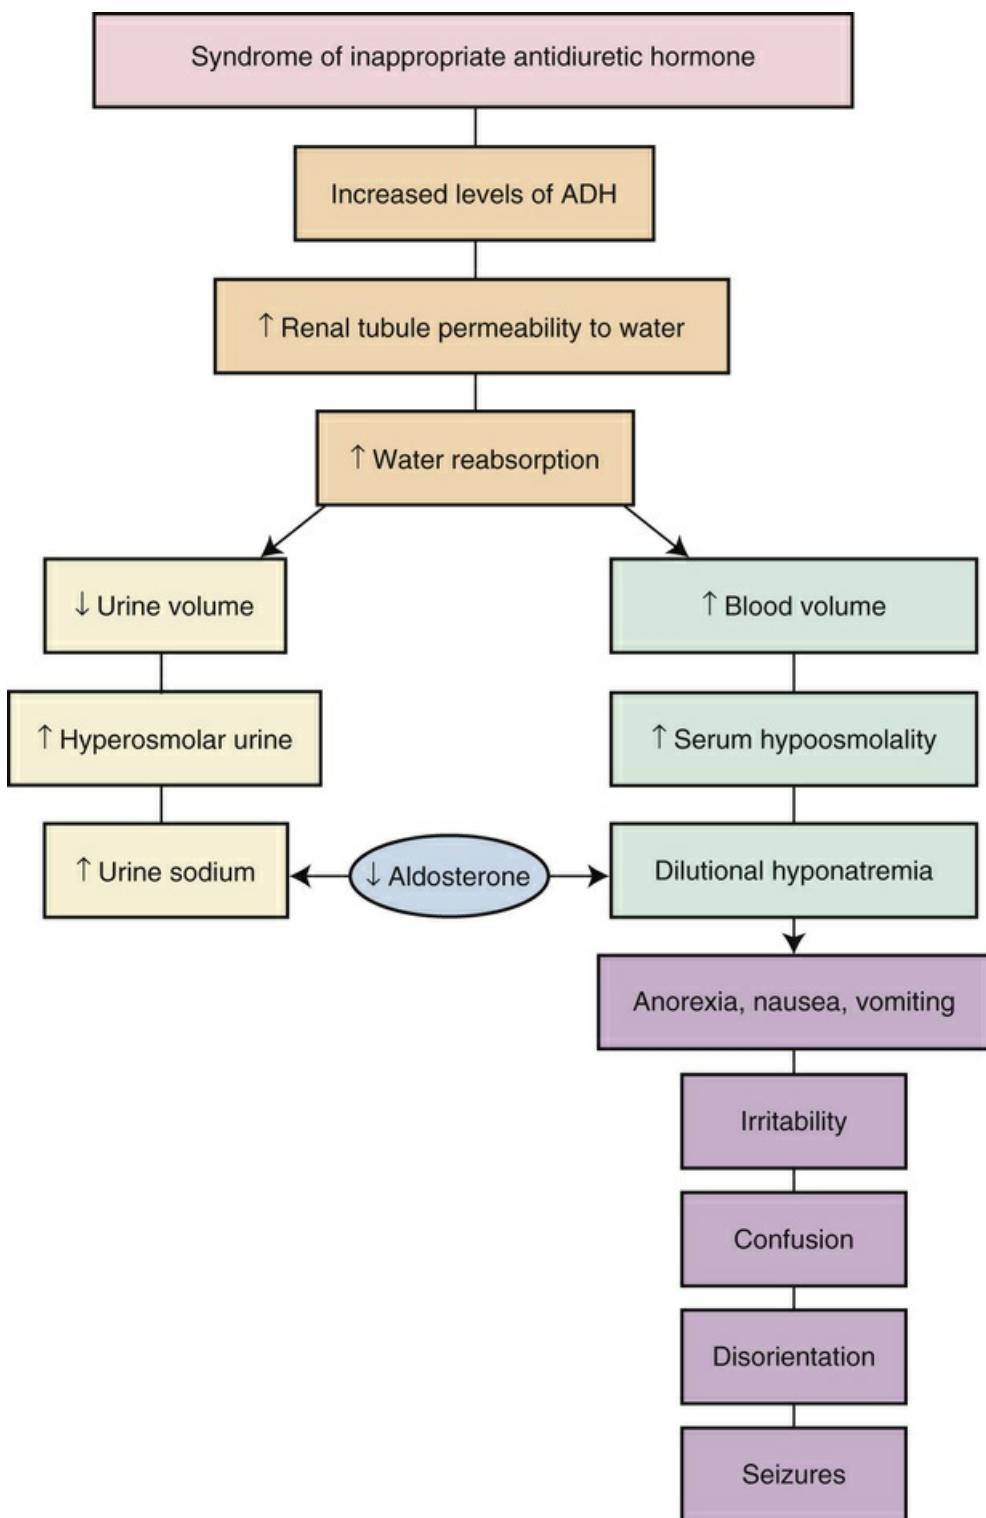

treatment of DI. Oral intake is encouraged to replace fluid losses and is supplemented with intravenous (IV) infusion as needed. In central DI, the hormone of choice to replace insufficient ADH is desmopressin acetate (DDAVP), available orally, IV, or nasally. Other hormone medication choices include vasopressin (Pitressin) via nasal inhalation or by injection. For fluid replacement, hypertonic saline is used, titrated to match the patient's urinary output.

Nursing management focuses on early detection, maintenance of fluid and electrolyte balance, and patient education. Baseline vital signs and weight are important to accurately document and monitor throughout therapy. Strict (hourly) intake and output monitoring are essential to correct fluid losses and to titrate IV fluid replacement.

Syndrome of Inappropriate Antidiuretic Hormone

Etiology and Pathophysiology

Syndrome of inappropriate antidiuretic hormone (SIADH) is the opposite of DI. Excessive amounts of ADH are produced, resulting in fluid retention ([Concept Map 36-2](#)). Numerous factors can cause SIADH, including malignancies and tumors pressing on the pituitary.

CONCEPT MAP 36-2 Pathophysiology of syndrome of inappropriate antidiuretic hormone (SIADH).
ADH, Antidiuretic hormone.

Signs and Symptoms

Signs and symptoms of SIADH include confusion, seizures, and loss of consciousness accompanied by weight gain and edema. **Hyponatremia** from fluid excess, with serum sodium less than 120 mEq/L, occurs frequently. This causes muscle cramps and weakness. Urine output is diminished.

Diagnosis

SIADH is diagnosed by performing urine and serum osmolality tests simultaneously. Results will demonstrate a decreased serum osmolality (less than 280 mOsm/kg) and elevated urine osmolality (more than 100 mmol/kg), which indicates the inappropriate excretion of concentrated urine in the presence of a dilute serum. Other laboratory tests to support the diagnosis include a decrease in blood urea nitrogen (BUN), hemoglobin, hematocrit, and creatinine clearance secondary to hemodilution and elevated urine sodium.

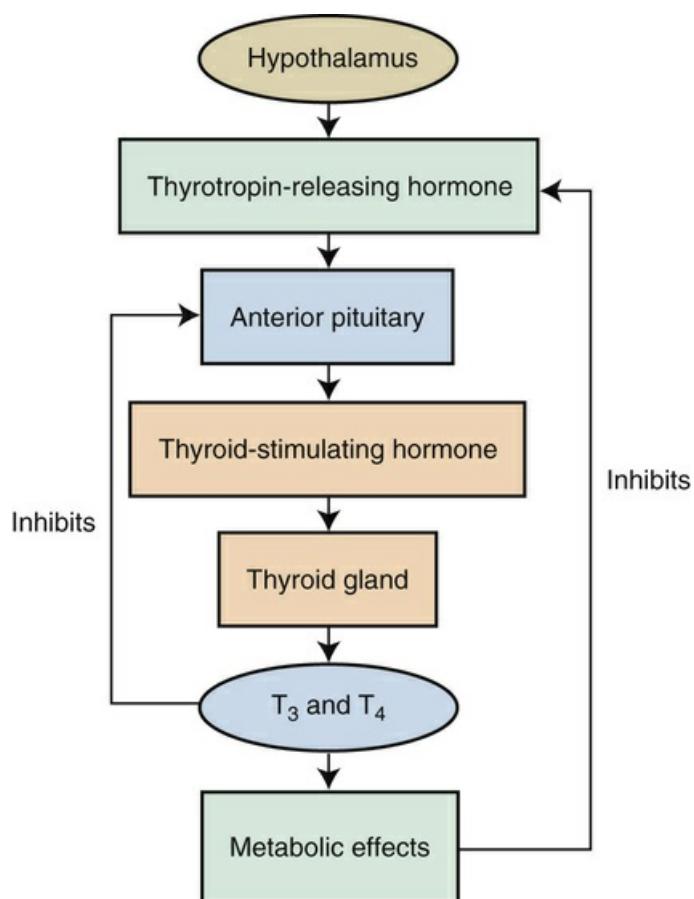

Treatment and Nursing Management

Treatment of SIADH is aimed at correcting the underlying cause; restricting fluids to 500 to 1000 mL/day; and administering sodium chloride, diuretics, and demeclocycline (a tetracycline) to increase excretion of water. Tolvaptan (Samsca) is approved for the treatment of hyponatremia in SIADH. Tolvaptan improves serum sodium levels within 8 hours when given as an IV infusion by blocking the action of ADH; however, there is a danger of overcorrection, and sodium levels need to be closely monitored.

Thorough nursing assessment and data collection are essential to monitor treatment and prevent complications of SIADH. Closely focus on the cardiovascular and neurologic systems and remain alert to the possibility of fluid shifts. Promptly notify the provider of any change in level of consciousness. Electrolytes are monitored closely (as often as several times per day), and daily weights are measured. Hyponatremia produces alteration in neurologic function and requires intervention. Too rapid of correction can result in permanent neurologic deficit. Careful monitoring and implementation of ordered fluids and medications are critical to a good outcome.

Disorders of the Thyroid Gland

Abnormalities in thyroid gland activity and resultant changes in the levels of thyroid hormones are among the most common disorders affecting the endocrine system. The thyroid gland secretes the hormones thyroxine (T_4), triiodothyronine (T_3), and thyrocalcitonin (see [Chapter 35](#)). The secretion of thyroid hormones is regulated by the hypothalamic-pituitary-thyroid control system ([Concept Map 36-3](#)). In other words, all three organs are involved in the closed-loop negative feedback system. Internal conditions, such as low thyroid and norepinephrine (NE) serum levels, can activate the hypothalamus, as can external conditions, such as low temperatures. In response to feedback received by the hypothalamus, thyrotropin-releasing hormone (TRH) is secreted. TRH acts on the pituitary gland, bringing about its release of thyroid-stimulating hormone (TSH). The TSH then acts on the thyroid cells, causing them to release thyroid hormones. When sufficient heat has been produced by increased metabolic activities (if a cold temperature was the stimulus), or when there are sufficient levels of thyroid hormone in the body fluids (if a deficit was the stimulus), feedback to the hypothalamus causes it to stop releasing TRH.

CONCEPT MAP 36-3 Regulation of thyroid hormone secretion by negative feedback control. T_3 , Triiodothyronine; T_4 , thyroxine.

Goiter

Etiology and Pathophysiology

A goiter is a greatly enlarged thyroid gland ([Figure 36-3](#)). One type of goiter is caused by a deficiency of iodine in the diet. Iodine deficiency can be prevented by increasing iodine intake—for example, by using iodized salt. Although the administration of iodine will not cure goiter, it will stop the continued enlargement of the gland. In the United States this is a rare cause of goiter; a

more common cause is an increase of TSH from a lack of thyroid hormone production.

FIGURE 36-3 Goiter. (From Ignatavicius DD, Workman ML: *Medical-surgical nursing: Critical thinking for collaborative care*, ed. 9, Philadelphia, 2016, Saunders.)

Signs, Symptoms, and Diagnosis

Because there may be no systemic symptoms or changes in the metabolic rate of a person with simple goiter, the first sign that is usually noticed is an enlargement in the front of the neck. Later, if the gland continues to grow bigger, it presses against the esophagus and causes some difficulty in swallowing. The goiter also can press against the trachea and interfere with normal breathing. The diagnosis of goiter is established by history and physical examination. Goiter can be associated with increased, normal, or decreased hormone production.

Treatment

If goiter resulting from iodine deficiency is treated early, the growth of the gland can be arrested, and in some cases the enlargement will eventually disappear. Medications prescribed include preparations containing elemental iodine (the iodide ion). If lack of thyroid hormone is causing increased tissue growth of the thyroid gland, supplemental thyroid hormone is given in the form of levothyroxine. A very large goiter that continues to grow and produces local symptoms of pressure—or one that presents the possibility of developing into a malignant growth or a toxic goiter—is surgically removed.

Nursing Management

Iodine preparations should be given well diluted and administered through a straw, because they can stain the teeth. Adverse effects of iodine preparations can include gastrointestinal upset, metallic taste, skin rashes, allergic reactions, and epigastric pain. Patients receiving thyroid supplements should be monitored for signs and symptoms such as tachycardia, palpitations, nervousness, headaches, and fatigue indicating overtreatment. Symptoms of inadequate treatment include weight gain, dry skin, hair loss, impaired memory, and cold intolerance.

Hyperthyroidism

Etiology and Pathophysiology

Patients at greatest risk for hyperthyroidism are adult women between 30 and 50 years of age. Primary hyperthyroidism is the result of an abnormality of function involving the thyroid gland itself and causes excessive circulation of thyroid T_4 and T_3 hormones. However, it is possible for only the T_3 level to be elevated if the patient has **Graves disease** (toxic nodular goiter) or toxic adenoma of the thyroid.

High serum levels of T_4 can be caused by either overactivity of the thyroid gland or by excessive

doses of T₄ given in replacement therapy. Primary hyperthyroidism occurs within the thyroid gland. **Secondary** hyperthyroidism usually is the result of an abnormality in another gland, such as the pituitary gland producing too much TSH and therefore overstimulating the thyroid gland.

Primary hyperthyroidism can result from an autoimmune disorder such as Graves disease, also called toxic goiter. Medications containing iodine, such as amiodarone (an antidysrhythmic heart medication) can predispose to hyperthyroidism. Infections are another possible cause. In addition, smoking is a risk factor for developing hyperthyroidism (Ross, 2014).

Signs and Symptoms

The earliest symptoms of hyperthyroidism may be weight loss (despite a good appetite) and nervousness. Symptoms can vary from mild to severe and may include weakness, insomnia, tremulousness, agitation, tachycardia, palpitations, exertional dyspnea, ankle edema, difficulty concentrating, diarrhea, increased thirst and urination, decreased libido, scanty menstruation, and infertility. The condition sometimes is not diagnosed in its early stages because of the vagueness of the symptoms. In some cases hyperthyroidism is misdiagnosed as a cardiovascular disease, because the symptoms are similar.

Older Adult Care Points

Older adults with hyperthyroidism may exhibit milder signs and symptoms or may exhibit an **atypical presentation**, such as shortness of breath, palpitations, or chest pain. Simple fatigue and slowing down may be the only presentation in this patient population.

If hyperthyroidism is not diagnosed correctly and continues untreated for any length of time, the patient can develop cardiomyopathy, heart failure, and cardiac-related death. The symptoms manifested by a patient with hyperthyroid are the result of an accelerated metabolic rate and a speeding up of all physiologic processes. Emotional upheaval occurs as a result of the action of thyroid hormones on the nervous system. The patient often reports episodes of emotional extremes with uncontrollable crying and depression followed by intense physical activity and euphoria. Patients with hyperthyroidism also exhibit an enlarged thyroid gland (toxic goiter) and abnormal protrusion of the eyeballs, or **exophthalmos** (Figure 36-4).

FIGURE 36-4 Exophthalmos of Graves disease. (From Lewis SL, Heitkemper MM, Dirksen SR, et al: *Medical-surgical nursing: Assessment and management of clinical problems*, ed. 7, St. Louis, 2007, Mosby.)

Diagnosis

Medical diagnosis is based on clinical manifestations of hyperthyroidism and the results of laboratory tests for thyroid hormone levels. One indicator of hyperthyroidism is identified by assessment of the heart rate while the patient is sleeping. A rate that is consistently above 80 beats per minute could signify a toxic state resulting from excessive levels of thyroid hormone. The provider may also order an electrocardiogram (ECG) to evaluate cardiac dysrhythmias and a chest x-ray to determine heart size. A nuclear thyroid scan may be indicated.

Treatment and Nursing Management

Hyperthyroidism may be treated medically by administering radioactive iodine and antithyroid drugs, mild sedatives, and beta-adrenergic blocking agents to control tremor, temperature elevation, restlessness, and tachycardia.

Antithyroid drugs are prescribed as the initial treatment of hyperthyroidism. Methimazole (Tapazole) is the main drug used. The patient must take the antithyroid drug at the prescribed time and strictly according to schedule. Propylthiouracil (PTU) is a second-line therapy because of its hepatotoxicity. These medications block the synthesis of thyroid hormone. Iodine preparations may be given to decrease thyroid hormone secretion.

Radioactive iodine (^{131}I), also known as **ablation therapy**, is the definitive treatment for hyperthyroidism; it destroys thyroid tissue. It is contraindicated in pregnant and nursing women, because it can disable the thyroid gland in the fetus or infant. The main disadvantage of ablation therapy is the possibility of **hypothyroidism** (deficient activity of the thyroid gland) caused by overeffective treatment. The hypothyroidism can occur immediately after treatment or long after it is completed; thus the patient must have ongoing follow-up.

Dosage depends on the size of the gland and the thyroid's sensitivity to radiation. Most patients can be dosed and treated as outpatients. The same radioactive iodine is used for treatment of thyroid cancers, with the dosing being higher, requiring precautions that are more stringent for cancer patients. After treatment, all body fluids can be radioactive for a short time. Because the iodine circulates in the blood and is excreted by the kidneys, precautions must be taken when handling needles, syringes, and other equipment likely to be contaminated with blood and bedpans, urinals, and specimen containers that are likely to be contaminated by urine.

All patients receiving radioactive iodine must be observed for signs of **thyroid crisis** resulting from radiation-induced thyroiditis (discussed later).

Safety Alert

Aspirin Contraindicated in Thyrotoxicosis

Use of acetylsalicylic acid (ASA) is contraindicated in patients with thyrotoxicosis. Aspirin interferes with protein binding and increases the free forms of T_3 and T_4 . ASA is used as an antiplatelet medication for cardiovascular disorders and is commonly found in combination analgesic medications.

Iodine preparations also may be given for a period of 10 to 14 days before surgery of the thyroid to reduce the vascularity of the gland and hormone production, minimizing the danger of releasing large amounts of thyroid hormone into the bloodstream during surgery, and to decrease the risk of hemorrhage.

Because many of the signs and symptoms of hyperthyroidism mimic those of cardiac disease, when caring for an older adult be alert to the possibility that such signs may be indicative of an endocrine disorder rather than a cardiac disorder. Physical and mental rest is extremely important, because physical stress and emotional upset can stimulate greater activity in the thyroid gland. Adequate rest is essential to conserve strength, but it is difficult for a person with hyperthyroidism to relax and get sufficient rest.

The diet of patients with hyperthyroidism should be sufficiently high in calories to meet metabolic needs. This will vary from person to person, but continued loss of weight is an indication that more high-calorie foods are needed. It may be necessary to refer the patient to a dietitian, who can work out a satisfactory diet that helps maintain normal body weight.

Patients who are being treated medically for hyperthyroidism must understand that they have an

illness that requires ongoing medication and frequent monitoring to assess the effectiveness of treatment. Sometimes it is difficult for the patient's family to accept and deal with the emotional outbursts and mood changes that occur when the disease is not under control. Once hormone levels return to the normal range, the mental and physical symptoms should subside.

Nursing interventions for selected problems of patients with hyperthyroidism are summarized in [Nursing Care Plan 36-1](#).

Nursing Care Plan 36-1

Care of a Patient With Hyperthyroidism

Scenario

Mrs. Jackson, age 35 years, has been having symptoms of hyperthyroidism. She complains of feeling "hot and soaked with perspiration all the time." She is 25 lb underweight, even though she reports a "ravenous" appetite. Her vital signs are P 110, bounding; RR 30 and somewhat irregular; BP 170/90. She had a physical examination at her provider's office, and her serum calcium level was 11.5 mg/dL. She was admitted for hypercalcemia and for possible thyrotoxicosis. Mrs. Jackson is very apprehensive, agitated, and irritable.

Problem Statement/Nursing Diagnosis

Anxiety/Anxiety related to excess circulating thyroid hormone as evidenced by nervousness and agitation.

Supporting Assessment Data

Subjective: "I don't understand what is happening to me. I feel so nervous all of the time."

Objective: Wringing her hands, eyes darting around the room, fidgeting in bed.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will verbalize reduction of anxiety and agitation within 3 days of receiving prescribed medication.	Keep environmental stimuli at a minimum.	Excessive stimuli can worsen anxiety and agitation.	Patient exhibits decrease in agitated behavior.
	No visitors other than family as requested by patient. Approach in a calm and unhurried manner.	A calm approach can decrease patient anxiety.	Patient states that she feels "less anxious."
	Provide 30-min rest periods before lunch, in afternoon, and after supper.	Rest can promote sense of calmness.	Took a nap before lunch.
	Administer antianxiety medications as ordered.	Medications can reduce feelings of anxiety.	Goal met.

Problem Statement/Nursing Diagnosis

Insufficient knowledge/Deficient knowledge related to lack of information about disease and treatment.

Supporting Assessment Data

Subjective: States that she does not know anything about hyperthyroidism or its treatment.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will verbalize basic understanding of disease and treatment before discharge.	Explain disease process; reinforce information about diagnostic tests and what to expect for each one.	Basic information about disease increases compliance and contributes to long-term self-management.	Patient verbalized basic understanding of hyperthyroidism.
	Stress importance of compliance and keeping appointments with provider.	Treatment of hyperthyroidism is lifelong.	Patient verbalized the importance of long-term follow-up.
	Encourage questions and help the patient to make a list. Reinforce options, as explained by the provider, for treatment.	Making lists is a self-management strategy that the patient can continue to use when talking to providers or others.	Patient verbalized correct rationale for treatment plan, but decided to ask provider about options. Continue plan.

Problem Statement/Nursing Diagnosis

Altered nutritional status/Imbalanced nutrition: less than body requirements related to increased metabolic rate.

Supporting Assessment Data

Objective: Lost 25 lb over past 6 months, although appetite has increased considerably.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will gain 2 lb/wk when thyroid production is under	Weigh weekly; encourage high-calorie between-meal snacks (e.g., peanut butter, dried fruits).	Weekly weight is more reflective of true weight trends (daily weight tends to reflect water	Patient demonstrated 4-lb weight gain in 10 days but remains less than ideal body weight.

control.	Increase caloric intake to 3000 calories per day. Try to accommodate food preferences. Arrange dietician consult.	gains/losses). High-calorie snacks can be helpful in "sneaking in" extra calories.	Eating peanut butter and wheat toast as a snack. Continue plan.
----------	---	--	---

Problem Statement/Nursing Diagnosis

Potential for injury due to heart damage/*Risk for injury (cardiac muscle) related to excess circulating thyroid hormone and excess serum calcium.*

Supporting Assessment Data

Objective: Thyroid levels: T₃, 230 mg/dL; T₄, 16 mcg/dL; calcium, 16 mg/dL.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will not develop permanent cardiac problems.	Check vital signs q4h.	Increases in pulse and blood pressure may indicate thyroid storm.	Patient's vital signs are BP 130/80, P 85, RR 28, T 100.6° F.
	Assess cardiac function each shift, including ECG monitoring, and watch for symptoms of worsening thyrotoxicosis, such as increased pulse, dyspnea, edema, and rising blood pressure; report as needed.	Hyperdynamic vital signs can be taxing on the heart and must be monitored closely. Alterations in calcium can affect cardiac function.	Patient denies dyspnea.
Patient will have controlled calcium levels within 2 wk.	Medicate with calcium channel blocker as ordered; observe for side effects.	Beta-adrenergic-blocking agents decrease sympathetic tone and decrease stimulation of the heart.	No dysrhythmias present. HR now 70.
Patient will have normal serum calcium by discharge.	Give medication to decrease calcium levels (diuretic) and monitor electrolyte levels.	Loop diuretics increase calcium excretion in the urine.	Patient's calcium level is 9.0 mg/dL; A.M. thyroid levels are pending. Continue plan.

Problem Statement/Nursing Diagnosis

Subjective: States she has been "very moody"; family says that she keeps changing her mind about things.

Supporting Assessment Data

Objective: States she has been "very moody"; family says that she keeps changing her mind about things.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will return to her baseline emotional stability when thyroid production returns to normal.	Assure her that mood swings are manifestations of her thyroid disorder.	Knowledge that emotional lability is disease related can decrease anxiety.	The frequency of emotional episodes has decreased to approximately once per week.
	Help patient to identify signals of mood change and suggest alternative coping strategies.	Early recognition of mood change allows patient to actively control behavior (e.g., feels irritable, so goes to a quiet corner to be alone).	Reports irritation whenever roommate turns on television; has asked the roommate to adjust the sound.
	Establish trusting relationship; be accepting of behavior; spend uninterrupted time with her each shift; display acceptance of her and her behavior.	Acceptance of behavior and spending time with patient increases trust and self-esteem.	Spent 15 min with the patient. She apologized for being "moody." Reassured that this moodiness will pass after the condition is stabilized.

Critical Thinking Questions

- Considering Mrs. Jackson's nervousness and agitation, how would you proceed to implement a teaching session about her hyperthyroidism?
- What specific nutritional suggestions might you offer Mrs. Jackson to help her gain weight?

BP, Blood pressure; *ECG*, electrocardiogram; *P*, pulse; *RR*, respiratory rate; *T*, temperature.

Thyroidectomy

Patients who do not respond well to antithyroid drug therapy, who are unable to take radioactive iodine, or who have greatly enlarged thyroid glands are candidates for a subtotal thyroidectomy. Patients with thyroid malignancy undergo a total thyroidectomy. In the subtotal procedure, two thirds of the glandular mass is removed. The remaining portion of the gland is left intact so production and release of thyroid hormones can continue. For most patients, however, surgery is a treatment of last resort, because the potential complications of hemorrhage, hypoparathyroidism, and vocal cord paralysis can be emotionally devastating. Many patients will be rendered into a state of hypothyroidism because of surgery or radiation therapy that alters thyroid function. It is then necessary to manage their illness with long-term thyroid replacement therapy.

Preoperative Nursing Care

Preoperative care is similar to any major surgery. If the patient appears nervous, tense, and

apprehensive, this should be reported to the surgeon. These symptoms may indicate improper control of the thyroid gland and may predispose the patient to the postoperative complication of “thyroid crisis” (see the following section).

Postoperative Nursing Care

The patient is placed in a Fowler's position (sitting upright to at least 90 degrees) to facilitate breathing and reduce swelling of the operative area. The head is maintained in a neutral position to relieve tension on the sutures. The surgical approach may be a standard incision, minimally invasive video-assisted, or robotic-assisted technique.

The vital signs are checked continuously in the immediate postoperative period, progressing to hourly once the patient is considered to be stable. The patient is watched closely for signs of bleeding and swelling at the operative area, which may cause swallowing difficulty or airway compromise. Any rise in temperature, pulse, or respiration rate should be reported immediately, because it may indicate a high level of thyroxine in the bloodstream. In many hospitals, a tracheostomy set is kept at the bedside of postoperative thyroidectomy patients in case severe respiratory complications develop. Other symptoms to be reported are persistent hoarseness or loss of the voice, which may indicate damage to the vocal cords. **Tetany** (muscular twitching and spasms) and thyroid crisis are other possible complications. These are rare, but be alert for the beginning signs and immediately report observations. Thyroidectomy may be performed as an outpatient procedure for some patients. Patient discharge teaching should include the signs and symptoms of the previously mentioned possible complications.

Tetany actually results from injury to, or accidental removal of, the parathyroid glands. Parathyroid hormone is important in regulating body calcium and phosphorus levels, and a deficiency of parathyroid hormone produces muscle cramps, twitching of the muscles, and, in some cases, severe convulsions from hypocalcemia (see [Chapters 3 and 35](#)). These symptoms represent a medical emergency and must be reported to the provider at once. Treatment consists of intravenous (IV) administration of calcium gluconate during the emergency stage and doses of calcium and vitamin D to maintain calcium balance in the body. The first parathyroid hormone replacement medication is currently in clinical trials ([Cusano et al, 2015](#)).

Thyroid storm (TS), also known as *thyroid crisis* or **thyrotoxicosis**, is another possible complication of thyroidectomy. In the postoperative setting, the condition is caused by a sudden increase in the output of thyroxine caused by manipulation of the thyroid as it is being removed. Newer surgical techniques have made this a rare occurrence. Another cause of TS may be improper reduction of thyroid medication before surgery.

In a patient with hyperthyroidism, TS also can be triggered by other factors unrelated to surgery ([Box 36-1](#)); these patients can also develop TS as a result of consuming an overdose of levothyroxine.

Box 36-1

Causes of Thyroid Storm

- Administration of drugs or dyes containing iodine
- Pregnancy and childbirth
- Myocardial infarction or cardiac emergencies
- Infection
- Severe emotional distress
- Trauma or surgery

The symptoms of TS are produced by a sudden and extreme elevation of all body processes. The temperature may rise to 106° F (41.1° C) or more, the pulse increases to as much as 200 beats per minute, blood pressure elevates, respirations become rapid, and the patient exhibits marked apprehension and restlessness. Unless the condition is relieved, the patient quickly passes from

delirium to coma to death from heart failure.

Assignment Considerations

Changes in Vital Signs

Remind the UAP to report any sudden changes in vital signs (give specific parameters) or behavior (give examples) in patients with thyroid disorders.

Treatment of thyroid crisis must begin immediately after the first symptoms are noticed, rather than waiting for laboratory confirmation. Measures are taken to reduce the temperature; cardiac drugs are given to slow the heart rate; and sedatives, such as a barbiturate, are given to reduce restlessness and anxiety. Adequate fluids must be given to fuel the increased metabolic rate, or profound dehydration may occur.

Safety Alert

Use Caution With Radiology Contrast Studies

Radiocontrast agents have iodine as a base. Imaging studies routinely use these substances. Patients with iodine deficiency are at risk for iodine-induced hyperthyroidism ([Hudzik and Zubelewicz-Szkodzinska, 2014](#)).

Think Critically

What specific assessments would you perform on a patient who returned from having a thyroidectomy 4 hours ago?

Hypothyroidism

Etiology and Pathophysiology

Hypothyroidism can be caused by inflammation of the thyroid gland (thyroiditis) that damages tissue, iodine deficiency, decreased TSH secretion, hypothalamus dysfunction, atrophy of the thyroid gland, or by treatment of hyperthyroidism that results in destroying too many thyroid cells and a resultant deficit of thyroid hormone. Genetic defects can cause congenital hypothyroidism, called *cretinism*. Cretinism is caused by a severe lack of thyroid hormone during fetal life and infancy and is characterized by growth failure. Underactivity of the thyroid gland can also be caused by a pituitary or hypothalamus dysfunction that causes inadequate stimulation of the thyroid, inducing secondary hypothyroidism.

Signs and Symptoms

Children with hypothyroidism have delayed physical and mental growth and become very sluggish within a few weeks after birth. Adults who have **myxedema** (very low thyroid production) have a decrease in appetite but an increase in weight because of a slow metabolic rate. Other signs are bagginess under the eyes and swelling of the face. There is a tendency for patients with hypothyroidism to be lethargic and to sleep for abnormally long periods during the day and night. The speech may be slurred, and the individual will appear sluggish in both mental and physical activities. Other signs and symptoms of hypothyroidism are cold intolerance, constipation and abdominal distention, flatulence, impaired memory, depression, husky voice, thinning eyebrows, hair loss, brittle nails, easy bruising, fatigue, muscle cramps, numbness and tingling, dry skin, and nonpitting edema. Gastrointestinal symptoms are the result of decreased peristaltic activity and can lead to paralytic ileus if untreated.

Older Adult Care Points

Older adults who exhibit lethargy, slow thought processes, and lack of enthusiasm could be

demonstrating signs of hypothyroidism rather than a brain disorder such as dementia. Hypothyroidism is particularly common in older women.

Diagnosis and Treatment

Medical diagnosis is based on clinical signs and symptoms and laboratory testing of serum levels of thyroid hormones and TSH. Hypothyroidism can be treated effectively with replacement of thyroid hormones. The dosage is gradually increased until a proper level has been reached, and then a delicate balance must be maintained so that the patient does not suffer from either hypothyroidism or hyperthyroidism. The results of treatment of hypothyroidism are striking, and most patients show a remarkable abatement of their symptoms. Nurses may not see many cases of hypothyroidism in the hospital setting, because treatment usually does not require hospitalization, however many hospitalized patients are receiving thyroid replacement therapy. Consider how medications and diagnostic testing may alter their usual metabolic control.

Nursing Management

Patients with chronic hypothyroid have very rough and dry skin, and they will need massage with lotions and creams to prevent cracking and peeling of the skin. Provisions for extra warmth must also be made for those who have an increased sensitivity to cold. It is important that the patient receive thyroid medication every day.

Patient Teaching

Self-Care Management of Hypothyroidism

- Take levothyroxine on an empty stomach, because many medications and foods, especially those rich in iron, fiber, calcium, or soy, interfere with absorption.
- Take levothyroxine at the same time each day; morning is usually recommended.
- It may take 6 to 8 weeks to feel benefit or improvement of symptoms.
- Levothyroxine is lifelong therapy; it should never be stopped by anyone except the practitioner who prescribed it.
- Contact your health care provider if you experience unusual bleeding, bruising, chest pain, palpitations, sweating, nervousness, or shortness of breath.
- Report signs and symptoms of myxedema (i.e., dizziness, respiratory distress, low blood sugar, or hypothermia) and hyperthyroidism (i.e., weakness, palpitations, agitation, increased urination, thirst, diarrhea, or insomnia).

Safety Alert

Thyroid Medications

In accordance with The Joint Commission's National Patient Safety Goals, nurses should increase awareness of look-alike, sound-alike products and help patients to recognize the exact name and purpose of their medications. Thyroid medications should not be changed by the patient to the cheapest generic brand, because even slight variations in the level of hormone can be dangerous. Prescriptions should be labeled "NO substitutions."

Do not rush patients with hypothyroid or give them the impression of being annoyed by their sluggishness. Forgetfulness, inability to express oneself verbally, and physical inertia are mannerisms that are a direct result of the thyroid deficiency, and you must recognize them as unavoidable as long as the condition is uncontrolled.

Myxedema Coma

Although rare, **myxedema coma** is life threatening. It can be precipitated in patients with hypothyroid by abrupt withdrawal of thyroid therapy, acute illness, anesthesia, use of sedatives or narcotics, surgery, or hypothermia. Signs and symptoms are loss of consciousness along with hypotension, hypothermia, respiratory failure, hyponatremia, and hypoglycemia. Treatment is IV administration of levothyroxine sodium, fluid replacement, maintenance of an airway and respiration, IV glucose administration, corticosteroids, and warming measures.

Thyroiditis

Etiology and Pathophysiology

Thyroiditis is an inflammation of the thyroid gland. There are three types: acute, such as infection related; subacute, for example, related to upper respiratory viral infection; or chronic, the most common type. **Autoimmune thyroiditis**, also known as **Hashimoto thyroiditis**, is a chronic form that usually affects women between 30 and 50 years of age. The body produces antibodies against the thyroid, which in turn destroy the gland. The reasons behind autoimmune thyroiditis are not fully understood; however, there seems to be a genetic predisposition, and it is more prevalent in people with other autoimmune disorders, such as rheumatoid arthritis.

Signs, Symptoms, and Diagnosis

The patient will experience a painless enlargement of the thyroid gland and may have dysphagia caused by the inflammation. In the initial stages the inflammation will overproduce thyroid hormone, and the patient will display symptoms of hyperthyroidism. Tissue destruction occurs with the autoimmune response, resulting in a hypothyroid condition. Diagnosis is based on laboratory tests, including serum thyroid hormone levels, TSH levels, and radioactive iodine uptake. Needle biopsy of the gland may be performed.

Treatment and Nursing Management

The treatment for chronic thyroiditis is thyroid hormone supplementation to prevent hypothyroidism and suppress TSH secretion. Thyroid function in this disorder is usually normal or low, rather than increased (as in acute thyroiditis). Left untreated, eventually hypothyroidism will develop. The goal of therapy is to decrease the size of the thyroid and prevent hypothyroidism. Surgery to remove part of the gland may be considered. Nursing management focuses on patient teaching and providing for comfort.

Thyroid Cancer

Etiology and Pathophysiology

Thyroid cancer has been diagnosed more frequently in recent years, partially because of increased use of ultrasound for screening. The most common form of thyroid cancer is papillary carcinoma (80%), which occurs most in younger women. This cancer is characterized by a slowly growing tumor that can be present for years before it is diagnosed. The cause of thyroid cancer is unknown but exposure to irradiation for face, head, and neck conditions increases the incidence. Other thyroid cancers include follicular carcinomas, medullary thyroid carcinomas, and anaplastic carcinomas (Sharma, 2015).

Signs and Symptoms

The first sign of thyroid cancer may be a nodule found on a routine physical examination. Only 5% to 10% of nodules are found to be cancerous. Other signs and symptoms of thyroid cancer, such as fatigue, depression, and weight changes, can be easily missed or attributed to other causes.

Diagnosis

The diagnosis of thyroid cancer is made by examination and diagnostic tests. An ultrasound examination is used to assess thyroid size and to locate any nodules. Iodine uptake studies also may be used to check for nodules. **Fine-needle aspiration**, in which a specimen of tissue is taken and

analyzed, is the definitive test.

Treatment and Nursing Management

The treatment for thyroid cancer is thyroidectomy. In some cases, radioactive iodine (ablation) therapy may be used in lieu of surgery to disable the gland (see [p. 844](#)). In 2011 the Food and Drug Administration (FDA) approved vandetanib, which inhibits tumor growth in symptomatic medullary thyroid cancer ([Pazdur, 2013](#)).

Disorders of the Parathyroid Glands

Hypoparathyroidism

Etiology and Pathophysiology

Hypoparathyroidism is most commonly caused by atrophy or traumatic injury to the parathyroid glands. This can occur as a result of accidental removal or destruction of parathyroid tissue during a thyroidectomy, irradiation of the thyroids or parathyroids, neck trauma, or idiopathic (having no known cause) atrophy of the glands. A deficiency of parathormone will result in a drop in serum calcium levels and an increase in phosphorus levels. Patients with chronic renal failure are unable to eliminate dietary phosphorus, and elevated phosphorus levels suppress parathyroid function and result in low calcium levels. There is an inverse relationship between phosphorus and calcium. High phosphorus levels decrease calcium levels.

Signs and Symptoms

Signs and symptoms of hypocalcemia include mild tingling, numbness, muscle cramps, and mental changes, such as irritability. **Chvostek sign** manifests as muscle irritability when the facial nerve is gently tapped. **Trousseau sign** manifests as a carpal spasm, elicited by inflating a blood pressure cuff 20 mm Hg above the systolic blood pressure. Tetany is a serious sign resulting from a lowered serum calcium level. In tetany, muscular twitching and spasms occur because of extreme irritability of neuromuscular tissue. If calcium levels continue to fall, the patient will suffer from convulsions, cardiac dysrhythmias, and spasms of the larynx.

Diagnosis

Medical diagnosis of hypoparathyroidism is established by clinical signs and laboratory data. An electrocardiogram (ECG) may demonstrate abnormalities that can lead to dysrhythmias, heart failure, and hypotension. A CT scan may reveal brain calcifications if the hypocalcemia is chronic. Changes in bone integrity may be seen on radiograph. Other laboratory tests that confirm the diagnosis include serum calcium, total protein, albumin, phosphate, magnesium, vitamin D, parathyroid hormone assay, and urine cyclic adenosine monophosphate (cAMP). Calcium is bound to protein, so alteration in protein levels can affect the serum calcium level.

Treatment and Nursing Management

Acute hypoparathyroidism with tetany is treated with IV calcium gluconate to raise serum calcium levels to normal range. Oral or parenteral administration of calcium salts is used in the acute phase. In chronic hypoparathyroidism, treatment is aimed at restoring and maintaining normal calcium levels in the blood. This can soon be accomplished by parathormone replacement therapy (currently in clinical trials), administration of vitamin D in massive doses to enhance absorption of calcium from the small intestine, and oral administration of calcium salts. Nursing care revolves around electrolyte replacement and patient teaching. Remind the patient that therapy for hypoparathyroidism is lifelong and advise the patient to wear a medical-alert bracelet.

■ Nutrition Considerations

Dairy Products Are High in Phosphorus

Nurses should teach patients with hypoparathyroidism to eat foods high in calcium but low in phosphorus. Milk, yogurt, and processed cheeses are high in phosphorus and therefore are not advised.

Hyperparathyroidism

Etiology and Pathophysiology

Hyperparathyroidism is an endocrine disorder most common in postmenopausal women due to the loss of bone protection from estrogen. Excessive synthesis and secretion of parathormone can occur,

typically as a result of benign enlargement of the parathyroid glands (adenoma) or hyperplasia of two or more glands. Hypercalcemia (calcium level above 10.5 mg/dL) occurs with hyperactivity of the parathyroid glands because the hormone pulls calcium out of the bones. Other causes of hyperparathyroidism are outlined in [Box 36-2](#). Severe hyperparathyroidism is called *Von Recklinghausen disease of the bone*.

Box 36-2

Causes of Hyperparathyroidism

- Parathyroid tumor (benign or malignant)
- Congenital enlargement
- Neck trauma or irradiation
- Vitamin D deficiency
- Chronic renal failure with hypocalcemia
- Lung, kidney, or gastrointestinal tract cancers

Adapted from Ignatavicius DD, Workman ML: *Medical-surgical nursing: Critical thinking for collaborative care*, ed. 6, Philadelphia, 2010, Saunders.

Signs and Symptoms

Signs and symptoms of hyperparathyroidism may be mild or severe; are usually the result of dysfunction of other organs or tissues related to high calcium levels; and include dehydration, confusion, lethargy, arrhythmias, anorexia, nausea, vomiting, weight loss, constipation, thirst, frequent urination, and hypertension. If hypercalcemia exists, there may be skeletal changes, including thinning of the bone and formation of bone cysts. A bone fracture often causes the patient to seek medical attention. The signs of hypercalcemia are manifested in virtually every major system in the body. Hyperparathyroidism and hypoparathyroidism are compared in [Table 36-2](#).

Table 36-2

Comparison of Hyperparathyroidism and Hypoparathyroidism

	Hyperparathyroidism	Hypoparathyroidism
Serum calcium levels	Increased	Decreased
Serum phosphate levels	Decreased	Increased
Bone resorption*	Increased	Decreased
Calcium and phosphate in urine	Increased	Decreased
Neuromuscular irritability	Decreased	Increased (may progress to tetany)

*Bone resorption, Taking calcium from the bone to increase serum calcium.

Diagnosis

Laboratory testing for persistent elevated serum calcium and low phosphate levels helps confirm the diagnosis. Serum parathyroid hormone is the best test for the initial confirmation. Serum albumin is also measured because serum calcium needs to be corrected for low albumin levels. Dual-energy x-ray absorptiometry (DEXA) to evaluate osteopenia or a bone survey for bone resorption may also be ordered (see [Table 32-2](#)).

Treatment

The treatment of hyperparathyroidism will depend on the severity of the symptoms produced by hypercalcemia and hypophosphatemia. Infusions of isotonic sodium chloride and administration of diuretic agents promotes urine excretion of excess calcium; phosphate therapy and calcitonin is given to inhibit calcium release from the bone.

Safety Alert

Caution With Diuretics

Thiazide diuretics should be used cautiously for patients with hyperparathyroidism, because they potentiate hypercalcemia by decreasing urinary calcium loss ([Sterns, 2013](#)).

Surgical removal of a major portion of the parathyroids (subtotal parathyroidectomy) is recommended for patients who have severe systemic disorders associated with excessively high levels of parathormone. A minimally invasive approach is used when imaging studies are able to isolate the involved gland.

Nursing Management

Nursing management for patients on diuretic therapy includes accurate measuring of intake and output (every 2 to 4 hours), daily weight, monitoring of serum electrolytes, ongoing assessment for electrolyte imbalance, and appropriate nursing intervention. The patient may be placed on continuous cardiac monitoring, depending on the degree of the electrolyte imbalances. Postoperative management is similar to that for thyroidectomy.

Disorders of the Adrenal Glands

Pheochromocytoma

Etiology and Pathophysiology

Pheochromocytoma is a rare tumor of the adrenal medulla that secretes **catecholamines** (epinephrine and norepinephrine). It often causes severe hypertension, and if left untreated it can lead to death. Research is demonstrating a genetic link to inherited gene mutations that predispose individuals to the tumor (Blake, 2014).

Signs, Symptoms, and Diagnosis

Signs and symptoms of pheochromocytoma are related to excess catecholamine release. Signs include tachycardia and severe hypertension (as high as 250/150 mm Hg) that can be intermittent or persistent. Profuse diaphoresis, severe headache, palpitations, nausea, weakness, and pallor may also be present.

Pheochromocytoma is diagnosed by measurement of serum catecholamines and 24-hour urine measurement of catecholamine metabolites. CT and MRI may be used to locate the tumor.

Treatment and Nursing Management

Treatment is surgical removal (often laparoscopically) of the tumor (adrenalectomy). Before surgery, the patient may be in hypertensive crisis and require close monitoring of vital signs and administration of IV antihypertensive medications. The patient should be monitored for signs of orthostatic hypotension related to medication therapy.

Adrenocortical Insufficiency (Addison Disease)

Etiology and Pathophysiology

Addison disease is characterized by decreased function of the adrenal cortex resulting in a deficit of all three hormones secreted by the adrenal cortex. The major problems are related to insufficiencies of the mineralocorticoids and the glucocorticoids. The insufficiency of the androgenic hormones can be compensated for by the ovaries and testes.

Insufficient production of the adrenocortical hormones can result from a disorder affecting the adrenal cortex itself (primary insufficiency) or from a disorder affecting the pituitary gland that stimulates adrenal secretion (secondary insufficiency). Disorders causing a primary insufficiency include idiopathic atrophy, inflammation, infection, and nonsecreting tumors of the adrenal cortex. Secondary insufficiency occurs when the pituitary gland fails to secrete ACTH because the gland is underfunctioning or was surgically removed (hypophysectomy) or after abrupt withdrawal of steroid therapy.

Think Critically

What signs and symptoms might you see in a patient who is developing Addison disease after stopping steroid therapy?

Signs and Symptoms

In the early stages of Addison disease, the clinical manifestations may be so vague as to be annoying to the patient but not serious enough to consult a provider. Hence it is easily missed or misdiagnosed. Later, as the hormone insufficiency worsens, there are severe symptoms associated with fluid and electrolyte imbalance and hypoglycemia. Considering the functions of the mineralocorticoids, a major problem is depletion of sodium (hyponatremia), which in turn causes depletion of extracellular fluid and potassium retention (hyperkalemia). The patient experiences generalized malaise and muscle weakness, muscle pain, orthostatic hypotension, and vulnerability to cardiac dysrhythmias.

Insufficiency of the glucocorticoids affects blood glucose levels and causes symptoms of hypoglycemia. There is also decreased secretion of gastrointestinal enzymes, which results in

anorexia, nausea and vomiting, flatulence, and diarrhea. These symptoms, as well as anxiety, depression, and loss of mental acuity, have been correlated to absence of the peaks of cortisol output that normally occur every 24 hours.

Diagnosis

Diagnosis of Addison disease is made by laboratory testing. Blood cortisol and aldosterone levels are evaluated, and an ACTH stimulation test can determine whether the problem lies in the adrenal gland or in the pituitary. CT and MRI scans may be used to locate a tumor, calcification, or gland enlargement. Abnormal serum electrolyte levels (hyponatremia and hyperkalemia), decreased glucose tolerance, elevated white blood cell count (leukocytosis), and abnormally low levels of free cortisol are among the criteria used to diagnose Addison disease (Griffing, 2014).

Treatment

Replacement therapy to provide the missing hormones usually brings about a rapid recovery, but the patient must continue taking the hormones as lifelong therapy. Prednisone is given to replace glucocorticoids; fludrocortisone is a synthetic adrenocortical steroid to replace the mineralocorticoid aldosterone.

Nursing Management

Nursing management of patients with Addison disease includes:

- Intensive care and support during Addisonian crisis when the patient is in a critical condition and in danger of death from fluid volume depletion, hypotension and shock, and impairment of cardiac function.
- Prevention of problems related to fatigue and orthostatic hypotension.
- Alleviation of gastrointestinal problems.
- Instruction of self-care.

Two important nursing measures are to provide both regular feedings throughout the day and adequate rest. The patient may feel well in the morning but may become progressively weaker and fatigued as the day goes on. If fasting is necessary for diagnostic studies or surgery, the patient with Addison disease probably will need IV glucose to prevent profound hypoglycemia. Maintenance doses of glucocorticoids are especially important whenever fasting is required.

Gastrointestinal problems bring on the possibility of altered nutrition due to anorexia, nausea and vomiting, and diarrhea. Specific fluid and electrolyte imbalances are covered in more depth in Chapter 3. Stress—even relatively mild physical or emotional stress—can quickly bring on an Addisonian crisis for a patient with Addison disease. The patient must avoid undue physical stress whenever possible and must learn effective coping mechanisms to deal with emotional stress (Nursing Care Plan 36-2).

Patient Teaching

Managing Addison Disease

Teach the patient about the signs and symptoms of inadequate or excessive steroid levels, the importance of prompt reporting, and the following points:

- The nature of the illness and what can be done to control it.
- The purpose of each medication and the side effects to be reported.
- The importance of taking the medication every day and of never stopping corticosteroids suddenly; they need to be tapered off slowly.
- Signs and symptoms to report to the provider immediately (worsening weakness, hypotension, confusion, infection).
- The importance of contacting the provider so that medication dosage can be adjusted to combat

the effects of stress.

- Diet adjustments to provide food throughout the day and a bedtime snack.
- The importance of following the prescribed diet to prevent gastrointestinal problems.
- Planned rest periods during the day and sufficient sleep at night, as well as prevention of physical stress.
- The need for a medical-alert tag or bracelet stating the patient has Addison disease and is on steroid therapy.

Think Critically

What specific interventions for a patient with Addison disease would you use to help teach the patient to decrease stress or to cope with stress?

Nursing Care Plan 36-2

Care of a Patient With Adrenocortical Insufficiency (Addison Disease)

Scenario

Mr. Cox, age 49 years, is admitted with a diagnosis of adrenocortical insufficiency (Addison disease). He has recently experienced weight loss, weakness, poor coordination, vomiting, changes in skin coloration, and loss of body hair. During initial assessment, Mr. Cox is found to be very irritable and easily upset by questions. His vital signs are BP 90/50, P 70 and slightly irregular, RR 16 and deep. He reports that he feels pretty good when he awakens in the morning but quickly becomes tired and his muscles begin to ache. He is concerned about his weight loss and change in appearance and also has noticed that he has been unable to "think straight." Admission laboratory data: blood glucose, 50 mg/dL; sodium, 90 mEq/L; potassium, 5.6 mEq/L; white blood cell count (WBC), 12,000/mm³.

Problem Statement/Nursing Diagnosis

Fluid volume deficit/*Deficient fluid volume related to low sodium.*

Supporting Assessment Data

Subjective: Feels very tired, weak, and uncoordinated.

Objective: BP 90/50.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient's BP and pulse will be within 10% of his normal baseline within 4 hr of admission.	Obtain vital signs on admission and as required.	Nursing judgment will dictate the frequency of vital signs; unstable patients may need q15min.	BP continues between 90/50 and 100/60. Provider notified. Will repeat BP in 1 hr.
	Monitor for signs of dehydration (i.e., thirst, dry mucous membranes).	Subjective and objective signs and symptoms of dehydration may occur before BP drops.	Reports thirst and dry sensation in mouth. Oral care given. Willing to take ice chips with subjective relief.
	Administer IV and oral fluids as ordered.	Fluid replacement will correct hypovolemia	IV infusing at 125 mL/hr. Oral fluid offered, but refused because of nausea; provider contacted for antiemetic order.
	Initiate I&O and track pattern over several days.	I&O should be balanced; however, in a hypovolemic state, output is likely to be less than input as the fluid balance recovers.	Intake for end of shift 1000 mL of IV fluid and 2000 mL of oral fluid; output 1000 mL of urine and 500 mL of emesis.

Problem Statement/Nursing Diagnosis

Altered electrolyte balance/*Electrolyte imbalance related to insufficient production of mineralocorticoids and glucocorticoids.*

Supporting Assessment Data

Subjective: Reports fatigue, weakness, mental acuity changes.

Objective: Blood glucose, 50 mg/dL; sodium, 90 mEq/L; potassium, 5.6 mEq/L.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will have a stable glucose 70-100 mg/dL. Patient will have normal serum sodium and potassium within 24 hr.	Observe for signs of hypoglycemia (i.e., shakiness, hunger, mental confusion); check fingerstick glucose and report promptly.	Hypoglycemia can be a warning sign of impending Addisonian crisis; brain tissue is very sensitive to low glucose levels.	Patient's blood glucose level is 110 mg/dL.
	Check to see that meals are served on time; provide snacks as needed.	Intake of nutritious foods is important to maintain adequate glucose and sodium levels.	Patient knows signs/symptoms of hypoglycemia. No problems noted at this time.
	Monitor serum sodium and potassium. Watch for signs of hyponatremia (i.e., lethargy, muscle cramps or weakness, headache) or hyperkalemia (i.e., weakness, cardiac dysrhythmias).	Identifying problems with electrolytes in the early phase and acting quickly to restore balance prevents complications.	Provider aware of admission laboratory values and patient condition. Phone order obtained to start an IV with normal saline at 125 mL/hr. Provider will reevaluate patient within the hour.

Problem Statement/Nursing Diagnosis

Altered coping ability/*Ineffective coping related to excess cortisol and mood swings.*

Supporting Assessment Data

Subjective: "Unable to think straight."

Objective: Very irritable and impatient; serum cortisol results pending.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will develop effective coping mechanisms; patient will use relaxation techniques before discharge.	Teach relaxation techniques and supervise practice; work with patient on other ways to decrease stress in daily life.	Effective coping skills are an important determination of how successfully a patient will manage a long-term illness.	Patient practicing relaxation exercise. Verbalized three methods (listening to music, writing in a journal, talking to brother) to decrease stress.
	Help patient to identify sources of stress and set priorities.	Identifying and prioritizing stressors helps patient to make a plan; indicates what type of resources are needed.	Identified job deadlines and financial concerns as major stressors. Decided to call his boss. Financial representative will come to see patient.
	Encourage verbalization of fears and concerns.	Verbalization of fears and concerns can be cathartic; identifies need for mental health referral.	Verbalized that chronic disease would "ruin everything." Agrees to talk to a mental health counselor.
	Discuss alterations in body image and changes that can be expected with therapy.	Anticipatory discussions provide time and opportunity to develop coping strategies.	Sees self as an active person who likes sports and social outings; discussed how the disease affects his self-image and ways that he can continue to participate. Continue plan.

Problem Statement/Nursing Diagnosis

Insufficient knowledge/*Deficient knowledge related to illness, medications, and necessary changes in lifestyle.*

Supporting Assessment Data

Subjective: States that he knows nothing about Addison disease, its diagnosis, or treatment; unfamiliar with corticosteroid therapy.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will verbalize understanding of medications and dosage schedule before discharge.	Answer questions and discuss medication purpose, side effects, and dose. Emphasize the importance of not suddenly stopping the medications.	Medication compliance is key for treating the disease and preventing complications.	Patient verbalized dosing schedule and the basic action of each medication. Wants a repeat teaching session about side effects.
Patient will verbalize plans for obtaining adequate rest before discharge.	Help him develop a balanced schedule that allows for periods of rest, work, social interaction, and recreation.	Once hormone levels are normalized, the patient with Addison can expect to resume normal activities, as long as rest periods are integrated into the schedule.	Patient described his intention to integrate rest with desired activities.
	Provide written instructions for symptoms of insufficient corticosteroid medication and those of excess medication.	Written instructions increase the retention of vital information. Patient must be able to self-identify and report problems.	Patient verbalized three signs and symptoms of insufficient hormone (weakness, fatigue, diarrhea) or excessive hormone (hunger, thirst, increased urination).
	Instruct him to report either set of symptoms to the provider promptly so medication can be adjusted.	Patient must know when to contact provider so that problems can be prevented.	States that he is happy to know that medication adjustment can be done to address stress and symptoms before things get out of control.
	Instruct to report periods of extra stress (minor illness, such as a cold, an emotional upset, or unusual physiologic or psychological stress) so that medication can be adjusted.	Patient must be aware that stress will have greater effect on his life because of Addison's disease.	Tells family to help him recognize minor physical or emotional stresses that he may overlook because those things are "part of my normal crazy life."
	Instruct him to wear a form of medical-alert identification with data concerning steroid therapy.	Medical-alert identification provides lifesaving information if he is ever unable to give health history.	States that he is a little embarrassed to wear jewelry that "publicly announces my problem," but agrees to seriously consider it.

Critical Thinking Questions

1. In implementing the patient teaching plan for Mr. Cox, when would you perform your patient teaching, and why?
2. Mr. Cox has put together a proposed activity schedule for after he is discharged from the hospital. He lives in a rural community and must go to the post office to get his mail each day. He asks if you would mind looking at the schedule and giving him feedback on it. The schedule

reads: 8 A.M. breakfast, 9 A.M. walk dog, 10 A.M. gardening, 11 A.M. walk to post office/get mail, 12 P.M. lunch, 1 P.M. nap, 2 P.M. watch television, 3 P.M. daughter over for visit. What if any suggestions would you give Mr. Cox, and why?

BP, Blood pressure; I&O, intake and output; IV, intravenous; P, pulse; RR, respiratory rate.

Acute Adrenal Insufficiency or Adrenal Crisis

The presence of cortisol in the body allows the blood vessels to function properly in response to epinephrine and other catecholamines by constricting. Conditions that decrease the amount of circulating cortisol interfere with the ability of the blood vessels to constrict. Patients with Addison disease have a decrease or absence of adrenal cortical secretions, primarily cortisol. Because cortisol is released in response to ACTH from the pituitary gland, abnormalities in ACTH release can also cause a reduction in circulating cortisol. Physical stress from the flu or other infection, or from surgery, can send a patient with Addison disease into **Addisonian crisis**. Another situation that can cause symptoms of acute lack of cortisol results from prescribed treatment. Steroids are given to treat many autoimmune diseases, and the body becomes dependent on this outside source of cortisol. If administration of the medication is stopped abruptly, acute cortisol insufficiency will occur.

Decreased levels of cortisol result in decreased sensitivity of the blood vessels to sympathetic stimulation. It is the sympathetic stimulation that maintains vascular tone. Lack of vascular tone causes vasodilation, producing hypotension. Cortisol helps maintain blood pressure (BP) and cardiovascular function, so the acute lack of it will decrease BP and produce typical signs and symptoms of shock. Other symptoms include severe abdominal, flank, or leg pain; tachycardia; nausea; and change in level of consciousness.

Treatment

Closely monitor vital signs, blood glucose, and sodium and potassium levels. Adrenal crisis requires immediate fluid replacement therapy to prevent irreversible shock. Intravenous hydrocortisone is given along with sodium, fluids, pressors, and dextrose until blood pressure becomes stable. Hyperkalemia must also be addressed with IV insulin and glucose, or calcium chloride (or calcium gluconate) and by monitoring arrhythmias and the patient's intake and output. Hypoglycemia is treated with IV glucose and with glucagon as needed; blood glucose is monitored every hour.

Excess Adrenocortical Hormone (Cushing Syndrome)

Etiology and Pathophysiology

Cushing syndrome is a rare disorder. The symptoms typical of Cushing syndrome are manifestations of excess levels of the hormones from the adrenal cortex. The condition can be caused by:

- Excessive secretion of ACTH by the pituitary, which may result from faulty release of corticotropin-releasing factor (CRF) from the hypothalamus or a pituitary adenoma.
- A secreting tumor of the adrenal cortex.
- Ectopic production of ACTH by tumors outside the pituitary, such as lung cancer.
- Iatrogenic Cushing syndrome from prolonged use of steroid therapy (the most common cause).

Signs and Symptoms

The signs and symptoms of Cushing syndrome are caused by excessive levels of cortisol ([Figure 36-5](#)). They include painful fatty swellings in the intrascapular space (buffalo hump) and facial area (moon face), an enlarged abdomen with thin extremities, bruising after even minor traumas, impotence, amenorrhea, hypertension, and weakness from abnormal protein catabolism with loss of muscle mass.

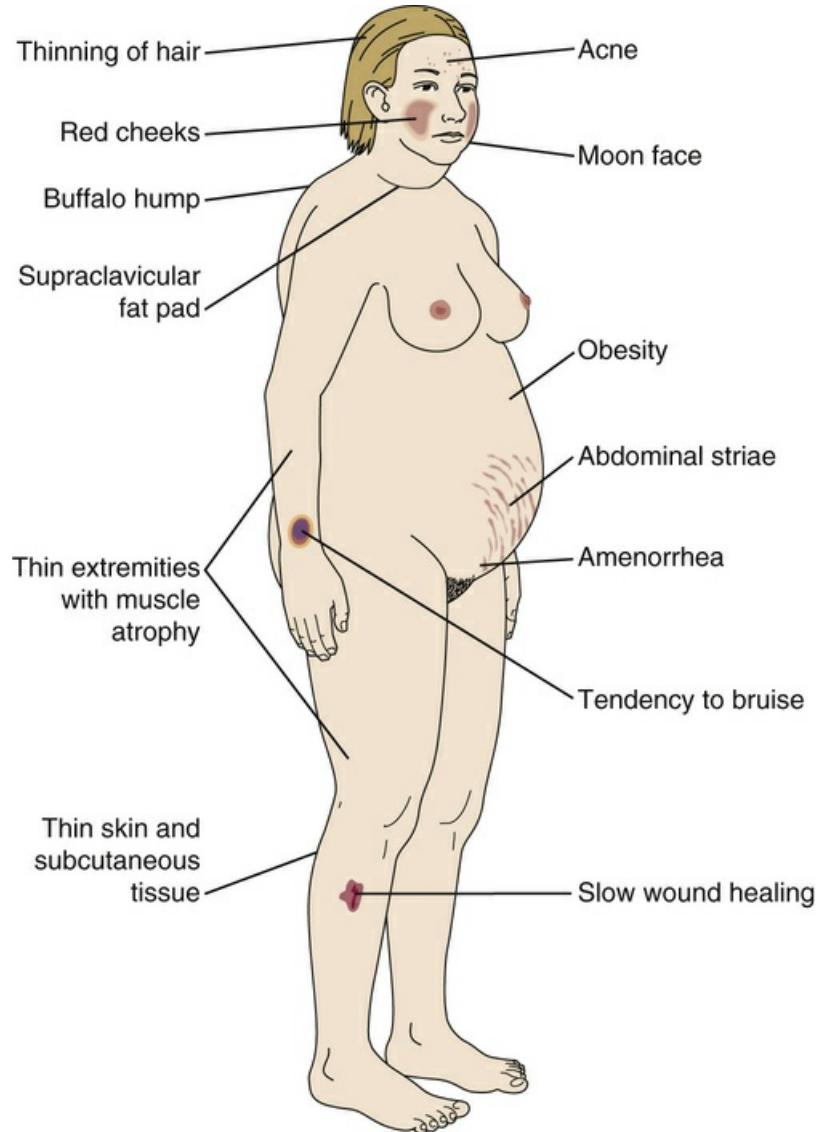

FIGURE 36-5 Common characteristics of Cushing syndrome.

Unusual growth of body hair (hirsutism) can occur in women with Cushing syndrome, and streaked purple markings in the abdominal area can occur because of collections of body fat. Patients with Cushing syndrome who have a familial predisposition to diabetes mellitus commonly develop type 2 diabetes from the anti-insulin, diabetogenic properties of cortisol.

Diagnosis

The diagnosis of Cushing syndrome is established by laboratory findings indicating consistently high levels of free plasma cortisol rather than the usual 24-hour fluctuations. A 24-hour urine test should be performed. If cortisol is elevated, a dexamethasone suppression test should be ordered: for the test, the patient is given a steroid at night, and blood and urine cortisol levels are then measured in the morning. Evening serum and salivary cortisol levels and a dexamethasone-corticotropin-releasing hormone test help with the diagnosis.

Treatment

Pituitary Cushing syndrome can be treated by microsurgery on the pituitary gland. If Cushing syndrome is arising from an adrenal tumor, adrenalectomy is indicated. In this instance replacement of glucocorticoids is necessary. When surgical intervention does not restore normal cortisol levels, medications or radiation may be used.

Clinical Cues

Secondary Cushing syndrome produced by long-term cortisone therapy is often reversible if the medication is tapered off and stopped. However, most people taking cortisone are taking it for other health disorders and cannot discontinue it, so management of Cushing syndrome symptoms is initiated. Steroids should never be taken for a condition other than the specific health disorder for which steroids are prescribed (Box 36-3).

Box 36-3

General Nursing Implications for the Administration of Corticosteroids

When giving a corticosteroid drug:

- Question the patient about history of peptic ulcer, glaucoma, cataracts, diabetes, or psychiatric problems (these conditions may contraindicate the use of steroids).
- Take an extensive drug history and seek specific drug information; many medications interact with steroids.
- Take baseline vital signs and particularly note blood pressure before the start of therapy; steroids may elevate the blood pressure.
- Assess for signs of infection before starting the therapy, because steroids may mask the signs and symptoms of infection.
- Check dosage very carefully and administer only the amount ordered. Spread topical ointment or cream very sparingly.
- Never stop steroid therapy abruptly; such abrupt withdrawal may cause death in a patient who has been on long-term therapy.
- Advise that increased stress, such as infection or surgery, may cause acute adrenal insufficiency.
- Give a daily dose in the morning.
- When not contraindicated, give a diet low in sodium and high in potassium.
- Give oral doses with food to decrease gastrointestinal irritation; medications for gastrointestinal protection are indicated.

Regarding possible side or adverse effects of the drug:

- Assess for side effects when patient has been on glucocorticoid therapy for more than 10 days.
- Monitor older adults for signs of osteoporosis. Give vitamin D and recommend weight-bearing exercise to prevent osteoporosis.
- Assess for changes in muscle strength.
- Watch for signs of depression in patients on high-dose steroid therapy.
- Monitor for signs of hypokalemia, such as nausea, muscle weakness, abdominal distention, and irregular heart rate.
- Monitor blood sugar of diabetic patients closely; glucocorticoids may cause hyperglycemia.
- Check blood pressure regularly during therapy to monitor for hypertension.
- Observe stool for signs of gastrointestinal bleeding.

- Monitor weight, because steroids may cause increased appetite and weight gain.
- Instruct to report slow healing of wounds to the provider.
- Advise patients on long-term steroid therapy that they should have regular checkups for glaucoma and cataracts.

Teach the patient to:

- Take oral doses in the morning with food.
- Not discontinue the drug abruptly but taper down the dosage before stopping it, and only with the approval of the practitioner who prescribed it.
- Be aware that increased hunger and overconsumption could cause weight gain.
- Watch for signs of hypokalemia, such as muscle weakness, fatigue, anorexia, and irregular heartbeat.
- Take the drug only as prescribed.
- Eat foods such as fresh and dried fruits, juices, potatoes, meats, and nuts that are high in potassium.
- Report signs of Cushing syndrome, such as moon-shaped face, puffy eyelids, edema in the feet, increased bruising, dizziness, bleeding, and menstrual irregularity.
- Carry a medical-alert card and wear a bracelet indicating steroid therapy when on long-term steroids.
- Avoid people with infections and stay away from crowds, especially during cold and flu season.
- Advise all other providers and dentists about steroid therapy.
- Be aware that more insulin may be needed if diabetic.
- Be aware that antibody response from immunization may be reduced while taking steroids; live-virus vaccines should not be used.
- Use aspirin and other NSAIDs cautiously; they will increase the risk of gastrointestinal bleeding when taken during steroid therapy.
- Be aware that steroids decrease the effect of barbiturates, phenytoin, and rifampin and that the doses of these drugs may need to be increased.
- Have clotting time monitored closely when taking an anticoagulant at the same time as the steroid.
- Be aware that taking steroids along with potassium-wasting diuretics may cause hypokalemia; increase potassium intake in diet.

NSAIDs, Nonsteroidal anti-inflammatory drugs.

Nursing Management

The nursing care of patients with Cushing syndrome is primarily concerned with helping them cope with the many systemic problems caused by the disorder. Assist the patient with psychosocial concerns presented by emotional **lability** (continually changing) and depression when these occur. The patient needs assurance that with proper treatment the symptoms will improve within 2 to 12 months. In some patients hypertension and glucose intolerance may continue to need management.

Community Care

Nurses in long-term care facilities must be alert for signs of thyroid dysfunction, especially among their older adult female patients. The nurse often is the one to notice subtle changes in the patient that have occurred over many months.

Nurses can be instrumental in preventing secondary Cushing syndrome by cautioning patients to seek means of treatment other than long-term steroid therapy for arthritis or allergies. The nurse must teach patients receiving a new prescription for steroids that this medication must be tapered, never stopped abruptly.

Get Ready for the NCLEX® Examination!

Key Points

- A pituitary tumor secretes GH and antagonizes the effect of insulin. Treatment consists of hormone therapy or surgery.
- Hypofunction of an endocrine gland typically mandates lifelong hormone therapy.
- Hypofunction of the pituitary gland is characterized by a decrease in pituitary hormones and metabolic and sexual dysfunction.
- DI can occur as a result of decreased production of ADH and can lead to hypernatremia, dehydration, and coma. Replacement of fluid, electrolytes, and hormones is required.
- In SIADH, excessive amounts of ADH are produced, resulting in fluid retention. Treatment includes correcting the underlying cause, restricting fluids, and administering medications. Cardiovascular and neurologic systems, electrolytes, and weight should be monitored.
- Signs and symptoms of hyperthyroidism are the result of an accelerated metabolic rate, although older adults may have milder or opposite symptoms. Ablation therapy and thyroidectomy are standard treatments.
- Hypothyroidism causes a decrease in appetite and an increase in weight. Myxedema coma can be precipitated by abrupt withdrawal of thyroid therapy, acute illness, or other stressors.
- The most common type of thyroiditis is autoimmune or Hashimoto. Treatment includes thyroid hormones or surgery.
- Thyroid cancer occurs most often in younger women. Treatment includes ablation therapy, thyroidectomy, or both.
- Hypoparathyroidism can occur from removal or destruction of parathyroid tissue. Treatment includes administration of calcium and vitamin D.
- Hyperparathyroidism is characterized by excessive synthesis and secretion of parathormone. Therapies include infusions of sodium chloride with diuretics, phosphate, and calcitonin; subtotal parathyroidectomy may be performed. Nursing care includes monitoring intake and output, weight, and electrolytes.
- Pheochromocytoma is a potentially fatal adrenal medulla tumor; treatment is surgical removal of the tumor.
- In Addison disease, there is decreased function of the adrenal cortex and a deficit of all hormones. Symptoms include severe fluid and electrolyte imbalances and hypoglycemia.
- Cushing syndrome involves excess levels of adrenal cortex hormones; it may be treated surgically.

Review Questions for the NCLEX® Examination

1. A 50-year-old man outputs 15 L of urine within a 24-hour period. He has poor skin turgor with low blood pressure and increased heart rate. The nurse would plan to administer which medication?

1. Furosemide (Lasix)
2. Desmopressin acetate (DDAVP)
3. Regular insulin
4. Spironolactone (Aldactone)

NCLEX Client Need: Pharmacological Therapies

2. A 45-year-old man has muscle cramps and weakness. He is weak and confused. Serum sodium is 115 mEq/L. The nurse should report the condition and obtain an order to:

1. give hypertonic (3%) IV saline.
2. encourage fluid intake.
3. infuse hypotonic intravenous fluids.
4. administer vasopressin.

NCLEX Client Need: Physiological Adaptation

3. A 35-year-old woman reports episodes of emotional extremes with uncontrollable crying and depression followed by intense physical activity and euphoria. She complains of drying of the eyes and difficulty swallowing. Her symptoms confirm a nursing problem of altered coping. What is a cause for this diagnosis?

1. Parathyroid hormone deficiency
2. Excessive thyroid hormone secretion
3. Deficient estrogen production
4. Growth hormone deficiency

NCLEX Client Need: Physiological Adaptation

4. A patient received large doses of radioactive iodine (^{131}I) for hyperthyroidism. Which nursing intervention(s) should be included? (Select all that apply.)

1. Monitor vital signs.
2. Restrict fluids.
3. Encourage low-fat, high-fiber diet.

4. Properly handle contaminated materials.
5. Encourage physical activity.

NCLEX Client Need: Reduction of Risk Potential

5. A nurse is caring for a patient after a thyroidectomy. What should the nurse monitor for? (*Select all that apply.*)

1. Bleeding and swelling
2. Hypothermia
3. Increase in pulse
4. Difficulty swallowing
5. Difficulty breathing

NCLEX Client Need: Reduction of Risk Potential

6. A patient complains of severe muscle cramping and muscle twitching after a thyroidectomy. The following orders are obtained. Place in priority order the actions of the nurse.

1. Seizure precautions.
2. Administer calcium gluconate.
3. High calcium diet.
4. Place on ECG monitor.

NCLEX Client Need: Reduction of Risk Potential

7. The nurse is reviewing the medications that each of her patients will receive during the shift. Which patient is likely to receive levothyroxine?

1. Patient who has von Recklinghausen disease
2. Patient who has hypothyroidism
3. Patient who has hyponatremia
4. Patient who has Graves disease

NCLEX Client Need: Pharmacological Therapies

8. A 25-year-old woman complains of amenorrhea with weakness, easy bruising, and painful, fatty swelling on the back. Which assessment question would be most appropriate to ask this patient?

1. Have you been taking steroid therapy for a prolonged period?
2. Have you been taking any medications that contain iodine?
3. Have you been taking lithium for several years?
4. Have you had a recent pregnancy with postpartum bleeding complications?

NCLEX Client Need: Pharmacological Therapies

9. A nurse provides patient instructions regarding taking iodine preparations. It is important for the nurse to include which instruction(s)? (*Select all that apply.*)

1. "Dilute the preparations well."
2. "Use a straw to prevent staining of the teeth."
3. "Watch for easy bruising."
4. "Report severe epigastric pain."
5. "Anticipate a metallic taste."

NCLEX Client Need: Pharmacological Therapies

10. A nurse is caring for a patient with adrenocortical insufficiency (Addison disease). Which set of laboratory values would be the primary interest for this patient?

1. Serum sodium, white blood cell count, and blood glucose
2. Serum calcium, serum phosphate, and vitamin D level
3. Urine osmolality, plasma osmolality, and urine specific gravity
4. Serum T₄, serum T₃, and thyroid-stimulating hormone

NCLEX Client Need: Physiological Adaptation

Critical Thinking Questions

Scenario A

Mrs. Timms has a tentative diagnosis of hyperthyroidism. She is 45 years old, 5 feet 7 inches tall, and weighs 102 lb.

1. What subjective and objective signs and symptoms would you expect Mrs. Timms to present during nursing assessment?
2. How would you prepare Mrs. Timms for diagnostic laboratory tests for thyroid function?
3. If Mrs. Timms' provider decides to treat her condition with large doses of radioactive iodine, what special nursing care will she require?
4. What other forms of therapy are used to treat hyperthyroidism?

Scenario B

Mr. Lau, age 37 years, is receiving adrenocorticoid hormones as replacement therapy for Addison disease.

1. What kinds of problems does insufficiency of the adrenal cortex hormones bring about?
2. What should be included in your instructions to Mr. Lau to help him manage his illness?

Scenario C

Mrs. Josten, age 48 years, is hospitalized for a cholecystectomy. She has Cushing syndrome, as well as gallbladder disease. She is 35 lb overweight and depressed.

1. What kinds of problems is Mrs. Josten likely to have as a result of her Cushing syndrome?
2. What would be your concerns in the immediate postoperative period?
3. What would you want to include in your discharge teaching plan?

Scenario D

A patient complains of fatigue, constipation, cold intolerance, flatulence, hair loss, and dry skin. You suspect that the patient may have a thyroid problem.

1. What other questions could you ask this patient?
2. What laboratory tests is the provider likely to order and what are the normal values for those tests?
3. The patient is prescribed levothyroxine. What teaching points should you share about the medication?

CHAPTER 37

Care of Patients With Diabetes and Hypoglycemia

Objectives

Theory

1. Compare and contrast the two major types of diabetes mellitus.
2. Analyze the four factors that influence the development of diabetes mellitus.
3. Explain the signs and symptoms of an insulin reaction (hypoglycemia) and discuss appropriate nursing interventions.
4. Summarize the acute and long-term complications of poorly controlled diabetes mellitus.
5. Identify sources of support and information for people with diabetes and their families.

Clinical Practice

6. Teach a person newly diagnosed with diabetes about the disease, treatment, and self-care.
7. Perform a focused nursing assessment and gather data for the management of type 1 and type 2 diabetes mellitus.
8. Interpret the results of laboratory tests used in the diagnosis and management of diabetes mellitus.
9. Assess for and gather data related to signs and symptoms that might indicate that a patient with diabetes is in early ketoacidosis.
10. Teach a patient how to recognize and self-treat hypoglycemia.

KEY TERMS

Diabetes Mellitus and Hypoglycemia

Diabetes Mellitus

Diabetes mellitus is a group of diseases in which there is disturbance in metabolism and use of glucose that is secondary to a malfunction of the beta cells of the pancreas. Beta cells are responsible for making insulin. Because insulin is involved in the metabolism of carbohydrates, proteins, and fats, diabetes mellitus is not limited to a disturbance of glucose homeostasis but alters other body functions as well.

Diabetes mellitus results in the body's failure to metabolize sugars and starch. Sugars accumulate in the blood and urine, and the by-products of alternative fat metabolism (ketones) disturb the acid-base balance of the blood, causing a risk of coma or death.

Nutrition Considerations

Whole Grains and Bran

Cho and colleagues (2013) found that consumption of whole grains, cereal fiber, and bran was associated with a lower risk for developing type 2 diabetes, cardiovascular disease, and obesity.

Types of Diabetes Mellitus

Nearly 291 million Americans (approximately 9.3% of the population) have diagnosed diabetes mellitus, and millions more have diabetes and do not know it. The cost of treating diabetes in the United States is approximately \$176 billion a year (National Diabetes Association, 2014).

Table 37-1 summarizes the major characteristics of various forms of diabetes mellitus. Type 1 diabetes—formerly known as *insulin-dependent diabetes mellitus* (IDDM)—accounts for about 5% to 10% of all cases. Type 1 diabetes occurs when the body's immune system destroys insulin-producing beta cells. There is no known way to prevent type 1 diabetes. People who have type 1 diabetes require injections of **exogenous** (from outside the body) insulin to maintain life, because they produce little or no **endogenous** (inside the body) insulin on their own. In general, people with type 1 diabetes are more prone to a serious complication, **ketosis**, associated with an excess production of ketone bodies, leading to **ketoacidosis** (metabolic acidosis). Moreover, type 1 diabetes is more likely to develop early in life. In fact, type 1 diabetes was formerly called *juvenile diabetes* or *ketosis-prone diabetes* because of its typical early onset and potential for ketoacidosis.

Table 37-1
Clinical Categories of Diabetes Mellitus and Characteristics

TYPE	CHARACTERISTICS
Type 1	Little or no endogenous insulin is produced. New patients can be any age but usually are young. Patient must receive exogenous insulin and follow prescribed diet and exercise program. Renal, cardiovascular, retinal, and neurologic complications are likely if disease is not kept under tight control.
Type 2	Patients rarely develop ketosis but may develop hyperglycemic, hyperosmolar syndrome (HHS). Patients vary in need for exogenous insulin. Oral anti-diabetic medications are given to help regulate blood glucose level. New patients are usually older than 30 years, and most are obese. Disorder often responds to diet and exercise.
Latent autoimmune diabetes (LADA) (slow onset type 1 diabetes or type 1.5 diabetes; type 1 diabetes, according to the World Health Organization)	Patients are typically not overweight, have no signs of metabolic syndrome, and may have a history of autoimmune disease. Patients demonstrate rapid failure of oral hypoglycemic drugs. Insulin should be started within 1 year of diagnosis.
Other specific types of diabetes with various causes	Types include drug- or chemically induced diabetes, diseases of the exocrine pancreas (cystic fibrosis), and genetic defects in the action of insulin or beta cell function.
Gestational diabetes	Occurs only during pregnancy. After pregnancy, women with gestational diabetes (2%–10% of pregnancies) have a 35% to 60% chance of developing diabetes within 5–10 years.

Type 2 diabetes—formerly called *non-insulin-dependent diabetes mellitus* (NIDDM)—makes up 90% to 95% of all known cases of diabetes. Type 2 diabetes is believed to begin with **insulin resistance**, in which insulin interaction with glucose becomes less efficient, and therefore glucose metabolism is abnormal. More insulin is produced by the pancreas to maintain cellular metabolism. Type 2 diabetes has a tendency to develop later in life than does type 1, and patients with type 2 rarely develop diabetic ketoacidosis. Box 37-1 lists the signs and symptoms of type 1 and type 2 diabetes. Factors associated with development of type 1 and type 2 diabetes are listed in Box 37-2.

Cultural Considerations

Ethnicity and Type 2 Diabetes

Type 2 diabetes is being diagnosed more frequently in children and adolescents, particularly in American Indians, African Americans, and Hispanic/Latino Americans.

Box 37-1

Symptoms of Type 1 and Type 2 Diabetes

Type 1

- Extreme thirst (polydipsia)
- Frequent urination (polyuria)
- Extreme hunger (polyphagia)
- Rapid loss of weight
- Irritability
- Weakness and fatigue
- Nausea and vomiting

Type 2

- Possibly polydipsia, polyuria, and polyphagia
- More commonly excessive weight gain
- Family history of diabetes mellitus
- Poor healing of scratches, abrasions, and wounds
- Blurred vision
- Itching
- Drowsiness
- Increased fatigue
- Tingling or numbness in the feet

Box 37-2

Factors Associated With Development of Type 1 and Type 2 Diabetes

Type 1

- Family history: genetic predisposition
- Previous infectious disease
- Race: more common in whites, American Indians/Alaska Natives less common in African Americans, Asians, or Hispanics

- Presence of islet cell antibodies in the blood

Type 2

- Older age
- Obesity
- Family history of type 2 diabetes
- History of gestational diabetes
- Impaired glucose metabolism
- Physical inactivity
- Race/ethnicity (African Americans, Hispanic/Latino Americans, American Indians, some Asian Americans, Native Hawaiian/Pacific Islanders)

Data from U.S. Department of Health and Human Services (USDHHS), Centers for Disease Control and Prevention: *National diabetes fact sheet: General information and national estimates on diabetes in the United States*. Atlanta, Ga., 2014, USDHHS.

Latent autoimmune diabetes (LADA) is a form of type 1 diabetes, according to the World Health Organization. Other names for this condition are *slow-onset type 1 diabetes* or *type 1.5 diabetes*. It is believed that the presence of islet cell antibodies in the blood (which are not present in healthy individuals) will eventually destroy the beta cells, and insulin production will cease. Patients with LADA are usually not overweight, have no signs of **metabolic syndrome**, and may have a history of personal or familial autoimmune disease. The diagnosis is based on three criteria: (1) onset after age 30 years, (2) islet cell antibodies circulating in the blood, and (3) insulin is not required sooner than 6 months after diagnosis. Patients can be misdiagnosed as having type 2 diabetes. Rapid failure of oral hypoglycemic drugs suggests LADA. Evidence-based management suggests that metformin can be used in the early phase, and insulin should be started within 1 year of diagnosis; both may offer some protective effects against the destruction of the beta cells, whereas sulfonylureas may hasten destruction of beta cells and therefore are not recommended (Poudel, 2012).

Gestational diabetes may occur as a result of the stress of pregnancy. It may be treated with diet, oral hypoglycemia agents, or insulin. After delivery, the condition must be reevaluated; approximately 35% to 60% of women with gestational diabetes go on to be diagnosed with type 2 diabetes in the years after delivery. The baby also carries an increased risk of type 2 diabetes later in life (Patel, 2014).

Etiology and Pathophysiology

At least four sets of factors influence the development of diabetes mellitus: genetic, metabolic, microbiologic, and immunologic.

Genetic factors are included in the etiology of diabetes, because diabetes tends to run in families. The risk of having some form of diabetes increases in proportion to the number of relatives who are affected, the genetic closeness of the relatives, and the severity of their disease.

Metabolic factors involved in the etiology of diabetes are many and complex. Emotional or physical stress can unmask an inherited predisposition to the disease, probably as a result of glucogenesis induced by increased production of hormones from the adrenal cortex (especially the glucocorticoids). Perhaps even more significant than metabolic factors is the association of type 2 diabetes and obesity. About 80% of patients with type 2 diabetes are obese (more than 20% above their ideal body weight), and there is a higher incidence of type 2 diabetes in people who lead a sedentary life and eat a high-calorie diet. **With weight reduction and increased physical activity, blood glucose can be restored to normal levels and maintained there—hence the importance of diet and exercise in the management of type 2 diabetes.** In type 2 diabetes there also seems to be a relationship to aging and a reduction in the function of the pancreatic beta cells and how they synthesize insulin.

Think Critically

What is one way in which you or your family members might decrease the risk of type 2 diabetes in later life?

Type 1 diabetes is classified as an autoimmune disorder. The immune system causes destruction of the insulin-secreting beta cells of the pancreas. When 80% to 99% of the cells have been destroyed, hyperglycemia develops. Some forms of type 1 diabetes may be related to the viral destruction of beta cells. It is not known if the viral infection initiates or accelerates autoimmunity causing beta cell damage ([Coppieters et al, 2012](#)).

Signs, Symptoms, and Diagnosis

The American Diabetes Association (ADA) recommends screening all adults for type 2 diabetes, especially those who are overweight and have one or more additional risk factors, starting at age 45 years, to be repeated every 3 years. Either hemoglobin A_{1c} (A_{1c} or Hb A_{1c}), fasting plasma glucose (FPG), or 2-hour 75-g oral glucose tolerance test (OGTT) are appropriate screening methods ([ADA, 2014](#)).

In addition to laboratory tests (see [Chapter 35](#)), the health care provider depends on clinical signs and symptoms of diabetes mellitus to establish a diagnosis. The classic symptoms of diabetes mellitus, regardless of type, are related to an elevated blood glucose level, or **hyperglycemia**. Hyperglycemia increases the concentration of the intravascular fluid, raising its osmotic pressure and pulling water from the cells and tissues into the blood. This causes cellular dehydration and the loss of glucose (**glycosuria**), electrolytes, and water in the urine. Cellular dehydration causes thirst and a resultant increased intake of water (**polydipsia**) and diuresis with increased urination (**polyuria**). Hunger (**polyphagia**) is the result of the body's effort to increase its supply of energy, even though the intake of more carbohydrates does not meet the energy needs of the cells.

Clinical Cues

Classic signs and symptoms of diabetes mellitus are polydipsia, polyuria, and polyphagia.

Fatigue and muscular weakness occur because the glucose needed for energy is not metabolized properly. Weight loss in patients with type 1 diabetes occurs for two reasons: (1) the loss of body fluid and (2) in the absence of sufficient insulin, the body begins to metabolize its own proteins and stored fat. The oxidation of fats is incomplete, and fatty acids are converted into ketone bodies and acetone. When the kidney is unable to handle accumulated ketones in the blood, ketosis occurs. The overwhelming presence of the strong organic acids in the blood lowers the pH and leads to a severe and potentially fatal acidosis. The metabolism of body protein when insulin is not available causes an elevated blood urea nitrogen (BUN) level. People with diabetes are prone to infection, delayed healing, and vascular diseases. The increased risk for infection is thought to be partly a result of decreased normal function of leukocytes and abnormal phagocyte function but is primarily from the hyperglycemic environment. Another contributing factor to infection and delayed healing may be decreased blood supply to the tissues because of atherosclerotic changes in the blood vessels. An impaired blood supply means a deficit in the protective cells brought by the blood to a site of injury.

Safety Alert

Immunizations

Because patients with diabetes are susceptible to infectious diseases, it is recommended that they regularly receive pneumonia and flu vaccinations.

Think Critically

If a friend complained of thirst, fatigue, and frequent urination, what questions would you ask? What would you suggest this person do?

Management of Diabetes

There is no cure for diabetes mellitus; the goal is to maintain blood glucose and lipid levels within normal limits and to control these factors to prevent complications. Studies have demonstrated that there are benefits of tight **glycemic control** (control of glucose in the blood) for people with both type 1 and type 2 diabetes. Patients attempting tight control follow an intensive therapy plan of blood glucose testing multiple times a day and insulin injections or an insulin pump. There are some risks associated with perfect control of blood glucose levels, and “tight control” is not indicated for every patient. The most serious control issue is hypoglycemia, or insulin reaction. Real-time continuous glucose monitoring (CGM) can be done through measurement of interstitial glucose, which is fairly close to plasma glucose. Some insulin pumps have CGM capabilities and can provide insulin as programmed to respond to changes in glucose levels.

Research has demonstrated that lowering A1C levels to 6.5% is associated with decreased microvascular complications (eye, kidney, and nerve diseases) of diabetes. If the patient is older and very frail or if the life expectancy is short, the American Geriatrics Association recommends an A_{1c} of 8% (Kirkman et al, 2012).

The protocol for control of diabetes mellitus is highly individualized and depends on the type of diabetes a person has, age, general state of health, ability to follow the prescribed regimen, and acceptance of responsibility for managing illness, along with a host of other factors.

The overall goal of diabetes management is achieved when fasting blood glucose stays within normal limits, A_{1c} tests show that blood glucose has stayed within normal limits from one testing period to the next, the patient's weight is normal, blood lipids remain within normal limits, and the patient has a sense of health and well-being.

Older Adult Care Points

Older adults experience hypoglycemia more quickly than do younger people, and older adults are more prone to hypoglycemic episodes. Older adults may progress to dangerously low levels of blood glucose before signs and symptoms are obvious. Severe hypoglycemia in the older adult can precipitate myocardial infarction, angina, stroke, or seizures. For this reason, “tight” control may not be the best plan for older adults.

Diet.

Diet is the cornerstone of diabetic treatment. Weight gain is common in persons with type 2 diabetes, because of high caloric intake and decreased availability of endogenous insulin to fully use ingested food. Weight gain can make a patient with type 2 diabetes more insulin resistant. In many cases, people with type 2 diabetes can control their blood glucose by reducing caloric intake and increasing physical exercise. There is no such thing as a “typical” person with diabetes, and because diabetes is an unstable and changing process, each patient's needs will change from time to time. A person can eat the “perfect” breakfast 3 days in a row, which results in a “perfect” postprandial (after-meal) blood glucose value, only to eat the very same breakfast the next day and have a high blood glucose measurement. This can be frustrating for the patient. The strategies that are effective in managing diabetes can be altered by many factors (e.g., stress, illness, activity, health beliefs), and the strategies that are effective for one person with diabetes may not be effective for someone else.

Medical nutrition therapy (MNT) is now recommended for all persons with either type 1 or type 2 diabetes. A registered dietitian (RD) or a certified diabetes educator (CDE) performs an in-depth assessment of the type of diabetes, height-to-weight ratio, usual dietary intake, food preferences, exercise level, and daily schedule. A range of interventions are considered when designing a plan that is individualized for the patient. These interventions include reduced fat intake, carbohydrate counting, simplified meal plans, healthy food choices, individualized meal planning strategies, exchange lists, **insulin-to-carbohydrate ratios** (adjusting insulin doses to match carbohydrate intake), physical activity, and behavioral strategies (ADA, 2014). In general, MNT is geared toward providing adequate nutrition with sufficient calories to maintain normal body weight and control of cholesterol, and to adjust the intake of food so that blood glucose is kept within safe limits.

Meal plans include diet guidelines consistent with recommendations for healthy adults. For patients with diabetes, distribution of calories is important for glycemic control. Breakfast calories should be 20% of the daily allotment, with lunch at 35%, dinner 30%, and late evening snack 15%. If

the patient chooses to eat sweets and they are substituted for carbohydrates and do not exceed 10% to 35% of total energy intake, it does not have a negative effect. Proteins should make up 15% to 20%; for patients with **diabetic nephropathy** (kidney disease secondary to high blood glucose level), protein intake of 1 g/kg of body weight is recommended. Meals should include 14 g of fiber per 1000 kilocalories, which is the recommendation for the general public. Reduction of saturated fats, *trans* fats, and dietary cholesterol also improves cardiovascular outcomes ([Academy of Nutrition and Dietetics, 2014](#)).

Clinical Cues

Emphasis should be placed on the positive aspects of the diet—on the foods allowed rather than those that are forbidden. A patient should not be made to feel guilty about having difficulty staying on the diet or the times when she “cheats” and eats foods that are not allowed.

Cultural preferences must be considered when devising meal plans. One of the most effective means of helping a person with diabetes follow the prescribed diet is by teaching about food values and how they affect diabetes. Initially, three or four teaching sessions performed by the RD or CDE lasting 45 to 90 minutes are recommended, with annual follow-up as a minimum. The ADA and the American Dietetic Association have worked together to devise simplified methods of calculating a diabetic diet and planning meals for a person with diabetes. Organizations such as the ADA and the Joslin Diabetes Center, affiliated with Harvard Medical School, have instructive material (see Online Resources at the end of the chapter) available for patient teaching.

Older Adult Care Points

Weight loss is seldom a goal for older adults with type 2 diabetes unless weight is more than $1\frac{1}{2}$ times normal for height and frame. Older adults are more susceptible to nutritional deficiencies from teeth problems, illness, and decreased appetite. Diet is typically managed by reducing concentrated sugars and by adhering to a meal schedule.

Think Critically

How would you obtain accurate data about what your patient with diabetes is eating each day?

Exercise.

Physical exercise is an important part of managing diabetes. Muscular activity improves glucose utilization for energy and improves circulation. In addition to lowering blood glucose levels by “burning up” the glucose, exercise makes the insulin receptors on cells more sensitive to the hormone, and thus improves utilization of the available glucose. Exercise has been shown to improve glycemic control in type 2 diabetes. Because diabetic control also considers blood lipid levels, exercise contributes to that control by reducing triglyceride levels and increasing high-density lipoprotein (HDL) levels. People with type 1 diabetes may decrease their cardiovascular risk with regular exercise even though it does not contribute to control of blood sugar.

The exercise program should be designed for the individual patient. The plan should consider the age and overall physical condition of the patient, ability to carry out the exercises regularly, how well controlled the diabetes is, and baseline blood glucose. Exercise can rapidly lower blood glucose levels and cause serious hypoglycemia.

All exercise programs should begin with milder forms of exercise and gradually increase until the patient's level of tolerance or the desired therapeutic effect is reached. A program should not be started until the blood glucose is under control. The exercise program should be planned so that the exercises are performed at the same time every day, preferably after a meal, when the blood glucose is highest. Blood glucose should be checked before beginning to exercise. The patient is encouraged to wear a medical-alert bracelet ([Figure 37-1](#)) and to exercise with a friend who knows the signs, symptoms, and treatment of hypoglycemia.

Patient Teaching

Home Treatment for Hypoglycemia

Patients should have an emergency plan and supplies for treating low glucose. When signs of hypoglycemia are present and the patient is able to swallow, give one of the following to provide 15 to 20 g of glucose or simple carbohydrates:

- $\frac{1}{2}$ cup (4 oz) of juice or regular soda (not diet)
- 1 cup (8 oz) of nonfat or 1% milk
- 6 or 7 hard candies, such as Life Savers (not sugar-free)
- 1 small box of raisins (2 tablespoons)
- Three glucose tablets
- 1 tablespoon of honey, sugar, or corn syrup
- 1 small tube of cake icing (2 oz) or glucose gel

Follow up with a longer-acting source, such as crackers and cheese or a meat sandwich
If the patient is unable to swallow (groggy or unconscious):

- Turn the patient onto the side.
- Administer 1 mg of glucagon by injection after mixing the solution in the bottle until it is clear.
Call 911 if unable to give injection.
- If the patient does not awaken within 15 minutes, give another dose of glucagon and inform a health care provider of the situation immediately.
- If a health care provider cannot be contacted, call 911 or the local emergency service.

Clinical Cues

Patients should be advised to check with their health care provider before starting an exercise program. Certain activities may not be advised if there are complications. For example, patients with neuropathy, retinopathy, or renal insufficiency may be unable to safely balance, see, or perform rigorous or strenuous activities.

Older Adult Care Points

Physical limitations may discourage older adults with diabetes from exercising. Older patients with diabetes are at risk of developing hypoglycemia up to 24 hours after exercising if the exercise is too strenuous. Walking, swimming, or stationary bicycle riding are considered to be among the safest activities for this group. Exercise should begin slowly and build up to 30 to 45 minutes, three or four times a week. The gradual increase helps prevent hypoglycemia, stress fractures, and cardiovascular complications.

FIGURE 37-1 Medical-alert bracelets.

Glycemic control during exercise.

General guidelines for exercise include practicing good foot care and wearing appropriate shoes and socks. This is very important if there is peripheral neuropathy resulting in decreased sensation. Some types of exercise can increase blood glucose by the release of epinephrine, but most will decrease blood glucose. Managing blood sugar during exercise is individualized to the patient and whether type 1 or type 2 diabetes is present. Gradual increase in activities and consultation with the provider are necessary for safe implementation of an exercise program. Key guidelines for safe exercise include knowing blood glucose before exercise. If blood sugar is low, a carbohydrate snack (20 to 40 g based on body weight) should be consumed before starting. Snacks during activity should be used to prevent hypoglycemia. The amount and frequency will be determined by the type and duration of exercise. A liquid or other readily absorbed source of carbohydrate is recommended.

Performing exercise when insulin or an oral antidiabetic agent is at its peak of action can bring on an acute hypoglycemic reaction. Eating a piece of fruit before even light exercise, if done between meals, also can help prevent hypoglycemia in people with type 1 diabetes. Once a patient begins to follow a regular exercise program, the insulin dosage and diet may need to be revised. In general, the patient may need to take less insulin and to increase caloric intake with regular exercise. Keeping a daily record of exercise, along with weight, insulin dosage, and blood glucose levels, can help motivate the patient to continue exercise.

Health Promotion

Insulin and Exercise

Advise patients to avoid injecting insulin into an area that will soon receive extra exercise (e.g., the leg). The abdomen is a good site for insulin injection, because absorption is steady, rapid, and not affected by exercise.

Oral hypoglycemic agents.

Oral hypoglycemic agents (OHAs) or antidiabetic agents may be prescribed for patients with type 2 diabetes to manage their blood glucose levels. These medications are not a form of oral insulin; pharmacologically, they are from completely different classes of medications. There are several major categories of OHAs that act in different ways to help achieve blood glucose control. Information about these medications can be found in [Table 37-2](#). Many of these individual medications are combined and sold under a variety of brand names.

Safety Alert

Sulfa Drug Allergy

Because the sulfonylureas are from the same family of drugs as the sulfonamide antibiotics, they must be given with caution to persons known to have an allergy to sulfa drugs.

Table 37-2
Oral Hypoglycemic Agents

GENERIC NAME (BRAND NAME)	MAIN SITE OF ACTION	HOW THEY CONTROL BLOOD GLUCOSE	OTHER CONSIDERATIONS
Biguanides			
Metformin (Glucophage) Also available in combination with other OHAs	Liver	Keep liver from releasing excessive insulin; make muscle cells more sensitive to insulin	Do not cause hypoglycemia or hyperinsulinemia Do not lead to weight gain Contraindicated in renal failure, liver disease, and acidosis
Alpha-Glucosidase Inhibitors			
Acarbose (Precose) Miglitol (Glyset)	Intestine	Reduce demand for insulin by slowing absorption of complex carbohydrates, resulting in less of a blood glucose "spike"	Contraindicated in people with inflammatory bowel disease or other intestinal diseases
Thiazolidinediones			
Pioglitazone (Actos) Rosiglitazone (Avandia)	Muscle cells	Make muscle cells more sensitive to insulin; decrease liver production of glucose	Contraindicated in people with congestive heart failure Actos and Avandia have black box warning for cardiac risk
Sulfonylureas (Long-Acting)			
Glimeperide (Amaryl) Glipizide (Glucotrol) Glyburide (DiaBeta, Micronase, Glynnase PresTab) Tolazamide (Tolinase) Tolbutamide (Orinase)	Pancreas	Stimulate pancreas to secrete more insulin	Quick action can cause hypoglycemia Contraindicated in advanced kidney or liver disease, or for those with sulfa allergies
Meglitinides			
Nateglinide (Starlix) Repaglinide (Prandin)	Pancreas	Stimulate insulin secretion, but shorter acting than sulfonylureas	Must be taken immediately before eating Lower risk of hypoglycemia than sulfonylureas
Dipeptidyl Peptidase-4 Inhibitors (DPP-4 Inhibitors)			
Sitagliptin (Januvia) Saxagliptin (Onglyza) Linagliptin (Tradjenta) Alogliptin (Nesina)	Endocrine system	Enhance a natural body system called the incretin system, which helps regulate glucose by affecting alpha and beta cells in the pancreas	May cause delayed gastric emptying (can affect absorption of other medications) Reduced dosage may be required in patients with renal impairment, because medication is excreted via the kidneys
Sodium-Glucose Cotransporter 2 Inhibitors (SGLT2)			
Canagliflozin (Invokana) Dapagliflozin (Farxiga)	Kidney	Blocks reabsorption of glucose in the kidneys	Do not use in renal failure Can cause fluid loss from glycosuria
Bile Acid Sequestrants			
Colesevelam (Welchol)	Digestive system	Used for altering cholesterol levels. Also can decrease blood glucose levels, the mechanism is poorly understood.	Can cause flatulence and constipation.

OHAs, Oral hypoglycemic agents.

Patients receiving OHAs should know that these medications do not eliminate the need for following their diet and exercise program. Some may be under the impression that if they go off their diet and indulge themselves, they can just take more pills to compensate. Others who have been on a diet and exercise program for a time and then have an OHA prescribed for them think it is acceptable to stop planning their meals and exercising regularly. All OHAs are capable of producing gastric irritation, nausea, vomiting, and diarrhea. Liver damage with jaundice, bone marrow depression, and allergic skin reactions may result in some patients. During illness and change in routine, insulin may be added to inpatient treatment. Most patients with type 2 diabetes controlled by OHA medications can return to their usual medication regimen after the acute episode is resolved and will not need long-term injectable insulin.

Clinical Cues

Metformin is the preferred drug for type 2 diabetes, so many patients take this OHA. Metformin should be held before surgery or a procedure requiring contrast media and for 48 hours afterward until renal function is verified.

Insulin therapy.

Insulin therapy can be prescribed for patients with either type 1 or type 2 diabetes. The goal of insulin therapy is to closely mimic **basal insulin**, which is the amount of insulin that would normally be produced by the pancreas throughout the day to maintain a healthy blood sugar level between meals. The pancreas also produces extra insulin after meals (**postprandial**). The health care provider can use a variety of rapid-acting, short-acting, intermediate-acting, and long-acting insulins that best suit the individual patient (Table 37-3). A single daily injection of intermediate- or long-acting insulin, or a combination insulin (such as Humulin 70/30 that combines short- and intermediate-acting insulins), can be used for some patients. The multiple daily injection (MDI) regimen is frequently prescribed and offers the advantage of being more physiologically appropriate. MDI combines short- and intermediate-acting insulins, injected two or more times a day. The patient could also be placed on an intensified regimen. This regimen relies on the patient's ability to accurately perform blood glucose monitoring. The basal dose, again, would be

intermediate- or long-acting insulin. A **bolus dose**, or **correction dose**, of short- or rapid-acting insulin is used to manage elevations in blood glucose and bring the next blood glucose measurement into range.

Clinical Cues

If a patient is on a **sliding scale** of insulin based on fingerstick glucose results and receives **rapid-acting** insulin before meals, make sure the food tray is in front of the patient before giving the insulin to help prevent hypoglycemic events.

Clinical Cues

If regular insulin and longer-acting insulin are to be mixed in one syringe, the regular insulin is drawn up first to prevent any contamination of the regular bottle of insulin with the longer-acting variety. “Clear to cloudy” is an easy way to remember which insulin to draw up first. The clear (regular) insulin is drawn up first, followed by the cloudy (longer-acting) insulin.  **Remember, every insulin dose must be verified by another nurse as it is drawn up, every time.** This habit will also help you meet the National Patient Safety Goal to increase the safety of administering medications.

 **Table 37-3**

Common Types of Insulins: Onset, Peak, and Duration of Action

PREPARATION	BRAND NAME	ONSET (Hr)	PEAK (Hr)	DURATION (Hr)
Rapid Acting				
Insulin aspart injection	NovoLog	0.25	1-3	3-5
Insulin lispro injection	Humalog	0.25	0.5-1.5	5
Insulin glulisine injection	Apidra	0.3	0.5-1.5	3-4
Human insulin inhalation powder	Afrezza	0.25	0.75-1.25	2-3
Short Acting				
Regular human insulin injection	Humulin R	0.5	2-4	5-7
	Novolin R	0.5	2.5-5	8
Buffered regular human insulin injection	Velosulin BR	0.5	1-3	8
Intermediate Acting				
Isophane insulin NPH	Humulin N Novolin N	1.5	4-12	16-24+
	ReliOn N	1.5	4-12	24
Insulin zinc suspension (Lente)	Novolin L	1	6-8	5.7-24
Insulin detemir injection	Levemir	1	6-8	5.7-24
Long Acting				
Insulin glargine injection	Lantus	2-4	None	24
Combination Insulin				
70% insulin aspart protamine suspension/30% insulin aspart injection	NovoLog Mix 70/30	0.25	1-4	24
75% insulin lispro protamine suspension/25% insulin lispro injection	Humalog Mix 75/25	0.25	1-2	16-20
70% human insulin isophane suspension (NPH)/30% human insulin injection (regular)	Humulin 70/30 Novolin 70/30 ReliOn 70/30	0.5	2-4	14-24
50% human insulin isophane suspension (NPH)/50% human insulin injection (regular)	Humulin 50/50 Novolin 50/50	0.5	3-5	24

Adapted from Ignatavicius DD, Workman ML: *Medical-surgical nursing: Critical thinking for collaborative care*, ed. 6, Philadelphia, 2010, Saunders.

Insulin cannot be taken orally or given via a feeding tube, because it is destroyed by gastric juices. Inhaled insulin was trialed in the late 1990s and was on the market in the early 2000s and then discontinued. An inhaled rapid-acting insulin has recently received FDA approval. The insulin is dispensed in a device much like the inhaled powders for lung disease. Insulin pens, filled with insulin, are another alternative to the traditional syringe-and-needle apparatus. The patient selects the correct dose on a dial, and the insulin is delivered by a small needle at the end of the pen.

Safety Alert

Insulin Pen Injectors

Patients must be careful when dialing the dose of insulin into a pen injector. If performed incorrectly, the numbers of the dosage will be transposed (e.g., 52 units instead of 25 units). This could potentially happen if the pen is held in the left hand, or if the number scale is held upside down.

Injectable insulin continues to be the most common delivery method, so it is critical that nurses be

educated in all aspects of injectable insulin therapy. Insulin injections are rotated within one body area to enhance absorption. Insulin enters the bloodstream at different speeds when given at different sites. The abdomen has the quickest absorption rate, followed by the upper arms. The thighs and buttocks have the slowest absorption, unless the injection is given before exercise when blood flow to those areas will be increased. Patients are given charts showing the places on the arms, legs, buttocks, and abdomen where insulin can be injected (Figure 37-2). They are then encouraged to keep a daily record of injection sites to help remember which sites have been used and to prevent the problem of altered or erratic absorption.

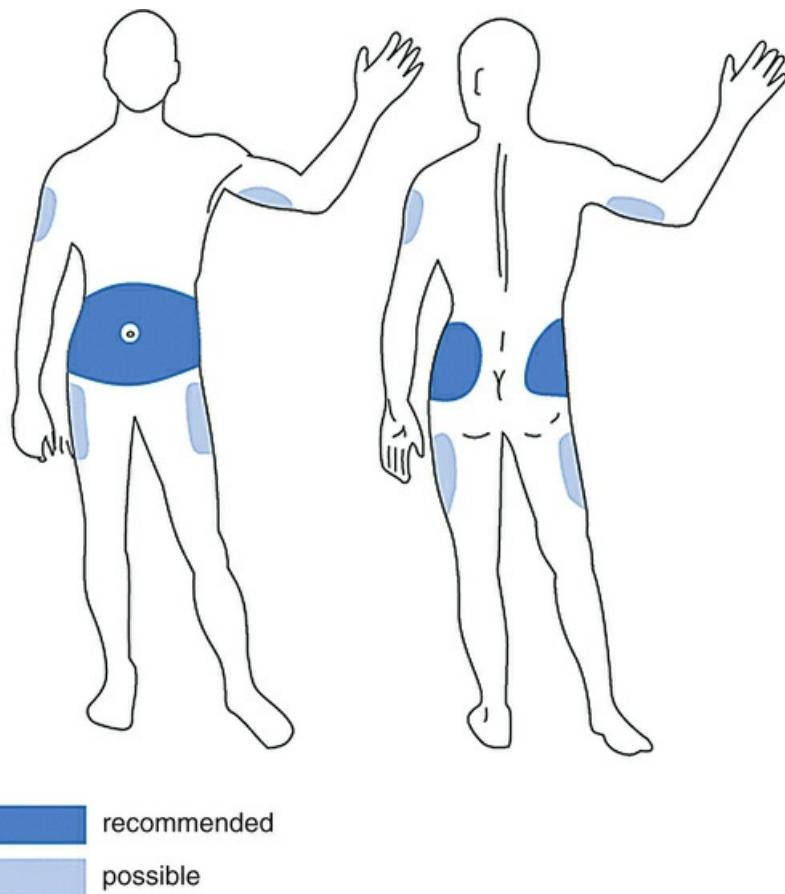

FIGURE 37-2 Rotation sites for injection of insulin. (Courtesy ACCU-CHEK® is a registered trademark of Roche.)

Insulin requirements change as metabolic needs are altered by diet, exercise, age, and even changes in seasons. In the summer, for example, many people are outdoors and exercising more than during the winter months. Also, as a person grows older, the level of physical activity may decrease. Insulin requirements also are altered when the patient has an infection or illness or is under added stress.

Clinical Cues

Some patients are able to use the insulin-to-carbohydrate ratio method. The patient must receive extensive MNT and be taught to interpret blood glucose patterns, to count carbohydrates, and to calculate bolus doses based on carbohydrate intake. One unit of insulin will cover 15 g carbohydrate for most patients (weight and insulin sensitivity must also be considered). See Table 37-4 for an example of lunch calculation. The diabetic educator should be contacted for assistance if a patient could benefit from this type of management system.

Table 37-4

Example of Carbohydrate Counting for Lunch

FOOD SOURCE	GRAMS OF CARBOHYDRATES
2 oz tuna, canned in water	0
1 hamburger bun	30
15 fat-free Pringles	15
1 tablespoon reduced-fat mayonnaise	0
1 tomato and 1 lettuce slice	0
1 medium dill pickle	0
Sugar-free pudding made with fat-free milk	15
Total:	60
Insulin (1 : 15 ratio):	4 units

Modified from Ignatavicius DD, Workman ML: *Medical-surgical nursing: Critical thinking for collaborative care*, ed. 6, Philadelphia, 2010, Saunders.

Think Critically

How would a patient know that her insulin requirement has changed?

Insulin pump.

An alternative to insulin therapy by daily injections is the insulin pump. These pumps can deliver a continuous infusion of insulin through an automated system composed of a battery-driven electronic “brain,” an electric motor and drive mechanisms, and a syringe (Figure 37-3). The syringe is attached to plastic tubing and a subcutaneous needle, which is inserted into the abdomen or thigh. Pumps are helpful in managing diabetes because they allow for improved blood glucose control; people using pumps tend to have fewer episodes of and less severe hypoglycemia compared with MDIs.

FIGURE 37-3 Insulin pump. (Courtesy ACCU-CHEK® is a registered trademark of Roche.)

The pump continuously delivers basal insulin to maintain blood sugar levels between meals and can be programmed to administer a bolus dose for meals or elevated blood sugar levels. CGM is possible via a small sensor inserted under the skin that monitors glucose in the interstitial fluid and not in the blood. Fluid and blood glucose are correlated, but CGM is not used to automatically deliver insulin because there is a lag in the glucose change in interstitial fluid after there has been a change in blood glucose. As the technology is refined, insulin pumps will be able to respond to glucose changes in the same time frame as islet cells. CGM devices can wirelessly send information

to the insulin pump or other monitoring equipment. Insulin pumps are recommended for patients who are willing and able to monitor their blood glucose frequently during the day and who can understand the principles of basal and bolus insulin and carbohydrate counting. As the technology gets more sophisticated and easier to use, the popularity of insulin pumps is increasing.

Clinical Cues

The insulin pump will have to be disconnected for certain diagnostic tests, such as magnetic resonance imaging. Most patients can safely be without the pump for an hour, but blood glucose should be checked before disconnecting and after reconnecting ([American Association of Diabetes Educators, 2014](#)).

Other injectable agents.

Historically, insulin was the only injectable medication for the management of diabetes; however, new injectable agents have been introduced. These medications do not replace standard diabetic medications, but are used to enhance the effect of existing medications. One new category of medications is called **incretin mimetics** because they mimic the action of **incretins**, hormones released from the intestine. In type 2 diabetics they lower postprandial blood glucose levels in a number of ways ([Table 37-5](#)). Other injectable medications to treat diabetes are synthetic hormones, such as pramlintide (Symlin), which can be used in types 1 and 2 diabetes. Although these medications are administered subcutaneously, none of these new medications should ever be mixed in the same syringe with insulin, and the patient must be monitored carefully for hypoglycemia.

Safety Alert

Pramlintide

The medication pramlintide has an FDA **black box warning** (a type of warning sometimes carried on prescription medications indicating the potential for serious adverse effects). This medication has the potential to cause severe hypoglycemia within 3 hours of administration. It is critically important that you observe the patient closely for any signs or symptoms of hypoglycemia.

 **Table 37-5**

Injectable Hypoglycemic Agents

GENERIC NAME (BRAND NAME)	DELIVERY METHOD	HOW THEY CONTROL BLOOD GLUCOSE	OTHER CONSIDERATIONS
Synthetic Hormone			
Pramlintide (Symlin)	Subcutaneous	Synthetic form of the hormone amylin Slows gastric emptying, suppresses glucagon release, suppresses glucose production by the liver, decreases appetite	Black box warning: potential to cause severe hypoglycemia; patients started on this medication should have their rapid-acting insulin dosage cut in half Pramlintide cannot be mixed with insulin and must be administered as a separate injection
Human Glucagon-like Peptide-1 Analogue (Incretin Mimetic)			
Exenatide (Byetta)	Subcutaneous	Mimics the action of incretins Stimulates insulin secretion, suppresses glucagon release, delays gastric emptying	Administer before breakfast or dinner (not lunch) to prevent severe hypoglycemia Give 1 hr after oral hypoglycemic agents
Liraglutide (Victoza)	Subcutaneous	Stimulates the release of insulin when blood glucose levels are elevated	Not a first-line treatment, but may be used in type 2 diabetes as an adjunct to diet, exercise, and oral hypoglycemic agents

Preoperative and postoperative insulin management.

The emotional and physical stress of surgery can increase the blood glucose level and alter the amounts of medication needed for glycemic control. Patients with type 2 diabetes may be taken off OHAs up to 48 hours before surgery and started on insulin by injection to achieve adequate control of their diabetes during this stressful period. The patient should be reassured that the diabetes is not worse, and that the insulin injections are only a temporary measure. A patient with type 2 diabetes will have bolus or correction dose orders (sliding scale) along with the usual insulin order. Blood sugar determinations are performed frequently.

For all patients with diabetes, intravenous (IV) fluids are begun as soon as the patient is ordered “nothing by mouth” (NPO) and are continued until the patient is eating again after surgery. During surgery, an insulin infusion of regular or short-acting insulin may be used, usually mixed in 5% dextrose or 0.9% NaCl solution, depending on hospital policy. Blood glucose is monitored closely

during surgery and every 2 to 4 hours postoperatively; urine is checked for ketones when glucose levels are high.

Clinical Cues

Be especially alert for signs of hypoglycemia in patients who are receiving an insulin infusion. Blood glucose is monitored hourly. The rate of infusion is adjusted according to an algorithm.

Islet cell and pancreas transplantation.

Clinical trials are under way for optimizing a procedure for treatment of type 1 diabetes by transplantation of insulin-producing islet cells. Cells are taken from the donor pancreas and injected into the hepatic circulation of the recipient, where the cells lodge and produce insulin. Lifelong immunosuppressive medications are still needed to prevent rejection of the cells. Whole organ transplantation of the pancreas is also done to replace insulin function. Many times a pancreas and kidney transplant are performed together using organs from the same donor. Altered renal function is a complication of type 1 diabetes, and transplant of both organs results in better outcomes (Lerma, 2013).

Complications

In general, people with diabetes are susceptible to two types of complications: short-term (acute) problems and long-term problems.

Short-term problems.

Acute complications arise when the blood glucose suddenly becomes either too high (hyperglycemia) or too low (hypoglycemia) (Table 37-6).

Safety Alert

Hyperglycemia or Hypoglycemia

When there is doubt as to whether a patient is experiencing hyperglycemia or hypoglycemia, treatment is begun for hypoglycemia until a blood glucose determination is obtained to prevent brain damage from extremely low cerebral glucose levels. Caution should be used to not overtreat with glucose. Hyperglycemia can worsen neurologic conditions. Rapid determination of blood glucose is essential to proper management. Hyperglycemia usually develops slowly and does not cause immediate changes in level of consciousness. Hypoglycemia can occur rapidly.

Table 37-6
Comparison of Hypoglycemia and Ketoacidosis

HYPOGLYCEMIA		KETOACIDOSIS
Etiology		
Overdosage of insulin		Failure to take insulin
Skipped or delayed meal		Illness or infection
Unplanned strenuous exercise		Overeating or too many carbohydrates
		Severe stress (surgery, trauma, emotional upset)
Symptoms		
Headache		Increased thirst (polydipsia)
Weakness		Increased urination (polyuria)
Hunger (polyphagia)		Acetone breath odor ("fruity")
Pallor		Dry mucous membranes and sunken eyeballs (dehydration)
Irritability		Nausea and vomiting
Lack of muscle coordination		Deep respirations (Kussmaul respirations)
Apprehension		Abdominal pain and rigidity
Shakiness		Paresthesias, weakness, paralysis
Diaphoresis with cool, clammy skin		Hypotension
Blurred vision		Minimal urine output (oliguria) or none (anuria) (late sign)
Rapid heartbeat		Stupor or coma (late sign)
Confusion		
Coma (late)		
Treatment		
If patient can swallow, give 3 glucose tablets or equivalent glucose gel, 6 oz of juice, 6 oz regular cola, 8 oz of 2% or skim milk, or 6-8 Life Savers candies.		IV fluid and insulin with correction of electrolyte imbalances.
If patient cannot swallow, administer glucagon IM.		Severe cases are hospitalized for stabilization.
If at the hospital, give D ₅₀ W solution IV.		
Prevention		
Eat meals 4-5 hr apart, plus prescribed snacks.		Take correct dose of insulin.
Take correct dose of insulin.		Consult health care provider when ill (even for minor illnesses).
Test blood glucose level regularly and more frequently during illness.		Follow diet; do not overeat and do not overload with
Eat extra food when exercising more than usual.		

IM, Intramuscularly; IV, intravenously.

When a patient is admitted to the hospital with hyperglycemia, decisions about the proper modes of therapy are based on the presence of objective and subjective symptoms. Type 1 diabetes is more likely to be complicated by ketoacidosis, whereas type 2 diabetes may cause hyperglycemic hyperosmolar state (HHS; previously called hyperglycemic hyperosmolar nonketotic syndrome, also abbreviated HHNC, HNKC, and HHNK).

Diabetic ketoacidosis.

Diabetic ketoacidosis (DKA) is a serious condition caused by incomplete metabolism of fats resulting from an absence or insufficient supply of insulin. When insulin is not present in adequate amounts to meet metabolic needs, the body breaks down protein and fat for energy. This produces an abundance of the by-products of fat metabolism, which are potent organic acids called *ketones*. In an attempt to rid itself of acidosis produced by ketones, the body increases respiratory rate and depth (Kussmaul respirations). Acetone, a ketone body, is excreted in the urine, causing acetonuria or ketonuria, and from the lungs, which can be detected in the characteristic fruity odor to the breath. As the kidney excretes excess glucose and ketones, it also eliminates large quantities of water and electrolytes. These pathologic changes are responsible for metabolic acidosis, dehydration, and electrolyte imbalances.

Signs and symptoms of DKA can be life threatening and are listed in **Table 37-6**. Intravenous fluids are administered first, then electrolyte imbalances are addressed in conjunction with an insulin drip. Electrolytes, especially potassium, and serum glucose are monitored closely. In the absence of insulin, potassium comes out of the cells, and patients present with hyperkalemia. As IV fluids are given and insulin is administered, potassium returns to the cells, causing hypokalemia. These potassium shifts are very important to monitor and manage so lethal cardiac dysrhythmias do not occur. **The goals of treatment are to restore the normal pH of the blood and other body fluids, correct the fluid and electrolyte imbalance, lower the blood glucose level gradually, and provide life-support measures as necessary.** Infection is the most common cause of DKA; however, other causes include poor compliance with the prescribed regimen of diet and insulin therapy and insulin pump failure. After the patient is stabilized, the underlying cause must be determined and treatment or corrective measures implemented.

Clinical Cues

If you suspect a patient is in DKA, immediately ensure that there is at least one patent IV access and anticipate an order for IV therapy.

Hyperglycemic hyperosmolar state.

Hyperglycemic hyperosmolar state (HHS) occurs in people with type 2 diabetes who experience high blood glucose levels because of illness or added stress, such as infection. Glucose levels greater than 600 mg/dL are common; in some cases the blood glucose can reach well over 1000 mg/dL. The extremely high level of glucose in the blood causes severe dehydration and circulating fluid volume depletion secondary to osmotic diuresis. Blood osmolality is considerably elevated (greater than 320 mOsm/kg). HHS is different from DKA because a small amount of circulating insulin remains available, resulting in the absence of ketosis and acidosis. Because ketosis and acidosis are absent, the gastrointestinal symptoms do not occur and the patient does not seek medical care early in the course of illness. The patient's mental state may progress from confusion to complete coma. Also—in contrast to DKA—a patient in HHS may experience generalized or focal seizures.

Older Adult Care Points

Older adults are at greater risk for HHS, because they become dehydrated more quickly than do younger patients. HHS may be the first indicator that the patient has diabetes. HHS most commonly occurs after a febrile illness or gastrointestinal flu, during which the patient has stopped eating properly and possibly has discontinued oral hypoglycemic agents.

Things that may precipitate HHS in a person with type 2 diabetes are (1) medications that

increase serum glucose levels or cause dehydration, such as steroids, thiazides, phenytoin, and beta blockers; (2) acute illnesses, such as infection, myocardial infarction, and stroke; (3) chronic illnesses, such as congestive heart failure and renal dysfunction; and (4) treatments, such as total parenteral nutrition and peritoneal dialysis.

Treatment of HHS focuses on fluid replacement and correction of electrolyte imbalances.

Because fluid replacement will initially be rapid, cardiovascular status and lung sounds must be assessed frequently. Small amounts of insulin may be used until the patient is stabilized. Blood glucose and intake and output must be monitored closely. The underlying illness that triggered the HHS must be identified and treated. HHS can be fatal, and mortality risk is directly correlated with higher elevations of blood glucose and the resultant severity of dehydration.

Rebound hyperglycemia.

Rebound hyperglycemia, also known as the *Somogyi effect*, follows a period of hypoglycemia, often during sleep. When hypoglycemia occurs, the body secretes glucagon, epinephrine, growth hormone, and cortisol to counteract the effects of low blood sugar. The patient may report nightmares and night sweats along with morning elevated serum glucose; if the patient increases the insulin dose, it worsens the problem.

The Somogyi effect is diagnosed by checking blood sugars during the night; once verified, the usual treatment is to lower the insulin dosage or move the time of the intermediate-acting insulin to bedtime. Changing or increasing the bedtime snack also helps.

The **dawn phenomenon** is characterized by elevated blood glucose in the morning. The dawn phenomenon is caused by release of growth hormone, glucagon, and epinephrine during the night, as part of the body's natural circadian rhythm. These hormones act to raise the body's blood sugar. The dawn phenomenon is the reason why most people with diabetes do not tolerate carbohydrates well in the morning. The treatment is an intermediate-acting insulin at night.

Hypoglycemia.

The word *hypoglycemia* means "low blood glucose." Hypoglycemia is a common complication of insulin administration in type 1 diabetes mellitus. Most often it is a response to either too large a dose of insulin or too much exercise in relation to the amount of food eaten. People with diabetes must be taught to monitor for the signs and symptoms of hypoglycemia: tremulousness, hunger, headache, pallor, sweating, palpitations, blurred vision, and weakness. Symptoms may progress to confusion and loss of consciousness. Individual reactions vary considerably. Some patients are alert with a glucose level of 40 mg/dL, whereas others at this level are comatose.

Treatment depends on the degree of hypoglycemia and level of consciousness. If the patient is alert enough to tolerate oral intake safely, glucose levels of 40 to 60 mg/dL respond to ingestion of food such as milk, crackers, or juice. Glucose levels of 20 to 40 mg/dL respond best to concentrated sugars, such as honey, table sugar, or juice. Patients must be taught how to self-treat hypoglycemia (see [Patient Teaching: Home Treatment for Hypoglycemia](#)). In the hospital, if the person is experiencing seizures or is not alert enough to tolerate oral intake safely or has a very low blood sugar, a solution of 50% glucose is given IV. When an IV access cannot be established, 1 mg of glucagon is administered intramuscularly. The injection is repeated in 15 minutes if symptoms are not resolved (see [Table 37-6](#)).

Long-term problems.

The long-term consequences of diabetes mellitus are chiefly the result of damage to the large and small blood vessels, termed *macrovascular* and *microvascular*. Elevated blood glucose levels over a period of years seriously damage blood vessels and the organs they serve. Diabetes is the seventh leading cause of death in the United States for all age groups ([Centers for Disease Control and Prevention, 2015](#)). In addition, cardiovascular disease and other causes of death often can be attributed to diabetes. Damage to the mechanisms that control blood vessel health occurs when blood glucose is elevated over a long period. The alterations in the macrovascular system result in coronary artery disease, peripheral arterial disease, and stroke. Microvascular complications result from damage to the small vessels at the capillary level. This causes diabetic nephropathy, neuropathy, and retinopathy.

Patients who have had diabetes for more than 10 years are likely to develop one or more of the complications of the disease. The less closely the blood glucose has been controlled, the more likely

the development of cardiovascular, eye, and renal complications. **Improperly treated or untreated diabetes is the leading cause of new blindness, renal failure leading to dialysis, and nontraumatic lower limb amputations.** Although not every person with diabetes will suffer from long-term complications, many will periodically be hospitalized for diabetic-related conditions.

Cardiovascular disease.

Two out of three people with diabetes die prematurely from heart attack or stroke. In compliance with The Joint Commission Core Measures, aggressive measures should be taken to prevent stroke in patients at risk. Tight glycemic control is the best strategy to prevent the vascular changes causing myocardial infarction and stroke.

Peripheral vascular disease.

Gangrene, which often leads to amputation, is far more common in people with diabetes. More than 60% of nontraumatic amputations occur among people with diabetes. Vascular changes typically cause very poor circulation in the feet and lower extremities. Healing of wounds in these areas is difficult because of poor blood supply. Because increased levels of glucose in the blood provide a good medium for bacterial growth and decrease the immune response, it is harder to eradicate infection. Learning and practicing excellent foot care are essential to prevent amputation. Multiple studies have identified early identification and intervention as tools to successfully prevent amputation.

Patient Teaching

Foot Care

- Inspect each foot daily for cuts, cracks, blisters, abrasions, or discoloration of the toes; report any abnormality to the health care provider. Use a mirror if unable to bend to see the bottom of the foot. Be certain to check between the toes.
- Wash the feet in warm (not hot) water, using mild soap; do not soak the feet, because this can cause cracking of the skin.
- Thoroughly dry the feet after washing, paying special attention to drying between the toes. Rub in a nonscented, nonmedicated cream if the skin is dry; do not put the cream between the toes.
- Cut the nails along the shape of the toe and file the nails to remove sharp edges. Have corns, calluses, and ingrown nails managed by a podiatrist.
- Wear a clean pair of cotton socks each day.
- Wear properly fitted shoes with a firm sole that do not pinch or bind the foot; never walk barefoot.
- Break in new shoes gradually.
- Never wear open sandals or sandals with straps between the toes.
- Use socks and blankets to warm the feet; do not use a heating pad or hot water bottle near them.
- Test the temperature of bath water with wrist or forearm before stepping into the tub or shower.
- Elevate the feet whenever possible to improve circulation.

Nephropathy.

Diabetic nephropathy occurs directly from changes in the renal blood circulation. Factors that influence whether a person with diabetes will develop kidney disease include genetics, blood glucose level, and blood pressure. After years of having to filter too much blood with elevated blood glucose, the filtering mechanism of the kidney begins to fail, allowing large particles that

normally would have been filtered out (such as protein) to exit through the urine. In the early phase of albuminuria, there are small amounts of protein in the urine. If nothing is done to prevent further damage, increasing amounts of protein are excreted in the urine. Finally, the patient enters end-stage renal disease and requires either a kidney transplant or dialysis to perform the filtering for the kidneys.

Nephropathy can be delayed and possibly prevented by keeping tight control of blood glucose. Research has demonstrated that tight blood glucose control reduces the risk of developing albuminuria and the progression to renal failure. In patients with type 1 diabetes and early albuminuria and hypertension, angiotensin-converting enzyme (ACE) inhibitors have shown to be beneficial in slowing the elevation of albuminuria.

Retinopathy.

Visual impairment and blindness are common sequelae of diabetes mellitus. The three most common visual problems are diabetic retinopathy, cataracts, and glaucoma. Retinal damage, which can cause visual impairment and blindness, occurs in most people with diabetes within 20 years of diagnosis. Changes in the retinal vessels lead to hemorrhages and to retinal detachment. A combination of laser intervention and medication has shown to be effective in reducing vision loss. Photocoagulation of destructive lesions of the retina with laser beams coupled with use of ranibizumab to decrease retinal edema has shown the best outcomes ([Bhavsar, 2014](#)). Tight glucose control, frequent eye examinations, and treatment can help preserve vision.

Diabetic neuropathy.

Approximately 60% to 70% of people with diabetes have mild to severe neuropathy. Pathologic changes in the nervous system cause symptoms such as paresthesia, numbness, and loss of function. **Diabetic neuropathy** primarily affects the peripheral nerves, causing sexual impotence in men, constipation, neurogenic bladder, and pain or anesthesia (lack of feeling) in the lower extremities. It is for this reason that foot care and daily inspection of the feet are so important. Because the patient often cannot feel cuts, blisters, or abrasions on the foot, there is great danger that a neglected sore might become infected. Although it may be mild at the beginning, eventually partial or almost total anesthesia of the affected part creates a potential for serious injury without awareness. In contrast, some patients experience debilitating pain and hyperesthesia; some lose deep-tendon reflexes. No single therapy has been shown to effectively treat pain from diabetic neuropathy. Other problems related to diabetic neuropathies are the result of autonomic nervous system involvement. These include orthostatic hypotension, delayed gastric emptying or **gastroparesis**, diarrhea or constipation, and asymptomatic retention of urine in the bladder.

❖Nursing Management

■ Assessment (Data Collection)

Assess every patient for signs and symptoms of potential diabetes mellitus. Assess the skin for signs of poor wound healing or areas of infection. The feet should be inspected for signs of beginning sores. The patient should be weighed to determine whether weight is within normal limits.

☒ Focused Assessment

Data Collection for Diabetes

The following questions should be asked to establish a database that indicates whether the patient may have diabetes, has poorly controlled diabetes, or has no signs of diabetes:

- Has anyone in your family ever been told he or she has diabetes? What about your parents and grandparents?
- Have you had any recent weight loss or weight gain?
- Have you become increasingly hungry over the past few months?
- Has your thirst increased? Are you drinking more fluids than you used to?

- Do you have to urinate (go to the toilet) more than you used to?
- Have you noticed that you are more tired than you were 6 months ago?
- Do you have any trouble with scratches and wounds healing or becoming infected?
- Have you noticed any numbness or tingling or “funny” sensations in your hands, legs, or feet?
- Is constipation becoming a problem?
- Are you having any sexual difficulties? Any impotence (men)? Any frequent vaginal infections (women)?

If the patient is known to have diabetes, ask these questions also:

- Do you feel that you can easily and correctly perform your blood glucose determinations? (Check the patient's performance using her own machine.)
- Are you having any trouble sticking to your dietary plan?
- How are you planning your meals?
- Are you taking your insulin/oral medication regularly?
- Are you having any problems in relation to the medication?
- Are you keeping records of your blood glucose readings and your insulin injections? (Check records, if available.)
- Are you seeing your primary health care provider at regular intervals?
- Are you having your eyes examined regularly?
- Are you visiting the dentist regularly?

For a patient newly diagnosed with diabetes, you must assess whether the patient is a good candidate for using a **glucometer** (blood glucose-monitoring machine) ([Figure 37-4](#)). The patient must have adequate peripheral circulation to easily obtain a drop of blood for the test. Manual dexterity is needed to perform the fingerstick to obtain a blood sample, place the blood in the right spot, and correctly read the meter. Patients with arthritis or visual impairment may have difficulty with these steps. The patient must be able to remember the correct sequence of the steps, and remember to do it at the designated times. Determining whether the patient can cope with learning the procedure and whether there is willingness to fit it into the daily routine are other assessment factors. Periodic assessment of glucose monitoring techniques, medication administration, and compliance with treatment regimen are essential. CGM can be used for those patients unable to manage a glucometer. The device can display the tissue glucose and signals a result that is too high or too low, alerting the patient to view the blood glucose value and to take corrective action ([Liess, 2014](#)).

FIGURE 37-4 Blood glucose monitor. (Courtesy OneTouch, part of Johnson & Johnson.)

Nursing Diagnosis

The following problem statements are common for patients with diabetes mellitus:

- Altered nutrition due to alterations in insulin availability or utilization.
- Insufficient knowledge due to newly diagnosed disease process, possible complications, and self-care needs.
- Potential for infection due to elevated blood glucose level.
- Limited coping due to denial of need for effective self-care.
- Altered sensory perception due to effect of elevated blood glucose on vascular and nervous systems.
- Potential for injury due to decrease in tissue perfusion and sensation in feet.
- Pain due to nerve damage secondary to peripheral vascular disease.

Specific nursing diagnoses can be chosen from the NANDA-I list (see inside back cover).

There are many other nursing problems related to the various complications that patients with diabetes may develop. Nursing care plans must be carefully individualized to the particular problems and needs of each patient ([Nursing Care Plan 37-1](#)).

* Nursing Care Plan 37-1

Care of a Patient With Diabetes Mellitus

Scenario

Mr. Blackburn, age 49 years, is 5 ft 7 in tall and weighs 350 lb. He was admitted to the hospital for surgical repair of a hernia. During the preoperative evaluation, his blood glucose value was 420 mg/dL. On further examination by the health care provider, Mr. Blackburn reported symptoms of extreme thirst, hunger, and excessive urination. Surgery was rescheduled; further workup confirmed the suspected diagnosis of type 2 diabetes mellitus. Mr. Blackburn was extremely upset at learning the diagnosis and not being able to have his surgery. His response to the diagnosis was to ask the surgeon if he could be prescribed "some pills" and "get on with it."

Problem Statement/Nursing Diagnosis

Altered nutritional status/Imbalanced nutrition: more than body requirements related to alteration in glucose utilization by cells.

Supporting Assessment Data

Objective: Blood glucose 420 mg/dL; weighs 350 lb.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will develop meal plan that will assist in maintaining ideal body weight and blood sugar within normal limits.	Perform dietary assessment (i.e., typical intake, nutritional knowledge, cultural preferences).	Patient's current diet and general knowledge of nutrition and cultural preferences can be considered and modified.	Normally eats a lot of fast foods, but likes fruits and vegetables and would like to improve diet.
Patient will demonstrate knowledge of correct meal planning within 3 mo.	Instruct in diabetic meal planning and carbohydrate counting.	The relationship of meal planning to control of chronic disease is new information.	States that he "doesn't get it" when asked about meal planning and carbohydrate counting.
	Assist with construction of an acceptable meal plan for attaining desired weight and to normalize serum glucose levels.	Any meal plan must be individualized for weight goals, lifestyle, and food preferences.	Able to correctly identify appropriate portion sizes of sample menu.
Hemoglobin A _{1C} and fructosamine assay levels will show compliance with dietary plan within 6 mo.	Reinforce health care provider's instructions to follow up for repeat laboratory tests and for additional dietary education.	Long-term goal is to achieve: Normal value A _{1C} : 3.9%-5.2% (of total hemoglobin) Normal value fructosamine assay: 1.5-2.7 mmol/L	A _{1C} and fructosamine assay level and reassessment of dietary success to be done at follow-up. Continue plan.

Problem Statement/Nursing Diagnosis

Insufficient knowledge/Deficient knowledge related to disease process, possible complications, and self-care.

Supporting Assessment Data

Subjective: Patient asks health care provider if he could be prescribed "some pills" and "get on with it."

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will verbalize basic knowledge about disease process within 1 mo.	Instruct patient about the disease process of diabetes using a variety of teaching methodologies based on the content and learning style.	Varied methods that target the patient's learning style increase retention of information (i.e., written material, demonstrations, videos).	Patient verbalized basic knowledge of disease process.
Patient will verbalize ways to prevent the complications of diabetes within 3 mo.	Instruct regarding the potential complications of diabetes and how to decrease the risk of complications. Instruct in oral medication or insulin administration.	Knowledge empowers patient to achieve self-care and to take preventive measures. Long-term self-management of medication is essential.	Patient states, "I need to lose weight." Patient acknowledges complications of diabetes but states he needs more information. Very resistant to the idea of insulin injections, but shows interest in learning about oral medications.
Patient will demonstrate proper foot care within 1 mo.	Instruct in proper foot care techniques (i.e., daily inspection, cleaning, foot attire). Seek feedback regarding material taught by verbalization and demonstration of skills.	Poor circulation and peripheral neuropathy can lead to infection or amputation. Provides opportunity for reinforcement, or praise. Reteaching or redesign of materials might be necessary.	Demonstrates proper foot care. Expresses appreciation of time spent in teaching him about various topics; requests written information about foot care and medication side effects.

Problem Statement/Nursing Diagnosis

Potential for injury/Risk for unstable glucose level related to type 2 diabetes mellitus diagnosis.

Supporting Assessment Data

Objective: Admitting blood glucose 420 mg/dL.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will have a premeal blood glucose of 70-140 mg/dL while in the hospital.	Monitor the blood sugar before meals and at bedtime or as ordered. Monitor for signs of hypoglycemia (i.e., hunger, sweating, confusion) and hyperglycemia (i.e., increased urination, thirst, rapid breathing).	Illness and stress will affect blood sugar level and patient is newly diagnosed, so response to therapy must be closely monitored. Hypoglycemia must be treated immediately because brain cells need a continuous source of glucose. Hyperglycemia can cause long-term damage, but can also be life threatening if ketoacidosis occurs.	Blood glucose 230 mg/dL at 6:00 A.M. Health care provider aware, and order for correction dose of insulin obtained. Does not exhibit any signs of hypoglycemia (i.e., weakness, anxiety, palpitations) or hyperglycemia (i.e., nausea, acetone breath, or dry mucous membranes). "Feels pretty good considering."
Patient will demonstrate blood glucose levels within acceptable limits within 1 mo.	Instruct in glucose monitoring technique appropriate to patient. Instruct to record blood glucose findings after testing.	Proper instruction, including return demonstration, is important in ascertaining correct fingerstick values. Keeping a daily record is important in monitoring day-to-day fluctuations in blood glucose.	Able to perform fingerstick and check value. "I'm good with gadgets." Likes to keep records. "It's good to have the data right where I can see it." Continue plan.

Problem Statement/Nursing Diagnosis

Altered self-esteem/Situational low self-esteem due to diagnosis of chronic disease requiring lifestyle changes or insulin injections for survival.

Supporting Assessment Data

Objective: Patient with newly diagnosed diabetes.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will verbalize own strengths within 1 mo.	Encourage verbalization of feelings related to diagnosis of diabetes and need for lifestyle changes. Allow expression of frustrations.	Verbalization of feelings is an important first step toward identifying one's own strengths. Frustration is a normal human response to a real or perceived threat.	Initially, very quiet; appears withdrawn and angry after health care provider informs of new diagnosis of diabetes mellitus. "I guess I am taking out my frustrations on you and the doctor." Reassured that frustration is normal.

Patient will express that control over the disease and life is possible.	Encourage exploration of strengths and positive measures of self-worth (i.e., roles, accomplishments).	Remembering past achievements can help patients realize their strengths.	States, "I am a hard worker. I own my own business—I can certainly learn to manage this too."
	Explain how control over disease and life is possible.	After feelings are expressed, patient will be more receptive to information. Knowledge and tools can help him achieve control.	"I think I am beginning to understand. Balancing food intake and insulin is like balancing a spreadsheet of expenditures at my business."
	Praise efforts at learning and practice of self-care techniques.	Positive reinforcement is a powerful tool for helping a patient accomplish acceptance of a situation.	Goal met. Reevaluate as needed.

Critical Thinking Questions

1. The RN has planned the first teaching session for Mr. Blackburn, which you are to help implement. The topics planned for today include meal planning, short-term complications of diabetes, long-term complications of diabetes, foot care, and actions/side effects/interactions of OHAs. If the RN asked for your collaboration on the plan, what would you recommend?
2. Mr. Blackburn has visitors coming to see him. You greet them in the hallway and notice they are carrying bags from Krispy Kreme and Baskin Robbins. How would you respond to this situation?

■ Planning

When caring for a patient with diabetes, you should know the schedule for meal tray delivery and plan glucose testing and insulin injections for appropriate times. Fingersticks for blood glucose testing should be performed 30 minutes before breakfast. If an hour has elapsed without insulin being given after the reading was obtained, the test must be repeated before insulin administration. If rapid-acting insulin is ordered, it should not be given until the food tray is in front of the patient.

When a patient is NPO for tests or procedures, monitor for signs of hypoglycemia and obtain the patient's food tray immediately when the patient returns from testing. The insulin dose should be adjusted according to health care provider order during the NPO period; insulin should not be withheld. Hyperglycemia must be anticipated and assessed for during hospitalization when the patient is undergoing the added stress of diagnostic testing, unknown diagnosis, unrelieved physical distress or surgery.

To prevent delays, make certain that the patient's insulin, appropriate syringes, or oral medication are readily available. Examples of expected outcomes for a patient with diabetes mellitus include:

- Patient will demonstrate understanding of glucose monitoring and glucose-lowering medications.
- Patient will attain a body weight within normal limits within 6 months.
- Patient will demonstrate knowledge of disease process, possible complications, and self-care methods.
- Patient will constantly monitor for signs of infection.
- Patient will develop coping methods to perform self-care.
- Patient will verbalize ways to preserve and protect vision.
- Patient will demonstrate methods to prevent injury to feet.
- Patient will verbalize that pain is within acceptable limits after medication and nonpharmaceutical measures are administered.

■ Implementation

Intervention is geared toward assisting the patient with self-care, performing blood glucose determinations, administering medication when the patient is ill and cannot self-administer, observing for signs and symptoms of complications, assessing learning needs, and carrying out a teaching plan as indicated. Be sure to encourage others involved in the patient's care to be alert for signs and symptoms.

■ Assignment Considerations

Observations

Remind the UAP to report any breaks in the skin observed while giving physical care to a patient with diabetes. Report excessive urination or changes in vital signs, such as increasingly rapid respirations.

Monitor the trend of blood glucose, A_{1c}, and fructosamine assay readings over time, rather than focus only on the current reading. Assess how well the patient is eating and taking fluids. Intake and output recordings are appropriate if the patient is ill or having surgery. Any type of stress can alter the control of the patient's diabetes. Electrolytes also should be monitored, with particular attention to potassium levels, which can shift suddenly when insulin is insufficient.

Every patient taking insulin should be monitored for hypoglycemia after insulin injections. After injection of each type of insulin, you must know when hypoglycemia might occur and should assess the patient at that time. Patients are taught to report signs of hypoglycemia promptly, to prevent a crisis.

Monitoring for signs of ketoacidosis also is essential. Some of the earliest symptoms may be polyuria, fatigue, anorexia, abdominal pain, and a "fruity" smell to the breath. Look for beginning signs of dehydration with decreased tissue turgor, sunken eyeballs, and dry mucous membranes (see [Table 37-6](#)). Report such findings to the health care provider promptly.

Patient Education

The patient must be able to self-manage diet, medication, and progress. In addition, adjustments in lifestyle, recreational choices, and self-image will probably need to be made. The patient must be taught the correct steps for blood glucose monitoring (see [Figure 37-4](#)).

Noncompliance can be devastating to the patient's welfare and can mean the difference between leading a nearly normal life or becoming an invalid; eventually, noncompliance may mean the difference between life and death for a person with diabetes. Many hospitals and clinics have developed standardized teaching programs for diabetes education, because the task of diabetic teaching is very challenging and complex ([Figure 37-5](#)).

FIGURE 37-5 Nurse teaching patient with diabetes.

Major topics covered in a standardized program usually include:

- Pathophysiology of diabetes mellitus, including functions of the pancreas and contributing or precipitating factors in the development of diabetes
- How to manage a diet program
- Blood glucose monitoring at home
- Foot care
- Urine testing when blood glucose level is higher than 240 mg/dL to check for acetone
- Identification tag, identification card, and medical information (see [Figure 37-1](#))
- Information on what to do on "sick" days, especially when nauseated or vomiting and unable to maintain diet
- Community resources and help groups available to patient with diabetes and family
- Travel tips
- Devices that make insulin administration easier (especially for older adults, visually impaired patients, or patients with arthritis)

Patient Teaching

What to Do on Sick Days

A bad cold, flu, or minor gastrointestinal upset can create problems for diabetic patients.

Medication

- Take insulin as prescribed. Adjust the dosage as directed, depending on blood glucose readings.
- If taking an oral hypoglycemic, take usual dose. Do not increase the dose unless ordered to do so by the health care provider. If vomiting and unable to take medication by mouth, the health care provider may temporarily prescribe insulin.

Diet

- Eat a normal diet on schedule.
- If nausea and vomiting occur, replace carbohydrate solid foods in the normal diet with liquids that contain sugar (fruit juice, regular soft drinks, or Jell-O).
- Take at least 1 cup of water or calorie-free, caffeine-free liquid each hour. If nauseated, take small sips to help prevent vomiting.

Monitoring

- Test blood glucose at least every 4 hours and record result. If severely ill, check blood glucose every 2 hours.
- Test urine for ketones if blood sugar level is higher than 300 mg/dL.

Notifying the Health Care Provider

- Call the health care provider right away for vomiting or abdominal pain or a temperature higher than 100.2° F (38.8° C).
- Notify the health care provider if blood glucose is higher than 200 mg/dL or if urine test shows ketones.
- Report to the health care provider if blood glucose level that was higher than 200 mg/dL does not come down with an additional dose of insulin.
- If unable to reach the health care provider, go to the hospital emergency department.

Patient Teaching

Instructions for Traveling

- Carry twice the medication or insulin you expect to need in case of travel delays. Take copies of prescriptions with you. Wear a medical-alert bracelet or tag, and carry a medical information card in a purse or wallet.
- Carry an emergency supply of fast-acting sugar at all times in case of a hypoglycemic episode. Also carry longer-acting foods, such as peanut butter and crackers.
- Pack dried fruit, nuts, and seeds as snacks. Because these are high calorie, measure portions in advance.
- Check your blood sugar frequently. Changes in time zones, eating, and activity level can affect

blood glucose.

- If ill, seek medical attention immediately before a dangerous condition occurs.
- Stick to prescribed meal plans as much as possible, substituting available foods according to food group classification.
- Obtain sufficient rest and avoid stressful situations as much as possible to prevent stress-induced hyperglycemia.
- It is best to travel with someone who is familiar with diabetes and treatment. It is advisable to inform the airline or ship personnel about the diabetes.
- Obtain the usual amount of exercise or adjust food and medication accordingly.
- Drink a glass of water every 2 hours to prevent dehydration.
- Protect insulin from temperature extremes.
- Eat something at least every 4 hours.
- Call airlines and ship companies ahead of departure to request diabetic meals, or take your own.
- Before departure, research food substitutions, so that personal meal plans are consistent.
- Remember time zones: going westward lengthens the day; take more insulin. Going eastward shortens the day; take less insulin.

Patient Teaching

Working With an Older Adult Who Has Diabetes

- Assess hearing and vision. Use aids as appropriate and ensure adequate lighting.
- Set a time for the teaching session that is agreeable to the patient.
- Arrange a quiet, nondistracting environment for the session.
- Be certain that the patient is comfortable before beginning.
- Keep the sessions short—no more than 15 to 20 minutes at a time.
- Limit information to a few major concepts per session.
- Go slowly and seek feedback that the patient has understood each point when finished presenting it.
- Allow time for the patient to jot down important points.
- Repeat key concepts frequently; if the patient does not understand, try rephrasing the concept.
- Use bold-type printed materials with a white or yellow background.
- Leave printed materials that are illustrated with simple drawings and that are not crowded with text.
- Printed materials should be written at a fifth- to tenth-grade reading level depending on the patient.
- If the patient becomes frustrated or distracted, stop the session and reschedule it.

- Summarize what has been taught and what has been learned at the end of the session.

The patient and significant others, staff nurses, health care providers, diabetic specialist, nurse educator, dietitian, podiatrist, and periodontist are all involved in the educational process. Because of frequent updates and changes in diabetes management, all persons responsible for the care of patients with diabetes should read and continue to study and learn about the current protocols.

Evaluation

For a patient with diabetes, the learning that has taken place and compliance with the treatment regimen are the essential components. Monitor A_{1c} and fructosamine assay levels to determine the degree of control of blood glucose. Question the patient about exercise and diet and give feedback. Observe demonstrations of learned skills for insulin injection, proper foot care, dietary planning, and glucose monitoring. If the expected outcomes are not being met, the nursing care plan must be revised. Collaboration with the health care provider and dietitian are necessary to design or redesign a plan that is effective.

Hypoglycemia

Etiology and Pathophysiology

The organs involved in meeting the challenge of carbohydrate ingestion include the intestines, liver, and pancreas (specifically, the beta cells that produce insulin). Thus any condition affecting these organs and their systems can lead to hypoglycemia. Examples other than diabetes mellitus include gastrectomy and surgical bypass procedures. These types of surgery may restrict adequate glucose absorption. Tumors of the pancreas (insulinomas), liver disease, and disorders of the adrenal cortex and pituitary gland can also produce abnormally low blood glucose levels. People who abuse alcohol and other substances are also prone to hypoglycemia. Hypoglycemia related to diabetes is more common, has a different cause, and is treated differently.

Signs and Symptoms

Signs and symptoms of hypoglycemia include rapid heartbeat, tremulousness, weakness, anxiety, nervousness, and hunger. Symptoms can occur rather suddenly, within 4 hours after a meal is eaten. Some physiologic symptoms may be mistaken for indications of a psychiatric illness. These symptoms include irritability, personality change, temper tantrums, and other psychoneurotic manifestations.

Diagnosis and Treatment

Diagnosis of hypoglycemia is made with measurement of blood glucose values. A source of possible infection is investigated. The patient's insulin levels and C-peptide levels can also be measured. The diagnosis may be made using a glucose tolerance test or a medically supervised fast. Computed tomography (CT) scan, ultrasound, and other diagnostics may be used if an insulinoma (insulin-secreting tumor) is suspected.

Hypoglycemia is treated by modifying eating patterns. Smaller and more frequent meals that are relatively free of simple sugars are recommended. The diet should be high in proteins and low in carbohydrates, and carbohydrates should be complex ones, such as those found in whole fruits, vegetables, and whole grains. Refined sugar and white flour are omitted. Cases in which gastric surgery and intestinal bypass are believed to be the cause of hypoglycemia may be treated with drugs that reduce intestinal motility, allowing for greater absorption.

Complications

Untreated fasting hypoglycemia can lead to severe **neuroglycopenia** (shortage of glucose in the brain) and possibly death.

Nursing Management

In addition to information about the patient's physical and mental symptoms, assessment should include a detailed history of eating habits. Does the patient eat regularly? How often during each day? What kinds of foods constitute a typical meal? Does she crave sweets? Have there been

episodes of weakness, sweating, visual disturbances, and confusion or inability to concentrate? If these symptoms have occurred, when are they most noticeable (i.e., in a fed or fasting state)? Nursing interventions for patients with hypoglycemia include explaining the nature of the disorder and the need for diagnostic testing, objective observation and reporting of symptoms, and reinforcement of dietary instruction and restrictions.

Community Care

One major objective of *Healthy People 2020* is to “increase the proportion of persons with diabetes who receive formal diabetes education.” Nurses play a crucial role in home care and in teaching the older adult population who have diabetes. If nurses could follow the progress of these patients over the years with good assessments and implement ongoing patient education programs, the incidence of complications could certainly be decreased.

Long-term care nurses must be alert to the signs of diabetes. When a resident does not properly recover from a viral illness, in-depth assessment for signs of diabetes is proactive. Home care and clinic nurses must be persistent in assessing compliance with diabetic regimens and must also be instrumental in teaching the public about the signs and symptoms of diabetes and self-care to prevent complications (see Online Resources). At present, diabetes is costing the United States more than \$245 billion a year in health care expenditures. This is an area where nurses can be instrumental in cutting health care costs.

Get Ready for the NCLEX® Examination!

Key Points

- Diabetes mellitus involves a disturbance in glucose metabolism. Type 1 diabetes usually appears at a young age, and the patient requires insulin for life. Type 2 diabetes usually develops later in life, but is now being diagnosed more frequently in younger people. Gestational diabetes may occur in pregnancy. Patients with LADA may be initially misdiagnosed with type 2 diabetes. The goal in diabetes is to maintain blood glucose and lipid levels within normal limits to prevent complications.
- The cornerstone of therapy for people with diabetes is diet and exercise. Insulin must be taken for type 1 diabetes; OHAs (and insulin) may be prescribed for type 2.
- The diet plan provides optimal nutrition and calories to maintain normal body weight and allows adjustments to food intake to keep blood glucose within safe limits.
- The emotional and physical stress of surgery and illness can increase the blood glucose level and alter the amounts of medication needed.
- Basal insulin is the amount of insulin that would normally be produced by the pancreas throughout the day.
- A bolus or “correction” dose of short- or rapid-acting insulin is used to manage elevations in blood glucose and bring the next blood glucose into range.
- DKA is a serious condition caused by incomplete metabolism of fats as a result of the absence of insulin marked by metabolic acidosis, dehydration, and electrolyte imbalances.
- HHS occurs in people with type 2 diabetes because of illness or stress. Glucose levels are often between 600 and 1000 mg/dL, leading to severe dehydration.
- Hypoglycemia is often a response to either too much insulin or too much exercise in patients with diabetes. Monitor for hypoglycemia after insulin injections.
- If there is doubt whether the patient is suffering from hyperglycemia or hypoglycemia, treat for hypoglycemia until you obtain a blood glucose level.
- The long-term consequences of diabetes mellitus result from damage to large and small blood vessels. Cardiovascular disease, nephropathy, peripheral vascular disease, retinopathy, and neuropathy can all be reduced by strict blood glucose control.

Review Questions for the NCLEX® Examination

1. A 30-year-old woman is admitted for urinary tract infection with sepsis. A urinalysis reveals presence of ketones, glucose, and nitrates. Which question would the nurse ask to further assess possible diabetes mellitus?

1. “Have you noticed an extra roundness to your face?”
2. “Have you had more gas or abdominal bloating?”

3. "Have you been thirstier than usual? Do you find you urinate more now?"
4. "Have you experienced any pain or discomfort with urination?"

NCLEX Client Need: Health Promotion and Maintenance

2. Which teaching technique(s) would be most useful for an older adult patient with diabetes? (*Select all that apply.*)

1. Set a time for the teaching session that is agreeable to the patient.
2. Invite the patient to join a teaching session for patients newly diagnosed with diabetes.
3. Allow time for the patient to jot down important points.
4. Use bold-type printed materials with a white type on a dark blue or black background.
5. Keep the sessions at a limit of 1 to 2 hours and give frequent breaks.
6. Teach all necessary information in one session.
7. Repeat key concepts frequently; if the patient does not understand, try rephrasing the concept.

NCLEX Client Need: Physiological Adaptation

3. A patient newly diagnosed with diabetes is given diet instructions. What should the nurse do to effectively motivate the patient to comply with dietary recommendations? (*Select all that apply.*)

1. Emphasize good food choices.
2. Apply diet prescriptions to patient-preferred foods.
3. Instill guilt to self-regulate when "cheating" occurs.
4. Focus on the benefits of diet compliance.
5. Involve meal preparers in diet teaching.

NCLEX Client Need: Physiological Adaptation

4. A 50-year-old woman was recently diagnosed with type 2 diabetes mellitus and desires to start a healthy lifestyle to control her disease. What is the initial recommendation that the nurse should make?

1. Engage in brisk walking.
2. Lose 10 to 15 pounds.
3. Maintain adequate glucose control.
4. Develop an exercise schedule.

NCLEX Client Need: Reduction of Risk Potential

5. The nurse answers the call light for a patient with diabetes. The patient states she feels shaky and weak. The nurse notes pallor and moist skin. List in priority order the actions of the nurse.

1. Give patient 6 oz of juice.
2. Document interventions.
3. Check fingerstick glucose.
4. Assess level of consciousness.

NCLEX Client Need: Physiological Adaptation

6. A patient who works as a personal trainer is diagnosed with insulin-dependent diabetes. What should the nurse teach regarding self-administration of regular insulin?

1. If you have a strenuous workout, skip your insulin for the day.
2. Inject the insulin before moderate exercise.
3. Exercise during the insulin peak of action.
4. Use the abdomen as an insulin injection site.

NCLEX Client Need: Physiological Adaptation

7. The home health nurse is visiting an older adult patient who has successfully managed her type 2 diabetes for years. During the visit, the nurse notes that the patient has severe arthritis; poor vision; and several dry, red areas on the lower extremities. What is the priority patient problem?

1. Potential for noncompliance due to social circumstances.

2. Potential for ineffective self-health management due to aging.
3. Potential for infection due to poor peripheral perfusion.
4. Potential for disturbed sensory perception due to degenerative changes.

NCLEX Client Need: Physiological Adaptation

8. A nurse determines the fingerstick blood glucose reading for a patient with diabetes is 750 mg/dL. What is the nurse's priority action?
1. Immediately notify the RN and the health care provider.
 2. Assess the vital signs of the patient.
 3. Check the record to verify whether the patient has type 1 or type 2 diabetes.
 4. Administer prescribed sliding scale insulin.

NCLEX Client Need: Reduction of Risk Potential

9. The nursing assistant tells you that a patient with diabetes has a blood glucose level of 60 mg/dL. What symptoms would the nurse be most likely to observe with this glucose level?
1. Confusion, tremulousness, pallor, sweating, and weakness
 2. Dry, flushed skin and mild irritability
 3. Deep, rapid breathing and abdominal pain
 4. Incoherent moaning, combativeness, and seizure activity

NCLEX Client Need: Physiological Adaptation

10. During a routine checkup, the health care provider tells a patient with diabetes that test results reveal albuminuria. Which long-term complication is specific to this test result?
1. Metabolic syndrome
 2. Nephropathy
 3. Retinopathy

4. Peripheral vascular disease

NCLEX Client Need: Reduction of Risk Potential

Critical Thinking Questions

Scenario A

Mrs. Lopez is 42 years old and has had type 2 diabetes mellitus for the past 10 years. She is admitted to the hospital for treatment of an infection of the great toe on her left foot, which is the result of improper care of an ingrown toenail. She is 45 lb overweight and admits to frequent binges of eating foods not on her diet. She does not exercise regularly because she says the housework she does gives her enough exercise. When asked about the OHA and diet that have been prescribed for her, she tells you that she only takes her medicine and follows her diet "most of the time."

1. Describe the essential components of a teaching plan for Mrs. Lopez to help her manage her illness better. Why is foot care an important part of this plan?
2. What could you suggest to Mrs. Lopez to help her lose weight?
3. What do you think might motivate Mrs. Lopez to accept more responsibility for managing her illness?
4. What laboratory testing would be recommended to track Mrs. Lopez's compliance with her treatment regimen?

Scenario B

Mr. Tobin is a 22-year-old construction worker who has recently experienced fatigue, excessive thirst and urination, and weight loss. A routine urinalysis revealed glycosuria and a trace of acetone. His health care provider has arranged for Mr. Tobin to have additional diagnostic testing to determine whether he has diabetes mellitus.

1. If Mr. Tobin is found to have type 1 diabetes mellitus, what kind of information will he need to manage his illness?
2. How would you explain the importance of good or tight control of his blood glucose levels to Mr. Tobin?
3. What criteria could be used to determine whether his diabetes is under control?

Scenario C

Mr. Smith is 76 years old and has recently been diagnosed with type 2 diabetes mellitus. It has been difficult to control his blood sugar, and his health care provider has added insulin to his treatment regimen. Mr. Smith was issued a glucometer by the hospital but says that the test strips are too expensive for him to buy very often. Mr. Smith lives alone, cooks for himself, and likes a glass of wine with dinner. Other than an occasional fishing trip, he does not exercise regularly.

1. How would you approach a teaching program for this patient?
2. What resources could you suggest that might assist him to purchase the test strips for the glucometer?
3. How can a glass of wine be incorporated into an acceptable meal plan for a patient with diabetes?
4. What sort of exercise program could you recommend to this patient?

Scenario D

You are making a home visit to a patient who normally administers her own insulin. On arrival you

notice that she has tremulousness, is pale and sweating, and she seems more irritable and distractible than usual. She reports taking her insulin, but she is unable to tell you when she took it, or exactly how much she injected. She thinks her last food was during supper, last night, but she is unsure.

1. You check her blood glucose level with her home device and get a reading of 55 mg/dL. What does this value indicate?
2. Based on your assessment of the patient's symptoms and the blood glucose level, what is your next nursing action?
3. How will you determine that it is safe to leave the patient?

UNIT XIII

Reproductive System

OUTLINE

Chapter 38 Care of Women With Reproductive Disorders

Chapter 39 Care of Men With Reproductive Disorders

Chapter 40 Care of Patients With Sexually Transmitted Infections

CHAPTER 38

Care of Women With Reproductive Disorders

Objectives

Theory

1. Review the female reproductive organs and their role in overall health.
2. Examine normal physiology considering age-related changes to the female reproductive system.
3. Discuss common menstrual disorders and nursing interventions for each.
4. Compare methods of contraception.
5. Examine causes and treatment of infertility.
6. Present changes associated with menopause, treatment options, and nursing interventions.
7. Explain the screening procedures recommended for maintaining reproductive health.
8. Compare and contrast benign and malignant disorders of the female reproductive system.
9. Understand the role of robotic gynecologic surgery as an alternative to open surgery.
10. Distinguish the nurse's role during screening procedures, data collection, and education of women concerning reproductive health.

Clinical Practice

11. Demonstrate techniques of breast self-examination and vulva self-examination to a patient.
12. Use the nursing process in the care of a woman with a reproductive disorder.
13. Carry out interventions for patients with common disorders of the female reproductive tract.

sentinel node biopsy (SĒN-tī-nĕl nōd Bī-ōp-sē, p. 912)
stress incontinence (STRĒS īn-KŌN-tī-nēns, p. 905)

The female reproductive system depends on hormones produced by the endocrine system for correct development and reproductive function. A variety of hormones released in a specific order at specific times trigger the formation of internal and external sexual organs in the developing fetus. Puberty and sexual maturation are also dependent on accurate release of hormones at the appropriate time in the cycle. As the childbearing years draw to a close, hormone production slows until the reproductive cycle ceases altogether.

Reproductive health can be disrupted by a variety of disorders, such as infertility; spontaneous abortion; premature labor; infection; and the growth of abnormal tissue, including cancerous and noncancerous tumors. Nursing care of patients with diseases of the female reproductive system is further complicated by the emotional effects of such disorders. The reproductive organs represent the biologic aspect of sexual identity, and women may feel their personal identity is threatened by disorders of this system.

Anatomy and Physiology of the Female Reproductive System

Primary External Structures

The **vulva**, or **pudendum**, is the external female genitalia. It is made up of the following structures:

- The **mons pubis** is a rounded mound of fatty tissue that protects the symphysis pubis. It is covered with pubic hair.
- The **labia majora** are two elongated, raised folds of pigmented skin that enclose the vulvar cleft. The pubic hair extends along these folds.
- The **labia minora** are soft folds of skin within the labia majora. They are soft, shiny, and made up of fat tissue and glands and have no hair follicles.
- The **clitoris** is located at the top of the vulvar cleft, above the urethral opening. It is made up primarily of erectile tissue and is highly sensitive to touch. It is a primary source of pleasurable sensation during sexual activity.
- The **urethral meatus**, or external opening of the urethra of the urinary bladder, is located below the clitoris within the folds of the labia minora.
- The **vaginal vestibule** is situated below the urethral meatus within the labia minora and is the entrance to the vagina.
- The **perineum** is the flat muscular surface between the vagina and the anus.

Primary Internal Structures

- The **vagina** is a muscular tube lined with membranous tissue with transverse ridges called rugae. It connects the external and internal female sexual organs (Figure 38-1).

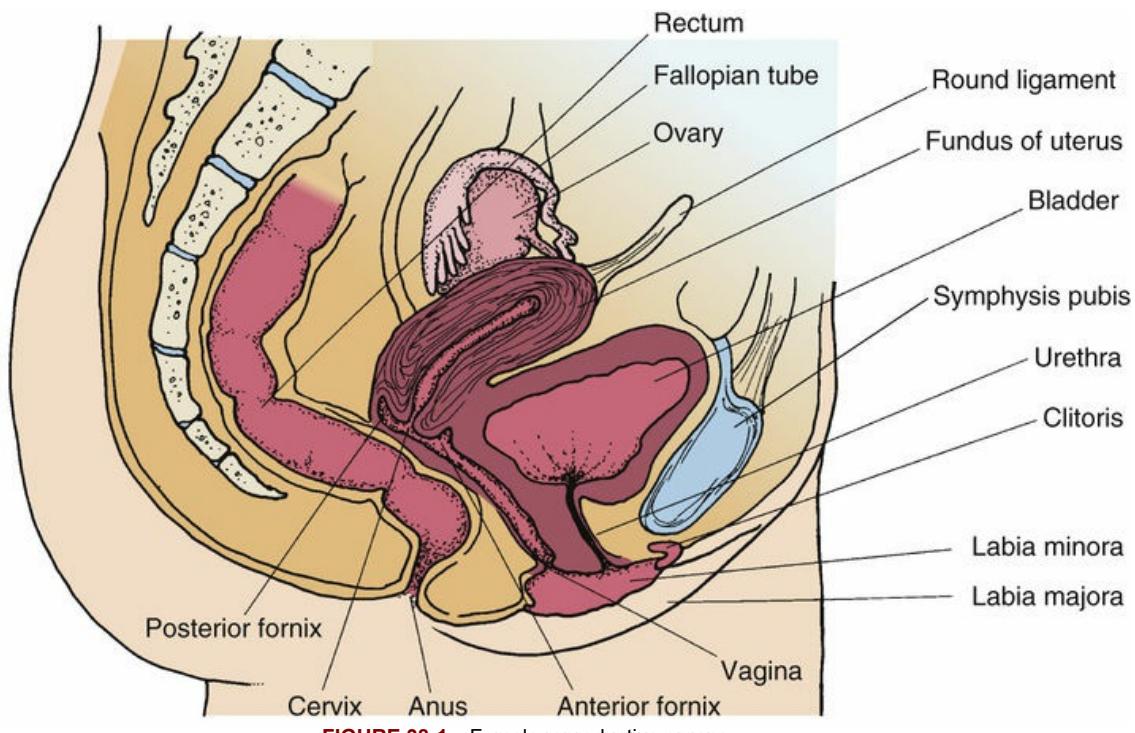

FIGURE 38-1 Female reproductive organs.

- The **uterus** (womb) is a hollow pear-shaped organ with a thick muscular wall. It lies at the upper end of the vagina. It is capable of expanding to many times its normal size to accommodate a

growing fetus. The lower opening of the uterus is the **cervix**, which dilates during labor to allow for delivery of the infant.

- There are two **fallopian tubes** that branch outward from the right and left sides at the top of the uterus. They form the pathway for the **ovum** (egg) from the ovary to the uterus.
- There are two **ovaries**, one located near the end of each fallopian tube. These almond-shaped glands excrete estrogen and progesterone into the bloodstream. At birth, the ovaries contain all the eggs (**oocytes**—primitive ova or eggs) the woman will ever produce, approximately 400,000 in each ovary, most of which will never mature for possible fertilization.
- The **bony pelvis**, located at the base of the body between the hips, supports the pelvic organs, including the growing uterus during pregnancy. It is assisted by the **pelvic floor**, a collection of strong muscles and supportive tissues that brace the pelvis and provide both support and protection for the pelvic organs.

Accessory Organs

- The breasts or **mammary glands**, located on the upper chest, are the accessory organs. They are composed of fibrous, adipose, and glandular tissue and are responsible for **lactation** (milk production), which provides nourishment for the infant.

Phases of the Female Reproductive Cycle During the Childbearing Years

- The **ovarian cycle** has two phases:
 - **Follicular phase:** This is the first 14 days of a 28-day cycle. **Follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)** stimulate the maturation of ova in preparation for fertilization. Estrogen peaks when the ovum is released (**ovulation**), about 14 days before the next menstrual period. The ovum lives up to 24 hours after fertilization.
 - **Luteal phase:** This is days 15 to 28 of a 28-day cycle. LH and progesterone are the primary hormones released in this phase. The blood supply to the uterus increases in preparation for possible implantation of a fertilized ovum. If fertilization and implantation do not occur, the lining of the uterus will degrade and be shed during menstruation, and the cycle begins again.
- The **menstrual cycle** has four phases (Box 38-1).

Box 38-1

Stages of the Menstrual Cycle

Days 1-5

Stage I: Menstrual Stage (Dismantling Stage)

1. Endometrium sloughs away as menstrual flow begins.
2. Progesterone and estrogen are no longer secreted.

3. New follicle starts to mature.

Days 6-14

Stage II: Growth and Repair (Estrogen or Proliferative Stage)

1. Follicle grows, and egg matures.
2. Endometrium returns to normal state and then begins to thicken in response to estrogen.

Stage III

1. Ovulation occurs 14 days before menses, regardless of length of menstrual cycle. It takes place when the follicle ruptures and releases egg. If pregnancy does not occur, the corpus luteum deteriorates, estrogen and progesterone decline, and the thickened tissue on the endometrium of the uterus is sloughed off and is discharged via the vagina as a menstrual "period."

Days 15-28

Stage IV: Secretory Stage (Postovulatory or Progesterone Stage)

1. Corpus luteum secretes progesterone.
2. Endometrium continues to thicken in response to estrogen and progesterone. Uterus prepares to receive fertilized ovum.

Sexual Development in the Fetus

- During the first weeks of pregnancy, the male and female sexual organs are undifferentiated. After the 7th week, rapid changes occur, and by the 12th week the external genitalia are formed and fully differentiated as male or female. The internal structures also are forming during this period.

Sexual Maturation

- The period of sexual maturation is called *puberty*. It usually occurs between ages 9 and 17 years for girls; the average onset is 12 years of age. It involves a period of accelerated growth, after which the hips begin to widen and the breasts begin to develop. Axillary and pubic hair appears. Puberty is completed by the onset of the menstrual cycle, or **menses**. The beginning of menstruation is called **menarche**. **Menstruation** (shedding of the uterine lining) will continue at intervals of approximately 4 weeks throughout the childbearing years, except when pregnancy occurs.

Menopause

- Toward the end of the childbearing years, women enter the phase known as the **climacteric** period. The menses become irregular in both pattern and flow and eventually cease altogether. **Menopause** has occurred when the menses have completely ceased for at least 12 months.

Aging-Related Changes

- After menopause, some atrophy of the female organs, loss of elasticity, dryness of the vaginal membranes, and reduction of bone mass occur because of the decrease in estrogen levels. Loss of natural tissue elasticity may allow internal organs to sag, or **prolapse**, into the vagina.

Women's Health Care

Women's health care can be defined as the promotion of the physical, psychological, and spiritual well-being in women. The growth of the women's movement in America was the beginning of the recognition that there are health needs unique to women, and legislation gradually emerged that included women as subjects in research studies. Research trials concerning the safe dosages and efficacy of drugs had previously been conducted on male subjects and generalized to apply to women. However, currently it is recognized that there are differences between men and women in many areas, and now even the growth norms for children are published with separate charts for girls and boys.

In the late 19th century, female physicians were rare, and by 1900, only 6% of all physicians were women. The women's health movement of the 1960s expanded women's rights to control their bodies and motivated women to learn more about their bodies and understand wellness. Childbirth education classes flourished, and alternative birthing centers emerged. The 1972 Civil Rights Act prohibited discrimination based on gender in educational institutions, and by 2012 more than 47% of medical doctors were estimated to be women ([Association of American Medical Colleges, 2013](#)).

In 1990, the Women's Health Equity Act (WHEA) was passed, containing laws that increased women's access to health services. The Office of Research on Women's Health (ORWH) was formed as part of the National Institutes of Health.

In the 21st century, women were increasingly economically independent and empowered to make health care decisions. Health care education for adolescents includes information concerning puberty, menstruation, and sexuality. Teenagers need information concerning safe sex, contraceptives, and choices concerning high-risk behaviors. Adult women require information concerning Papanicolaou (Pap) smears, breast self-examination, nutrition, exercise, and lifestyle management. Perinatal education is important. Older women require information regarding menopause, long-term illness, and disabilities that affect health care needs. Today many older women live alone with below-poverty-level income and lack caregivers or easy access to health care facilities. Nurses must have an understanding of these needs and of the normal physiologic changes of each age group to devise a plan of care to maintain health or treat illness.

Clinical Cues

Healthy People 2020 Goals Related to Women's Health

Healthy People 2020 includes the following goals related to women's health care:

- Increase the number of women older than age 40 years who have mammograms to curb the rise in breast cancer.
- Increase the number of women older than age 21 years who have Pap tests according to current guidelines.
- Reduce the occurrence of hip fractures in older women with osteoporosis.
- Reduce the number of sexually transmitted infections (STI) and pelvic inflammatory disease (PID) in women.

Women of all ages need to be knowledgeable about the function of their bodies, health care needs, and signs and symptoms of wellness as well as illness. This chapter focuses on the health of the reproductive system and reviews common gynecologic problems with suggested nursing interventions.

Young women typically first enter the health care system for a Pap smear or for contraceptive advice. Support, reassurance, and understanding of cultural and personal needs are the primary responsibilities of the nurse during this first contact. A complete history; physical examination; age-appropriate screening tests with clear interpretations; referrals; and education concerning nutrition, lifestyle, and health care to meet individual needs are essential responsibilities of the nurse and the

health care team.

Normal Menstruation

During the first year after menarche, the menstrual cycle may be somewhat irregular, but by the second year a regular cycle of approximately 28 days is normally established.

Attitudes and ideas regarding menstruation are formed early. They are based on the thoughts and beliefs expressed by other women and on personal experience. Incorrect perceptions about this normal process may increase physical discomfort or cause a young woman unnecessary embarrassment or fear. Although there has been significant improvement in communication with preadolescent young women about the changes they will experience, many still need further education. It is important for nurses to understand their own attitudes about sexuality and the reproductive process before attempting to provide information for women on these sensitive issues. A healthy view of menarche as a natural physiologic process marking reproductive maturity should be encouraged.

Normal Menstrual Bleeding

Menstrual bleeding occurs about 14 days after ovulation and lasts between 2 and 8 days. Menstrual blood consists of endometrial tissue, blood, mucus, and vaginal and cervical cells. The amount of actual blood loss is only 40 to 80 mL. Blood flow may be heavy at first but gradually reduces to spotting. The color may change from bright red to brown, and the blood may have a musty odor. Once a menstrual pattern is established, a change from this pattern is reason to consult a health care provider. The length of the cycle can be influenced by stress, drugs, nutrition, and illness. Women should be encouraged to keep a calendar of their individual menstrual cycle to determine regularity and recognize deviations. Mild cramping may occur, and some mood swings may be associated with the hormonal changes. **Mittelschmerz** is a sharp pain in the right or left lower quadrant, sometimes felt at midcycle around the time of ovulation, and may last a few hours. Some women are sensitive to this phenomenon and others never experience it.

Normal Vaginal Discharge

The vagina is a warm, moist, dark vault in which microorganisms can flourish. Normal vaginal secretions contain cervical mucus, endometrial fluid, exudate from the Bartholin glands and Skene ducts, and products of normal flora. The main line of defense against infection is lactic acid, which causes an acidic pH. Any change in this pH can result in infection. An increase in secretions normally occurs during pregnancy and at the midpoint of the menstrual cycle when ovulation occurs, and a decrease in secretions normally occurs after menopause.

Normal vaginal discharge has an off-white color and is odorless. If the vaginal discharge develops an odor, changes in color or consistency, or causes irritation or burning of the vaginal mucosa, a health care provider should be consulted.

The Normal Breast

Breasts are made of adipose tissue, milk-producing glands called lobules, ducts, and fibrous tissue that rest on the chest muscle. They may not be completely symmetric (one may be slightly larger than the other) and may feel a bit lumpy and tender, especially during the middle of the menstrual cycle. Age, pregnancy, medication, and diet can affect the way the breasts feel. As women age, the denseness and adipose tissue content decrease, whereas birth control pills, hormone replacement therapy, and pregnancy may cause the breasts to increase in size.

Menstrual Dysfunction

Premenstrual Syndrome and Premenstrual Dysphoric Disorder

Premenstrual syndrome (PMS), also known as *ovarian cycle syndrome*, is the presence of physical, psychological, or behavioral symptoms that regularly recur within the luteal phase of the menstrual cycle and significantly disappear during the remainder of the cycle. These signs and symptoms, which occur between ovulation and menstruation, include abdominal bloating, breast tenderness, irritability, appetite changes, fatigue, mood swings, and a fear of losing control. Management

includes lifestyle diet and exercise changes, stress management, and prevention of fatigue (Hatcher et al, 2011).

Premenstrual dysphoric disorder (PMDD), a more serious problem, is described officially in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-V, 2013), a classification of disorders that is published by the American Psychological Association. It is believed to be the result of abnormal serotonin responses to normal changes in estrogen levels during the menstrual cycle. The symptom criteria used to diagnose PMDD occur between ovulation and the onset of menstruation and begin to improve between the menstruation and ovulation phases; they are not present in the week after the menstrual period. Diagnosis is based on specific symptoms in a pattern throughout more than 3 months. Symptoms include depressed mood; anxiety; irritability; difficulty in concentrating; change in appetite and sleep; and physical symptoms such as breast tenderness, bloating, weight gain, and headaches. Symptoms may interfere with the normal lifestyle or work responsibilities.

Strategies for self-care may include stress management exercises; some lifestyle changes; and maintaining a healthy diet rich in complex carbohydrates and fiber, avoiding simple sugars, salty foods, and caffeine, and prevention of hypoglycemia. Exercise may increase beta-endorphin levels, which results in relief of depression and mood elevation. Although eating chocolate has shown to elevate depressed moods, consumption should be limited. Peer support groups, psychological counseling, and prescribed medications can also be helpful. Medical management commonly includes oral contraceptives (low estrogen, progestin dominant), diuretics during the luteal phase of the menstrual cycle, and nonsteroidal anti-inflammatory drugs (NSAIDs). Serotonin reuptake inhibitors such as fluoxetine (Sarafem) or sertraline (Zoloft) or short-acting anti-anxiety drugs such as paroxetine (Xanax) may be initiated 2 weeks before menses and discontinued when menses begins. This drug regimen has been approved by the Food and Drug Administration (FDA) for the management of menstrual disorders.

Dysmenorrhea

Dysmenorrhea is painful menstruation, a very common gynecologic complaint. There are two classifications of dysmenorrhea.

Primary dysmenorrhea.

Primary dysmenorrhea usually occurs 6 to 12 months after the menarche (when the process of ovulation becomes established and regular menstruation occurs). It is believed to be caused by the release of high levels of prostaglandins in the first 2 days of menstruation, causing uterine contractions and vasoconstriction that result in abdominal cramps with measurable intrauterine pressures similar to the pressure seen in the second stage of labor (Hatcher et al, 2011). Backache; weakness; decrease in appetite; and central nervous system symptoms such as dizziness, headache, and poor concentration may also occur but rarely last longer than 48 hours, coinciding with the decrease in prostaglandin levels. Pelvic examination results are normal.

Primary dysmenorrhea is the leading cause of recurrent short-term school absences in adolescent girls. The most important management of a young adolescent or adult with dysmenorrhea is to promote an attitude of positive sexuality and self-worth. Correction of myths and misinformation is essential, and management is related to the woman's individual responses.

A heating pad promotes vasodilation and often relieves cramps. Back massage and soft rhythmic massage of the abdomen (**effleurage**) can also relieve discomfort. Exercises such as the **pelvic rock** relieve discomfort by releasing endorphins, suppressing prostaglandins, and shunting the blood flow away from the pelvic organs, which results in less pelvic congestion. The pelvic rock is performed in the hands-and-knees position, alternating arching the back and contracting abdominal and gluteal muscles while exhaling and then hollowing the back and relaxing the muscles while inhaling. Several complementary and alternative medicine (CAM) therapies can also be helpful, such as aromatherapy and meditation. A balanced low-fat diet with foods that are natural diuretics, such as cranberry juice, asparagus, and watermelon, may decrease edema-related symptoms. Medications such as NSAIDs are prostaglandin inhibitors and may relieve many discomforts. Health care providers may prescribe an oral contraceptive (OC), which provides relief from menstrual discomforts along with advantages of contraceptive protection. Seasonale is an OC that provides longer periods of pain-free amenorrhea by allowing only four menstrual periods per year, and its use is becoming popular. The FDA has also approved the drug Lybrel, which prevents

menstruation for 1 year (Hicks, 2010). Many herbal preparations and over-the-counter CAM medications are available for self-treatment. Nurses should be aware of side effects and interactions of CAM therapies with prescribed drugs.

Think Critically

Why should nurses ask patients about over-the-counter medications and herbal remedies they are taking and document their use?

Secondary dysmenorrhea.

Secondary dysmenorrhea typically occurs after 25 years of age and is caused by pelvic pathology such as endometriosis, pelvic inflammatory disease, uterine polyps, or fibroids. Pain associated with secondary dysmenorrhea is characterized by a dull lower abdominal pain that radiates to the back or thighs. The pain may occur before the menstrual period and last throughout the days of menstrual flow.

Management involves treating the cause of the pelvic pathology. Temporary relief may be obtained with the same therapies used for primary dysmenorrhea (Table 38-1).

Table 38-1

Drugs Commonly Used to Treat Dysmenorrhea

CLASSIFICATION	SIDE EFFECTS	NURSING IMPLICATIONS
Nonsteroidal anti-inflammatory drugs (NSAIDs) Ibuprofen, Motrin, Naproxen	Nausea, dyspepsia, itching, rash.	Contraindicated in hemophilia, bleeding ulcers, bleeding disorders. Should not be taken with aspirin. (Check labels on cold/allergy medications that may contain NSAIDs.) Should be taken around the clock when menses start to treat discomfort. Patient should take with meals and not consume alcohol.
Mefenamic acid (potent prostaglandin synthesis inhibitor) Cox-2 inhibitors	Diarrhea, nausea, abdominal distention.	Contraindicated in hemophilia, bleeding ulcers, bleeding disorders. Similar precautions to NSAIDs.
Oral contraceptives	Women who smoke should not use hormone therapy. Risks and benefits should be discussed with health care provider.	Use with caution in women with blood clotting disorders, cardiovascular disorders, or cancer.
Levonorgestrel-releasing intrauterine system (LNG-IUS)	Requires invasive application and medical follow-up.	Can be used in combination with contraceptive therapy.

Sexual disorders.

In August 2015, the FDA approved the first drug for female sexual dysfunction, dubbed “female Viagra” (*Medical News Today*, 2015). This drug, flibanserin (Addy) is for women with hypoactive sexual desire disorder (HSDD), which develops in approximately one in ten premenopausal women. An oral dose of 100-mg is taken daily and, if no improvement is seen in 8 weeks, discontinued. Because there is a potentially serious interaction with alcohol, it carries a boxed warning and may only be prescribed by clinicians who have received training and is available only in certified pharmacies.

Contraception

Many women start sexual relationships before they are ready to have children. Others have children and do not wish to have more. For these women, information concerning techniques of contraception is essential to prevent unwanted, unintended pregnancies. Many sexually active women of childbearing age are concerned about regulating, planning, or preventing pregnancy. With the assistance of a health care provider, they can select the birth control method best suited to their physical health, sexual activity, desire to have children at a future date, cultural and religious beliefs about family regulation, and lifestyle.

Contraceptive Options

Women should make an informed decision concerning methods of reliable birth control, and nurses are responsible for providing comprehensive education concerning the advantages, limitations, and side effects of the various contraceptive drugs and devices. Some methods of birth control provide protection against sexually transmitted infections (STIs), but some do not. Newer contraceptive regimens reduce the hormone-free interval, thereby decreasing the occurrence of menstrual periods. The best contraceptive methods for adolescents and young adults are abstinence, the use of planned contraception, the correct use of condoms to prevent STIs, and lifestyle counseling. In the United

States, 47% of high school students report sexual experience, and 40% denied using protection ([Centers for Disease Control, 2014b](#)). *Healthy People 2020* goals include increasing condom use at first intercourse to 73.6% in females and 88% in males. [Figure 38-2](#) illustrates the correct application of a condom and a diaphragm. [Table 38-2](#) reviews the various methods of contraception.

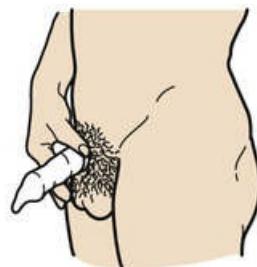

HOW TO USE A MALE CONDOM

1. Apply condom before any contact with vagina because sperm are present in secretions *before* ejaculation.
2. Squeeze air from the tip of condom, and hold it while unrolling condom over erect penis. Leave a half-inch space at tip.
3. Use water-soluble lubricants, if needed.
4. To remove condom, hold it at the base of penis to prevent spillage as you withdraw from the vagina.
5. Dispose and use a new one each time. Be sure to check expiration date on condoms.

A

Squeeze air from tip of condom

Hold condom at base of the penis to prevent spillage

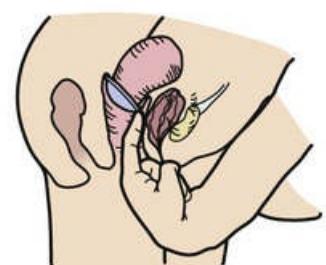

HOW TO USE A DIAPHRAGM

1. The diaphragm can be inserted up to 4 hours before intercourse. Apply spermicide on the rim and inside the center of diaphragm.
2. Compress diaphragm using thumb and finger of one hand, and use other hand to spread the labia.
3. While squatting (or placing one foot on a chair), insert into vagina with spermicide toward cervix. Direct diaphragm inward and downward behind and below cervix.
4. Tuck the front rim of diaphragm into the pubic bone, and feel cervix through the center of diaphragm.
5. Leave in place at least 6 hours after intercourse.
6. To remove, assume squatting position and bear down. Hook a finger over top rim, and pull diaphragm down and out.
7. Wash diaphragm with mild soap and dry after each use. Dust with cornstarch, if needed, and inspect occasionally for small holes.

Table 38-2
Methods of Contraception

HOW METHOD WORKS	SIDE EFFECTS/PRECAUTIONS	DEGREE OF EFFECTIVENESS/USAGE NOTES
Abstinence Sexual contact is avoided.	Reliable method of preventing pregnancy and STIs.	100% if used consistently
Fertility Awareness Methods Basal Body Temperature (BBT) BBT is measured and charted daily on awakening. Coitus is avoided on the day of temperature rise and for 3 subsequent days.	Temperature must be taken before any activity, or it will rise above its basal level. The special thermometer should be kept at bedside.	80%-90% for all fertility awareness methods if done correctly
Calendar or Rhythm Method Woman charts her monthly menstrual cycle on a calendar and avoids intercourse during fertile period.	Not effective for woman with irregular menstrual cycles. Several months of charting are necessary to establish clear pattern of menstrual cycle.	Fertility awareness methods that monitor multiple parameters (e.g., symptothermal method) may be more effective, but most important aspect of success is faithful adherence to the method; also, the woman must feel comfortable enough with her body to make the necessary observations each month
Ovulation or Billings Method Cervical mucus changes are assessed. During ovulation, mucus is clear with high stretchability ("egg white" consistency). Degree of stretch is tested by pinching a small amount of cervical mucus between the thumb and forefinger and stretching it between them (called <i>spinnbarkeit</i>). During ovulation, mucus smeared on a glass slide will dry into a "fern" pattern.	Woman must feel very comfortable with her body and confident in her ability to detect and assess changes.	
Symptothermal Method Variety of parameters are recorded, including cervical mucus changes, BBT pattern, mittelschmerz (brief sharp abdominal pain that may occur with ovulation), increased libido (sexual drive).	More effective for women with regular menstrual cycles. Requires significant accurate record keeping.	
Chemical Predictor Test A test kit that contains a chemically treated strip that will turn color when estrogen or luteal hormone levels are present in urine.	Increase in hormone levels occurs 12-24 hr before ovulation.	
Mechanical or Barrier Contraception Intrauterine Device (IUD) A small, sterile, flexible plastic device that is inserted by a provider into the uterus. Can be a copper device (ParaGard) or a device containing the hormone levonorgestrel (Mirena). Can provide 5 yr of protection.	May increase menstrual flow or cause cramping or low back pain. Increased incidence of PID in women with multiple sex partners, women whose partners have multiple partners, and women with previous incidence of PID. Patient must check placement by feeling for string once each month.	Up to 99% effective; must be removed by health care provider
Male Condom A sheath commonly made of latex that is placed over the erect penis before intercourse. Oil-based lubricants such as petroleum jelly can cause latex to break down and reduce effectiveness. Some condoms, made of polyurethane, are compatible with oil-based lubricants.	Inexpensive, readily available, easy to use correctly. <i>Precautions:</i> (1) Leave space at tip for semen to collect to prevent it being forced upward out of the condom; (2) store in a cool place, and not for excessively long, to prevent breakage from aging of the latex or heat damage; (3) handle carefully to prevent spilling semen and possibly introducing it into the vagina.	88%-98% if used properly; use of spermicide increases effectiveness to 98%-99%
Lea's Shield A one-size reusable silicone barrier that is held in place by the vaginal walls. Used with a spermicide and inserted before each intercourse act. Lea's Shield is a one-size prescription and is nonhormonal.	Effectiveness enhanced with use of spermicide. Provides STI protection. Should not be left in place for more than 48 hours or used during menstruation. Woman should urinate before and after insertion.	84%-90%
Female Condom Sheath with retaining ring that is placed in the vagina before intercourse. Open end with large entrance ring extends outside the vagina. Can be inserted up to 8 hr before intercourse.	The penis must remain inside the sheath, not between the sheath and the vaginal wall. Acceptance of the method has been slow, because it is more expensive and more difficult and time-consuming to place properly than the male condom. Effectiveness is enhanced with use of spermicide. Provides protection against STIs.	79%-90%; most failures occur when the penis is withdrawn too far and reenters the vagina beside rather than within the condom
Diaphragm A latex or rubber dome-shaped cup that fits snugly over the cervix. Spermicide is applied to the cervical side of the diaphragm, and it is inserted into the vagina so the fitted ring holds it securely in place at the top of the vagina to wall off the cervix. The spermicide enhances effectiveness, should there be a leak around the edge or tear in the diaphragm.	A diaphragm must be fitted professionally and should be refitted annually, with a gain or loss of 7-10 lb, and particularly after pregnancy.	82%-94%
Cervical Cap Filled with spermicidal jelly and fitted over the cervix. Fem Cap is prescription fitted to each woman.	Can be in place up to 48 hr before sexual intercourse. Similar to diaphragm. It is recommended that women void before and after insertion and after intercourse. Should not be used during menstruation.	82%-94%
Vaginal Sponge A nonprescription soft polyurethane sponge traps and absorbs semen and has spermicidal properties.	Sponge is moistened with 2 tablespoons of water and squeezed before insertion. Must remain in place 6 hours after intercourse. Prolonged use can increase risk for toxic shock syndrome.	82%-94%
Spermicidal Methods Gels, Foams, Creams Work by killing sperm within the vagina. Must be applied before intercourse.	Available without prescription. More effective when used as an adjunct to condoms, diaphragms, and caps.	Foam alone, 79%-90%; creams and gels alone, 79%
Hormonal Methods Oral Contraceptives (OCs) "The pill" contains a combination of synthetic estrogen and progestin, hormones that prevent ovulation and thicken cervical mucus, making it difficult for sperm to travel upward (also true for injectable and timed-release hormonal methods). Traditionally based on a 28-day cycle with 7 hormone-free days that result in monthly menstruation. Seasonale is an OC that reduces menstrual periods to four times a year. Lybrel is an OC that is taken 365 days a year and suspends menstruation indefinitely.	Prescription required. Must be taken faithfully to be effective. <i>Precautions:</i> Not recommended for women older than 35 years who smoke or women with a history of heart or liver disease, breast or uterine cancer, blood clots or venous inflammation, or unexplained vaginal bleeding. At least three regular ovulatory cycles should be evidenced before adolescents start OC use. May cause nausea.	97%-99.9%
"Minipill" Contains a small dose of progesterone and no estrogen. Causes endometrium to be hostile to implantation.		97%-99.9%
Low-Dose Regimens Mircette uses low-dose estrogen for 5 of the 7 traditionally "hormone-free" days, resulting in shorter, lighter menses. Loestrin 24 Fe provides 24 days of combined hormones with a 4-day hormone-free interval. Yasmin is similar to Loestrin, but has been shown to relieve symptoms of premenstrual dysphoric syndrome.	There is evidence of increased risk of venous thromboembolism in users of OCs containing drospirenone or levonorgestrel (Parkin et al, 2011).	97%-99.9%
Injectable Contraceptives (Depo-Provera) Synthetic timed-release progestin is injected q12wk, preventing	Injections given in clinic or office. Must be repeated q12wk to	99.7%

ovulation.	remain effective. <i>Precautions:</i> See oral contraceptives.	
Sustained-Release Implants Implanon, a thin, flexible rod containing synthetic hormone, is placed under the skin of the forearm in a minor surgical procedure. Effective for 3 yr.	Small incision required to place and to remove. Less popular now that injection is available. <i>Precautions:</i> See oral contraceptives.	98.4%–99.4%
Emergency Contraception Taken orally the day after unprotected intercourse, it induces menses and prevents implantation in the uterus.	Not to be used as a routine form of contraception. Women receiving the “morning-after” pill should also receive assistance in choosing an effective, ongoing method of contraception.	97%–99.9%
Vaginal Ring The NuvaRing (etonogestrel and ethinyl estradiol) is a flexible silicone ring inserted into the vagina for 3 wk and removed for 1 wk to allow for menstruation.	Leukorrhea and vaginal infection are possible side effects. Other side effects are similar to OCs, but fewer GI problems are experienced because it does not pass through GI tract.	97%–99.9%
Skin Patch A transdermal skin patch containing norelgestromin and ethinyl estradiol applied to dry skin of back, buttocks, upper arm, or torso. Replaced weekly for 3 wk. Not applied in week 4 to allow for menstruation.	The FDA is investigating evidence that a higher level of estrogen is absorbed during sunbathing or while in saunas, increasing risk for complications (symptoms similar to OCs). Risk of thromboembolus may be higher than with OCs.	97%–99.9% (may not be effective in women >200 lb [90 kg])
Delayed Menstruation <i>Seasonale</i> is an OC that delays menstruation so that the woman experiences four menstrual periods a year. <i>Seasonique</i> is an OC that provides 84 days of combined hormones followed by a week of low-dose estrogen rather than a hormone-free interval. The four menstrual periods a year are lighter and with less discomfort.	A popular choice. Requires follow-up research concerning long-term effects.	97%–99.9%
Permanent Contraception Tubal Ligation (Female) (Surgical or Nonsurgical Hysteroscopic Technique)	Fallopian tubes are surgically cut or tied to prevent sperm from reaching ovum. Nonsurgical transcervical insertion of an Essure microchip into each fallopian tube causes local inflammation and closure of fallopian tubes.	100%
Vasectomy (Male)	The vas deferens (sperm ducts) are cut and tied to prevent sperm from entering ejaculatory fluid.	Use another form of birth control until two sperm analyses are negative.

FDA, Food and Drug Administration; GI, gastrointestinal; PID, pelvic inflammatory disease; STIs, sexually transmitted infections.

Data from Fantasia H: Options for intrauterine contraception, *J Obstet Gynecol Neonatal Nurs* 34(3):375–379, 2009; Fischer M: Implanon: a new contraceptive implant, *J Obstet Gynecol Neonatal Nurs* 34(3):361–368, 2009; Fontenot H, Harris A: Latest advances in hormonal contraception, *J Obstet Gynecol Neonatal Nurs* 34(3):369–371, 2009; Hacker N, Gambone J, Habel C: *Essentials of obstetrics and gynecology*, ed. 5, Philadelphia, 2010, Saunders; Hatcher R, Trussell A, Nelson W, et al: *Contraceptive technology*, ed. 19, New York, 2007, Ardent Media; Theroux R: Hysteroscopic approach to sterilization, *J Obstet Gynecol Neonatal Nurs* 34(3):356–360, 2009; and Yranski P, Gamache M: New options for barrier contraceptives, *J Obstet Gynecol Neonatal Nurs* 37(3):384–389, 2009.

Natural Family Planning

Natural family planning, also known as fertility awareness, involves identifying signs of ovulation and abstaining from intercourse during periods of fertility. (The ovum is viable up to 24 hours after ovulation, and the sperm are viable up to 72 hours in the fallopian tube.) The **basal body temperature (BBT)** technique involves monitoring the BBT each morning and noting a rise that occurs at ovulation. A cervical mucous test, called the *Billings method*, can also be used to track the occurrence of ovulation. The **calendar or rhythm method** is based on the knowledge that ovulation occurs 14 days **before** menstruation, and therefore keeping track of the individual's menstrual cycle can help predict the time of ovulation. The **Marquette method** of family planning incorporates the use of an electronic hormonal fertility monitor that tracks the levels of the urinary metabolite of estrogen and LH. Natural family planning requires the commitment of both partners and close, accurate monitoring during the menstrual cycle. Douching, withdrawal, and breast-feeding are unreliable methods of contraception.

Oral Contraceptives

OCs are the most popular method of reversible hormonal contraception in use. They are effective if used properly and offer some noncontraceptive benefits such as relief from breast tenderness, bloating, and PMS symptoms, but do have contraindications and cautions for users ([Figure 38-3](#)). Nurses should counsel women concerning options and collect data that can determine which contraceptive choice is best. The health care provider assists the woman in making the final choice. Traditional OC regimens are based on a 28-day cycle with a 7-day hormone-free interval that allows for menstruation and gonadotropin levels to rise and ovarian follicular growth to occur. When the OC cycle is not resumed on schedule, the risk of unplanned pregnancy occurs. Newer OCs reduce the hormone-free interval, thereby reducing menstrual discomforts as well as decreasing the risk of contraceptive failure. Seasonale, an OC that provides delayed menstruation so a woman has only four menstrual periods a year, is very popular (Hicks, 2010). An alternate regimen (Lybrel) involves low-dose combined hormones for 365 days per year without a hormone-free interval, which allows a woman to postpone menstruation indefinitely. Smoking increases the risk of complications related to OC therapy, especially in women older than 35 years ([Gabbe, 2012](#)).

Clinical Cues

It is important to tell patients that birth control pills and most other birth control methods are not 100% effective in preventing conception. Abstinence is the only 100% effective method to prevent pregnancy.

FIGURE 38-3 Contraceptives. (From McKinney EM, James S, Murray SS, et al: *Maternal-child nursing*, ed. 2, Philadelphia, 2005, Saunders.)

Emergency Contraception

Known as the *morning-after pill*, emergency contraception is indicated after unprotected intercourse. It is not meant to be used on a regular basis, but was developed to decrease the number of unwanted pregnancies and elective abortions. Emergency contraception prevents pregnancy by preventing ovulation or fertilization or by slowing transport of the sperm and egg or altering the uterine lining to prevent implantation. Plan B One-Step is one tablet of levonorgestrel only, to be taken within 72 hours of unprotected sex, that is available to women without prescription and was approved in July 2013. The American Congress of Obstetricians and Gynecologists (ACOG) stated that emergency contraception is safe for women of all ages (ACOG, 2013). (See **Legal and Ethical Considerations** box.) The woman should be referred for counseling and follow-up care after use of any emergency contraception. An emergency contraceptive ulipristal (Ella) has been approved by the FDA and requires a prescription. It prevents pregnancy by prolonging ovulation and can be taken up to 5 days after unprotected sex. The woman is advised to take an antiemetic before each dose to minimize nausea and vomiting. Because emergency contraception is not effective if the woman is already pregnant, failure to menstruate by 21 days after initiation of therapy requires evaluation for pregnancy. There is no evidence that emergency contraception causes abortion, ectopic pregnancy, or fetal anomalies if taken when the woman is already pregnant (Hatcher et al, 2011).

Legal and Ethical Considerations

The “Morning-After” Pill

Although the “morning-after” contraceptive pill can be sold over the counter, there has been some unwillingness by certain pharmacists to provide it. They claim it is against their religious principles. Is it ethical for pharmacists to withhold medication from a woman because of their own personal beliefs? In 2014, the Supreme Court ruled that private enterprises do not have to provide health coverage that the company deems morally objectionable.

A copper intrauterine device (IUD) can be inserted up to 7 days after unprotected sexual

intercourse to prevent implantation of the zygote in women who prefer long-term contraception. A woman who seeks emergency contraception should be educated concerning methods of birth control and prevention of STIs.

Information concerning emergency contraception is provided at www.NOT-2-LATE.com

Infertility

Many women wish to have children but have difficulty conceiving. For these women, preconception guidance and perhaps infertility treatments may be helpful. Preconception guidance involves gathering data concerning the woman and her partner to provide information necessary to make an informed, individualized decision concerning conception or fertility assistance. Screening for genetic disorders may be required.

Cultural Considerations

Fertility

Symbols and rites that celebrate fertility are practiced by many cultures. In the United States throwing rice at the bride and groom is a wish for family growth. Distributing candy or cigars in celebration of a birth is also common in the United States. In some countries, rubbing the swollen abdomen of a statue of a fertility goddess is a popular practice for women seeking to conceive.

Primary infertility is the inability of a couple to conceive a child after at least 1 year of active, unprotected sexual relations without using contraceptives. **Secondary infertility** is the inability to conceive after having once conceived or to maintain a pregnancy long enough to deliver a viable infant. Approximately 10% to 20% of couples in the United States have infertility, and increasing numbers of couples are seeking medical intervention. Infertility services also assist women without a male partner who wish to have a child.

The ability to conceive depends primarily on both partners having normal reproductive physiology, physiologically and psychologically sensitive interaction, and proper timing of intercourse. Factors in men that contribute to infertility include problems with the sperm, abnormal ejaculation, abnormal erections, and abnormal seminal fluid. Chapter 39 presents a discussion of problems in the male reproductive system. Factors contributing to infertility in a woman include:

- Problems with ovulation
- An abnormality in the pathway between the cervix and fallopian tube
- An abnormality in the endometrium of the uterus, or malformation of the uterus
- Tumors in the reproductive tract
- Vaginal or cervical environment that is inhospitable to sperm motility or viability

Repeated pregnancy loss can be caused by an abnormality in fetal chromosomes that results in spontaneous abortion, abnormalities of the cervix or uterus, disorders of the endocrine or immune system, infections, or environmental factors such as toxic agents. Preconception counseling helps the couple evaluate problems or risks related to conception (see the Communication box).

There are many causes of infertility; some involve a problem in the woman, and some in the partner. Diagnostic tests include a detailed health history and laboratory tests such as serum prolactin levels and other endocrine evaluations, semen analysis, sperm antibody agglutination studies, and chromosome studies. Tests for tubal patency and other possible abnormalities in both the male and female reproductive tract may also be needed.

Communication

Emotional Impact of Infertility

The emotional impact of infertility is intense. Some couples become almost desperate to conceive. Be alert to evidence that psychological intervention may be needed to assist the couple to deal with the stress of their situation. Indications that a referral may be needed include, but are not limited

to, inability to focus on anything other than the desire to have a child and tension in the relationship of the couple, including blaming each other.

Nursing Management

Interventions nurses can discuss with patients regarding infertility may include nonmedical actions such as:

- Using water-soluble lubricants during intercourse, because these do not have spermicidal properties.
- Having the male partner avoid environments that cause high scrotal temperatures, such as saunas, which can reduce sperm production as well as the life span of the sperm.
- Using condoms when the woman has an elevated antisperm antibody level. After several months, condoms can be removed during the woman's fertile period.
- Stress management, nutrition counseling, and lifestyle analysis.

Interventions for infertility can also involve medical therapy such as the use of drugs that stimulate ovulation.

Complementary and Alternative Therapies

Herbal Products and Fertility

Because use of CAMs such as herbs and oils is common, women should be instructed that use of herbs and oils such as licorice root, wormwood, fennel, ephedra, goldenseal, flaxseed, pennyroyal, cascara, sage, and periwinkle should be avoided while trying to conceive and carry a pregnancy (Hoffman, 2015).

Herbal products that may be used to promote fertility include nettle leaves, dong quai, and red clover flowers. Vitamin E, calcium, and magnesium supplements have also been used. There is currently no scientific evidence that these herbal products are effective.

Assisted Reproduction

Assisted reproductive therapies (ARTs) are available but are associated with many ethical and legal issues, such as the risk for having a multifetal pregnancy, freezing embryos for later use, and the use of a surrogate mother. Donor eggs or donor sperm can be used, making future legal challenges for custody a possibility. It is now possible for a child to have five parents: sperm donor, egg donor, gestational surrogate, and the parents who will rear the child! Micromanipulation allows the removal of a single cell from an embryo for genetic analysis. Defective genes can be replaced. Success rates of ART vary, and the procedure is usually expensive and rarely covered by health insurance. **Box 38-2** lists some types of ART procedures.

Box 38-2

Examples of Assisted Reproductive Therapy (ART) Procedures

- *In vitro fertilization (IVF-ET)*: Woman's eggs are collected from the ovary, fertilized in a laboratory, and transferred into the uterus at the embryo stage of development.
- *Zygote intrafallopian transfer (ZIFT)*: After in vitro fertilization, the ovum is placed into the fallopian tube at the zygote stage of development.
- *Therapeutic donor insemination (TDI)*: A donor's sperm inseminates the female.
- *Intracytoplasmic sperm injection*: Injection of one live sperm directly into the mature egg.
- *Surrogate mother*: The surrogate mother can be inseminated with one partner's sperm or be implanted with an egg fertilized by one partner's sperm in vitro. The egg is transferred to the

uterus of the surrogate mother; she becomes a gestational carrier.

Menopause

Menopause is defined by the World Health Organization as the cessation of menses for 12 consecutive months because of a decrease in estrogen production. The **perimenopausal** or **climacteric period** is the time around the actual cessation of the menstrual cycle.

Signs and symptoms of the climacteric period and menopause include hot flashes (a sensation of warmth), hot flushes (a visible redness and moistness of the skin), and night sweats caused by vasomotor instability resulting from low estrogen levels. These symptoms usually decrease as the woman's body adjusts to the lower level of estrogen. Changes in the menstrual flow and menstrual irregularity require the woman to "be prepared" for an unexpected menstrual period. The aging process and the decrease in estrogen levels can cause thinning of the vaginal walls (**atrophy**) as well as dryness and itching of the vagina (**pruritus**). These changes may result in painful sexual relations (**dyspareunia**) and can also lead to increased susceptibility to infections, because the vaginal pH increases.

☒ Older Adult Care Points

The significant reduction in estrogen after menopause (about 80% less than during the reproductive years) causes a decrease in natural vaginal lubrication. Women may be prescribed vaginal creams containing estrogen to restore moisture and elasticity to vaginal tissues. Estrogen cream used as a lubricant for sexual intercourse is discouraged, because the cream may damage latex condoms, and other methods of birth control should be used until full menopause occurs. Nonmedicated lubricants should be used for this purpose if necessary. Studies have shown that the estrogen contained in some vaginal creams can be systemically absorbed; therefore they should be used with caution.

The psychological response to menopause has resulted in referring to that period as "the change in life" that can challenge some women's personal coping skills and require family support to maintain a sense of purpose in life. Other women feel a sense of freedom from the need for contraception or medication for cramping.

Western culture values youth and beauty, and the onset of menopause may be seen by some women as a loss of attractiveness and the first step to old age. In other cultural groups, the wisdom gained from life's experiences is valued. Nurses must understand the perceptions of the woman and the family before designing and implementing a teaching plan.

Health Risks of Menopause

The major health problems that occur at or after menopause include the development of osteoporosis and coronary heart disease.

Osteoporosis.

Osteoporosis is a decrease in bone mass that increases the risk for bone fractures. The decrease in estrogen that occurs during menopause slows bone growth, and therefore bone deteriorates and thins before new bone growth occurs. Estrogen also enables vitamin D to assist in calcium absorption in the intestine, and a decrease in estrogen is associated with a decrease in calcium, which is essential to healthy bone tissue. **Box 38-3** provides a list of some lifestyle activities that may increase the risk of developing osteoporosis. The drug denosumab (Prolia) is FDA approved for increasing bone density in the treatment of osteoporosis in menopausal women ([Hanley et al., 2012](#)).

☒ Older Adult Care Points

Older women who are on long-term estrogen replacement therapy are at increased risk for endometrial cancer and breast cancer; it is particularly important that these women have annual pelvic examinations and have regular breast cancer screenings.

Box 38-3

Lifestyle Activities that Increase Risk of Osteoporosis

- Inadequate lifetime intake of calcium and vitamin D prevents reaching peak bone mass by age 30
- **Smoking:** Decreases estrogen production
- **Excessive alcohol intake:** Interferes with calcium absorption and depresses new bone growth
- **Excessive caffeine, cola or soft drink intake:** Results in imbalanced calcium and phosphorus or demineralizes bone

The first signs of osteoporosis are loss of height, back pain, and the development of a **dowager's hump** in which vertebrae fail to support the upper body in an upright position ([Figure 38-4](#)). The ACOG Women's Health Care Physicians recommend bone density screening for menopausal women. [Chapter 32](#) discusses osteoporosis in detail.

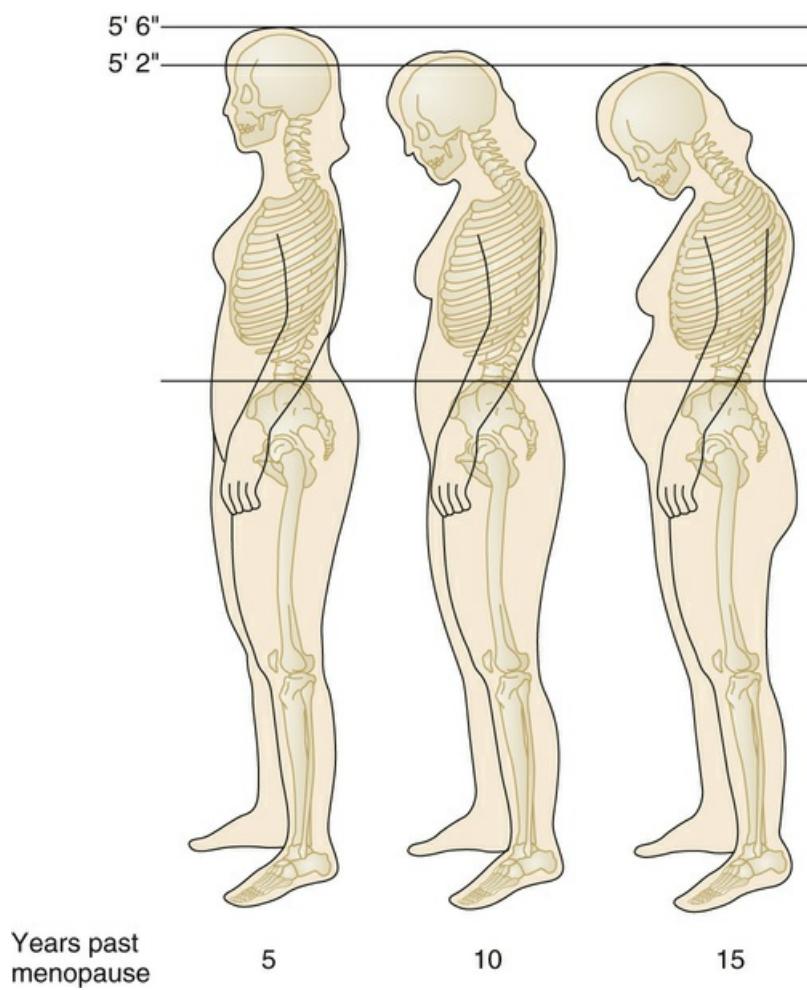

FIGURE 38-4 Osteoporosis. With progression of osteoporosis, the vertebral column collapses, causing loss of height and back pain. *Dowager's hump* is the term used for this curvature of the back.

Coronary heart disease.

Postmenopausal women are at increased risk for coronary heart disease because of changes in lipid metabolism and a rise in total cholesterol. Diet and exercise can help minimize the effects of these risks. See [Chapters 19](#) and [20](#) for details concerning cardiovascular diseases.

Treatment Options During Menopause

Hormone therapy.

Hormone replacement therapy (HRT) (with estrogen and/or progesterone) was once the cornerstone of interventions that reduced the discomforts of menopause (hot flashes and vaginal atrophy) and protected women from developing coronary heart disease and osteoporosis. Research has offered evidence that HRT can increase the risk of developing blood clots, stroke, and heart attack and even breast cancer. The ACOG recommends careful selection of patients for HRT and detailed education concerning risks of therapy. Current guidelines state that hormone therapy should be used by well-informed and well-monitored patients for menopausal symptoms only, at the lowest effective dose and shortest period of time ([Roush, 2012](#)). A combination of estrogen and bazedoxifene (Duavee) was approved in 2013 to treat vasomotor signs and symptoms associated with menopause and may prevent postmenopausal osteoporosis in women who still have their uterus in place ([Hester, 2013](#)).

Bioidentical hormones.

A bioidentical hormone such as oral estradiol, estradiol transdermal patches, or oral micronized progesterone (Prometrium) has a chemical structure identical to hormones produced in the human body but are clinically synthesized from steroid molecules taken from wild yam or soy. It differs from "natural hormones" such as conjugated equine hormone (Premarin), which comes from the urine of pregnant mares and has a chemical structure different from the human hormone.

Progesterone is a bioidentical hormone that has a different chemical structure from progestins. Both synthetic and bioidentical hormones interact with the same estrogen and progesterone receptors on target cells, but their physiologic side effects may differ. Bioidentical hormones are made (compounded) by individual pharmacies are not FDA regulated or approved. Bioidentical hormone drugs do not usually have package inserts. Nurses should be alert to research findings that involve "hormone therapy" and inquire whether the hormones researched are bioidentical or synthetic ([Food and Drug Administration, 2015](#)).

Minivelle, an estrogen-only transdermal patch, may be prescribed to treat vasomotor symptoms of menopause but may increase risk of dementia in women older than 65 years ([Liu and Minikin, 2013](#)).

Alternative therapies.

Some CAM therapies have been helpful in relieving specific discomforts of menopause. Homeopathy, acupuncture, and certain herbs may offer relief, but each may have contraindications as well. Herbal therapy has not been fully researched or regulated, and some side effects or interactions with food or drugs are possible. Phytoestrogens; soy products; and vitamins B, C, and E have also been helpful in relieving menopausal discomforts. Soy isoflavones have been found to be very effective in relieving vasomotor symptoms of menopause but depend on specific bowel flora for activation. Soy should not be used by women with estrogen-dependent cancers or women taking tamoxifen (Nolvadex) or aromatase inhibitors ([Glassy, 2014](#)). Medications such as alendronic acid (Fosamax) can be prescribed for women with osteoporosis, but side effects should be explained carefully. After taking alendronic acid, the woman must be able to sit upright for at least 30 minutes. Diet, physical exercise, yoga, and tai chi have remarkable value, and support groups are very effective in helping to manage menopause ([Glassy, 2014](#)).

Health Promotion

Using CAM Therapies for Menopause

Women should be encouraged to consult with a health care provider before using CAM therapies such as soy isoflavones, black cohosh, or other herbs. For some women with estrogen-dependent cancers, these substances may be contraindicated. Certain herbs may interact with other medications the patient is taking.

Nutritional Therapies

Managing Menopause

When phytoestrogens are recommended by the health care provider, teaching about these substances should be provided. Phytoestrogens are found in foods such as wild yams, cherries, dandelion greens, alfalfa sprouts, and black beans. Food sources of soy include tofu, soy milk, and roasted soy nuts.

Health Screening and Assessment

Health screening is a form of preventive care. **Primary prevention** is designed to decrease the probability of becoming ill, such as maintaining a health or nutrition history and providing immunizations. **Secondary prevention** is designed to focus on detection of specific diseases a patient is at risk for so that early treatment may be given (such as annual mammograms). **Tertiary prevention** minimizes the impact of an already diagnosed condition.

All adult women may be at risk for obesity, high cholesterol, high blood pressure, osteoporosis, and dental disease. Pregnant women or women planning pregnancy may be at risk for a folic acid deficiency that could result in a neural tube defect in the developing fetus; therefore, prenatal vitamins, including folic acid supplements, may be prescribed.

Health screening begins with the woman's visit to her health care provider. It is your responsibility to introduce yourself, ask pertinent questions, and document all information gathered. This phase is called *collection of data*. The data collected identify the patient and summarize her personal health history, the community in which she lives, and her available support system. Some information concerning the woman's culture, lifestyle, and usual coping mechanisms will enable the design of an individualized plan of care. All data collection should include information regarding use of nonprescription as well as prescription medications and CAM therapy.

Breast Self-Examination

Breast self-examination (BSE) is optional and may be done monthly, about 1 week after menstruation begins, or on a specific date each month after menopause. Research indicates that women examine their breasts effectively whether or not they have been taught by a professional, and intensive BSE instruction is unlikely to reduce mortality from breast cancer (Thomas et al, 2002). Mammography and magnetic resonance imaging (MRI) for women at high risk are the other current screening tests. Tomosynthesis (three-dimensional mammography) is the newest form of mammography. Testing for *BRCA1* and *BRCA2* gene mutations is performed on patients who have a high familial risk of breast cancer.

Other tests for breast cancer currently being researched include thermography and tissue sampling (National Cancer Institute, 2015).

Clinical Cues

If a woman is reluctant to have a mammogram recommended by her provider because she has previously experienced a fair amount of discomfort during the procedure, suggest that she take some acetaminophen an hour before the scheduled test (unless contraindicated). Also discuss the benefits of discovering breast cancer early versus the few minutes of breast discomfort from the compression of the machine.

Vulvar Self-Examination

Many women are unaware of the importance of vulvar self-examination (VSE). Although serious lesions in this area are less common than in the breast, early detection allows for rapid and often minimally invasive treatment. Delay in detection can lead to severe surgical disfigurement and even death. VSE should be performed monthly. It usually is done in a sitting position. One hand is used to hold a mirror, the other to separate the labia and expose the area surrounding the vagina. Using both touch (to palpate for lumps or thickening beneath the skin) and visualization, the self-examination begins at the top of the mons pubis and works downward to the clitoris, the labia

majora, the labia minora, the perineum, and finally the area around the anus. The woman should note any changes and report them to her health care provider. These include new moles, warts, or growths; new areas of pigmentation, especially white, red, or dark skin areas; ulcers or sores; and areas of continuing pain, inflammation, or itching. Most of these findings will not be malignancies and will require little, if any, treatment. Treatment of malignancies that have been detected early is typically relatively easy and can prevent deformative surgeries such as **vulvectomy** (excision of the vulva) and prevent **metastasis** (spread of a malignancy to other areas of the body).

Diagnostic Tests

The nurse often is asked to assist with various diagnostic tests. Providing the woman with a clear explanation of what will be done and what she can do to minimize discomfort is essential. A consent may be required with certain procedures, and the nurse is responsible for ensuring that the health care provider has obtained an informed consent. All questions should be answered clearly and accurately before the procedure has started. **Table 38-3** describes common gynecologic diagnostic tests.

Table 38-3
Common Gynecologic Diagnostic Tests and Diagnostic Procedures

PURPOSE	DESCRIPTION	NURSING IMPLICATIONS	
Pelvic Examination	Equipment: Gloves, vaginal speculum, lubricant, light, table with stirrups. Process: Inspection via the vaginal speculum; manual palpation through abdominal wall, vaginally, and rectally of internal organs.	Some discomfort during examination (decreased or eliminated if the patient remains fully relaxed). Nurse to ensure that patient is appropriately draped and correctly positioned in the stirrups. Examination time is usually 5-10 min.	
Pap Smear, Thin Prep	Equipment: Sterile specimen collection equipment. Process: Exudate, mucus, and cells obtained from surface of cervix with sterile swab or scraping tool and placed on laboratory slide or into preservative solution for pathology evaluation.	Cultures and smears of the cervix may cause mild bleeding and cramping.	
Endometrial Biopsy	To determine cause of postmenopausal bleeding, menstrual difficulties, infertility workup. Equipment: Same as pelvic examination plus suction biopsy apparatus. Process: A suction biopsy of the endometrium is performed via the cervical opening.	Severe cramping may occur during procedure. Patient is usually premedicated. Normally some vaginal bleeding follows; flow should not be heavy.	
Colposcopy	Endoscopic examination of the vagina and cervix to evaluate abnormal cells and lesions, particularly after a positive Pap smear. Equipment: Same as pelvic examination plus colposcope. Process: Area is visualized through the scope, with photos and possible biopsies of lesions requiring further study.	Patient is positioned as for pelvic examination. Procedure takes a few minutes. Biopsy may cause a small amount of bleeding and minor cramping. No tampons should be used until healing has occurred.	
Hysteroscopy	Endoscopic examination of the interior of the uterus; may also involve procedures such as biopsy or removal of fibroids, adhesions, and septums. Endometrial laser ablation (destruction of areas within uterine lining) may also be performed.	Equipment: Hysteroscope is inserted vaginally, usually under local anesthesia. May also be done in combination with laparoscopy. Process: Hysteroscopy is done in operating room. The cervix is dilated and the interior of the uterus is cleansed by scraping, suction, or both.	Occasional injury to cervix or uterine wall. If endometrial ablation is done, the woman will have difficulty becoming pregnant, because the lining destruction is permanent.
Dilation and Evacuation (D&E)	To detect cause of excessive bleeding; to remove hypertrophied uterine lining, retained placenta, or tissue remaining from incomplete abortion.	Equipment: Done in operating room. Process: The cervix is dilated and the interior of the uterus is cleansed by scraping, suction, or both.	Mild cramping and bleeding for up to 1 wk. Next period may be either early or late. Complications include uterine perforation, excessive bleeding, infection. Instruct patient to report heavy bleeding, clotting, sharp/severe abdominal pain, abnormal or foul discharge.
Mammography (see Chapter 8)	To screen the breasts for abnormal growths, particularly cancer.	Equipment: Done in the radiology department with special radiographic equipment. Process: A full-field digital mammography machine records images on a computer screen and can computer-enhance questionable images for increased accuracy.	Breast discomfort from compression of the tissue during the test; occasional mild bruising. Instruct patient to wear no deodorant or lotion on the upper body and to wear clothing that allows top to be easily removed.
Hysterosalpingography	To detect uterine tumors, adhesions, or developmental anomalies; detect tubal obstruction preventing ova from reaching uterus.	Patient is placed in the lithotomy position on fluoroscopy table with a speculum in the vagina. Contrast media is injected through the cervix. Fluoroscopy is performed and radiographs are taken.	Have patient void before the procedure. Vaginal discharge may occur for 1-2 days after the test and may be bloody. Instruct patient to report fever, pain, or other signs of infection.
Ultrasound (Sonogram)	Pregnancy: To determine gestation; screen for birth defects or placental abnormalities. Gynecology: To determine presence, location, and size of abdominal mass; determine whether a mass is <i>cystic</i> (fluid filled) or solid; locate intrauterine device; monitor ovulation in infertility.	Equipment: Ultrasound machine. Process: Sound wave transducer emits inaudible sound waves that record interior structures on the ultrasound screen. A video recording is made so results can be restudied and evaluated. A “picture” of the fetus may be provided to the parents.	Some tests require a full bladder, which may be uncomfortable during the test. The nurse should assist the woman to immediately empty her bladder after the examination. Skin should be clean, dry, and free of lotions or powder. During pregnancy, two or more ultrasound examinations may be required. The use of independent three- or four-dimensional ultrasound procedures for purposes of providing mementos to parents is not recommended, because the long-term effects of the extra energy used in these examinations on the fetus has not been researched.
Pelvic/Vaginal Ultrasound	To detect thickness of uterine lining, size of uterus, presence of fibroids; size of ovaries; and presence of cysts or tumor.	Process: Ultrasound transducer is passed over pelvic area or the transducer is inserted into the vagina and guided over areas of the surface.	Advise that there will be minor discomfort if vaginal transducer is used.
Breast Ultrasound	To differentiate benign tumor from malignant tumor. Useful in women with dense breast tissue and fibrocytic disease.	Process: A noninvasive painless procedure.	An ultrasound will not detect microcalcifications that a mammogram can detect.
PET Scan	To stage breast cancer and detect skeletal lesions.	Process: Performed in radiotherapy unit.	—
Breast MRI	Used for women with dense breast tissue.	Process: Images are taken with an MRI machine.	Premedication to lessen anxiety for women with claustrophobia may be advised. Patient must not wear metal during test.
Breast Biopsy			

To diagnose breast cancer. Usually performed when a suspicious breast lump is detected.	<i>Process:</i> A needle aspiration can be done on an outpatient basis under local anesthesia. An incisional biopsy can be done in a same-day surgery setting under local or general anesthesia. All removed tissue or fluid is sent to laboratory for analysis.	Check incision for bleeding. Encourage verbalization of fears. Schedule follow-up appointment for results of laboratory studies.
---	--	--

MRI, Magnetic resonance imaging; *Pap*, Papanicolaou; *PET*, positron-emission tomography.

The Pelvic Examination

Assemble the equipment and directs the woman to take deep breaths and relax all muscles during exhalation (**Box 38-4**). The woman can be instructed to bear down as the speculum is being inserted. The speculum is gently placed into the vagina by the health care provider. The blades are then opened to view the cervix. Specimens may be collected for laboratory examination. A Pap test may be obtained to determine the presence of abnormal cells (see Skill 38-1, Assisting With a Pelvic Examination and Pap Test, on the Evolve® website). After the examination, assist the woman to a sitting, then a standing position. Disposable tissues may be provided to wipe lubricant from the perineum. The patient usually dresses and returns to speak with the health care provider. Teaching may include the purpose of the tests performed and the need for routine checkups and Pap test every 3 years from ages 21 to 29, with human papillomavirus (HPV) testing every 5 years thereafter until age 65 (Smith et al, 2014).

Clinical Cues

Talking to the patient and holding her hand, if possible, during the examination aids with distraction and enhances relaxation.

Older Adult Care Points

Older women may feel that they no longer need regular mammograms and Pap smears, particularly if they are not sexually active. The American Cancer Society (2015) recommends screening mammography continue every 1 to 2 years for as long as the woman is in good health. Mammogram screening may be traumatic to much older women, and benefits are unclear for patients in this age group who are fragile and in poor health (Centers for Disease Control and Prevention, 2014b).

Box 38-4

Preparing a Woman for a Pelvic Examination

- The unit should provide privacy and good lighting.
- Assemble clean gloves and supplies.
- Orient the patient to the equipment and the purpose of the examination.
- Encourage the woman to void, because a full bladder will make the examination more uncomfortable.
- Position and drape the patient appropriately.
- **Lithotomy**
- **Side-lying**
- **Knee-chest**
- Stay with the woman, encouraging her with information to promote comfort.

Nursing Management

Assessment (Data Collection)

Collect essential data regarding the patient's reproductive history and gynecologic concerns. This can be difficult for both the patient and the nurse, because it involves discussing intimate aspects of the patient's body and personal life. Collecting data concerning sexual health and sexual practices is an important part of routine data collection. Sexual health information should include the "5 Ps": Partners; Practices; Protection from STIs; Past history of STIs; and Prevention of pregnancy (Pessagno, 2013). Also record information on the cultural beliefs and attitudes regarding sexuality and sexual identity, reproduction, and body image, all of which affect the assessment process. Ask questions in a tactful yet matter-of-fact manner and appreciate that the patient has the right to choose not to answer. A symptom diary can be very helpful. Note patterns of coping and available support persons.

Focused Assessment

Data Collection for Gynecologic History

Sample questions when collecting data from a patient with a gynecologic problem include:

- How old were you when you began menstruating?
- Are your periods regular? How often do they occur? How long do they last?
- How heavy is your flow? Do you ever pass clots or pieces of tissue? Do you have pain before or during your period?
- Do you have cramps, headaches, or abdominal or back pain at other times of the month?
- Do you have mood swings, depression, or periods of tearfulness associated with your menstrual cycle?
- Are you having any vaginal discharge or itching?
- Do you have bleeding or spotting between your periods?
- Do you have any problems urinating, including burning, pain, or incontinence?
- How many times have you been pregnant?
- Have you had any miscarriages?
- Have you ever had a pelvic infection?
- Do you perform breast and vulvar self-examination?
- When was your last Pap smear?
- When was your last mammogram?
- Are you taking any medications routinely?
- Are you currently using any method of birth control, and if so, which method?
- Do you feel comfortable with your method or have a desire to change methods?
- Do you have any specific concerns or questions that we have not talked about?

Cultural Considerations

Culture and Women's Health

Cultural considerations can be particularly significant in the area of women's health care. Cultural views regarding sexuality, reproduction, and the role of women in society will have a direct bearing on the type of care sought and the amount and type of information the woman is willing and able to provide. The nurse must not pass judgment based on her own cultural bias, but must be culturally sensitive and supportive to the needs of women from diverse cultural backgrounds.

■ Nursing Diagnosis

Problem statements commonly associated with gynecologic disorders include:

- Altered activity tolerance due to anemia from excessive blood loss, weakness, or disabling discomfort.
- Fluid volume excess due to premenstrual fluid retention.
- Altered skin integrity due to pruritus, genital lesions, and vaginal discharge.
- Pain due to menstrual cycle, decreased vaginal lubrication, or vaginal irritation.
- Altered sexual function dysfunction due to dyspareunia (painful intercourse) or emotional issues.
- Altered coping ability due to negative attitude about human sexuality or menstruation.
- Altered body image due to surgery, fear of mutilating surgery, and loss of femininity.
- Insufficient knowledge about practices of personal feminine hygiene, normal anatomy and physiology of the female reproductive organs, or safe methods of contraception.
- Altered self-esteem related to sterility, menopause, or surgery on a reproductive organ.

Specific NANDA-I diagnoses can be chosen from the NANDA-I list (see inside back cover).

Expected goals or outcomes include:

- Patient uses energy conservation techniques while maintaining activity levels within capabilities.
- Patient maintains adequate fluid volume with appropriate management techniques.
- Skin remains intact with healing of existing wounds.
- Patient verbalizes an acceptable level of pain relief and ability to engage in normal activities.
- Patient expresses satisfaction with physical intimacy patterns and experience.
- Patient develops improved method of communication, problem-solving techniques, and positive attitude to enable effective coping with signs and symptoms.
- Patient evidences enhanced body image and self-esteem with ability to accept altered body part or function.
- Patient demonstrates motivation to learn and verbalizes understanding of female hygiene and safe sex practices.
- Patient recognizes and accepts positive aspects of self.

■ Planning

Planning the care of a patient with a gynecologic problem depends on the specific disorder. However, prevention of infection, effective patient education, and emotional support are appropriate goals for the plan of care for all patients with a gynecologic problem. The needs of a patient who will have gynecologic surgery would include pain management, education regarding the procedure and follow-up care, infection prevention, and supportive care specific to the procedure. A woman who will lose the ability to bear children because of an early hysterectomy may have very different supportive needs from those of a postmenopausal woman undergoing the same procedure. Surgery for breast cancer brings fears of a major change in body image and the possibility of death if the disease is not controlled. These issues need to be addressed in the plan of care. The plan for a patient with an infection would include an appropriate medication schedule, monitoring for effectiveness of treatment (e.g., fever, swelling, pain resolving), and monitoring for signs of an allergic response to the prescribed antimicrobial agent.

In the clinic setting, women may be attending for annual visits, reproductive or contraceptive counseling, treatment of infections or STIs, prenatal and postnatal care, and a variety of other reasons. If the facility uses standardized care plans as a reference, they must be adapted to express the needs of the individual patient. Such plans are commonly used in hospitals, clinics, and other health care facilities.

The plan of care must address education, pain management needs, emotional and physical care,

family impact, cultural influences, and financial constraints. Specific goals of care for any patient are based on nursing observation and assessment, prescriptions for medication and therapies, the patient's personal desires and goals, and input from other members of the health care team. The patient should agree to the goals, and they must be clearly communicated to other care providers through well-written care plans and documentation, as well as team conferences when appropriate. [Nursing Care Plan 38-1](#) presents one example of a nursing care plan for a woman having a hysterectomy.

Nursing Care Plan 38-1

Care of a Patient After Hysterectomy

Scenario

Marilyn Blair, age 52 years, has just returned to the unit after abdominal hysterectomy for multiple fibroids, metrorrhagia, and greatly increased uterine size that caused abdominal pain. She has an IV infusion of 1000 mL normal saline in the left forearm, an indwelling urinary catheter, an abdominal dressing, and patient-controlled analgesia (PCA) pump containing morphine. Her vital signs are BP 138/82; P 86; R 16; T 98.2° F (36.8° C).

Problem Statement/Nursing Diagnosis

Pain/Pain related to abdominal surgery.

Supporting Assessment Data

Subjective: Pain at 7/10 on pain scale: "It hurts to turn."

Objective: Abdominal hysterectomy incision.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Pain will be controlled by prescribed analgesics, with no episodes of acute pain.	Instruct her in use of PCA pump. Give booster medication as prescribed if needed.	When patient feels in control, anxiety is reduced and less pain medication may be required.	Analgesia via PCA pump provides good relief.
	Assess location, type, and quality of pain q3-4h using a pain scale.	Assessing location and quality of pain may alert nurse to developing complications.	Pain at 3-5 on pain scale.
	Assist with repositioning and support with pillows to attain comfort. Provide quiet, darkened atmosphere for rest and sleep.	Changing position prevents stasis of circulation; comfortable, supported position promotes relaxation.	Assisted to reposition q2h. Sleeping long intervals on side with pillow behind back and between knees for comfort.
	Monitor for side effects of analgesics, especially respiratory rate. Administer antiemetic as prescribed at first signs of nausea to prevent vomiting and further pain.	Morphine can depress respiratory rate.	Respirations 18. No nausea or emesis.
	Check Foley catheter and tubing for patency frequently to prevent bladder distention.	Bladder distention can increase pain and cause infection from stasis of urine in bladder.	Bladder not distended, Foley draining clear urine. Continue plan.

Problem Statement/Nursing Diagnosis

Potential for fluid volume loss/Risk for deficient fluid volume related to potential hemorrhage.

Supporting Assessment Data

Objective: Abdominal hysterectomy.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Vital signs (VS) will remain stable; no signs of shock or hemorrhage.	Monitor VS frequently per postoperative protocol routine.	A rapid pulse and falling blood pressure can indicate development of shock.	VS are at baseline: BP 118/68; P 84; R 16.
	Check abdominal dressing and beneath patient for signs of bleeding with each set of VS; assess for bleeding from vaginal area.	Gravity can cause fluids to drain to a point beneath the patient.	Abdominal dressing clean and dry; no visible vaginal drainage.
	Assess for signs of intra-abdominal bleeding, such as increasing abdominal girth, decreasing bowel sounds, and increasing abdominal pain and rigidity.	Intra-abdominal bleeding is a complication of abdominal hysterectomy.	Abdomen soft; bowel sounds have returned; no evidence of intra-abdominal bleeding. Continue plan.

Problem Statement/Nursing Diagnosis

Potential for altered breathing pattern/Risk for ineffective breathing pattern related to pain.

Supporting Assessment Data

Subjective: "It hurts to take a deep breath."

Objective: Abdominal hysterectomy.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will have no signs of atelectasis or pneumonia as evidenced by clear breath sounds in all lung fields and afebrile status.	Assist patient to use an incentive spirometer, sit up to deep breathe, and cough q2h while awake; give small pillow and instruct her on how to splint incision before coughing.	Cough and deep-breathing exercises can prevent development of atelectasis. Pain can prevent patient from taking deep breaths.	Able to deep-breathe and cough at 8 and 10 A.M. and 12 and 2 P.M. Sitting on side of bed q2h while awake.
	Enlist aid of family or significant others in reminding patient to deep breathe.	Others can provide encouragement and support.	Family helping and reminding patient to do breathing exercises.
	Report adventitious, diminished, or absent breath sounds or crackles.	Abnormal breath sounds can be sign of developing complications.	Lung sounds clear bilaterally; all VS are WNL; T 98.0° F (36.7° C). Continue plan.

Problem Statement/Nursing Diagnosis

Potential for infection/*Risk for infection related to surgery.*

Supporting Assessment Data

Objective: Abdominal surgical incision.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will be without signs and symptoms of infection at discharge.	Administer prophylactic antibiotics as prescribed.	Antibiotics kill pathogens.	Tolerating prescribed medications.
	Monitor incision for signs of redness, swelling, purulent drainage, or hardness.	Redness, swelling, drainage, and pain at incision site may be signs of infection.	No incisional redness, swelling, hardness, or purulent drainage.
	Keep dressing clean and dry. Use careful aseptic technique when changing dressings.	A wound dressing must be kept clean and dry to prevent contamination that can cause infection.	Dressing clean and dry.
	Monitor WBC count and temperature.	—	WBC count WNL; afebrile.
	Assess vaginal drainage for signs of odor or change in character.	Odor or purulent appearance of vaginal drainage may indicate infection.	Vaginal drainage is minimal and without odor.
	Assess abdomen for signs of infection, increasing pain, localized tenderness, swelling, increased erythema (redness) around wound edges, decreased bowel sounds.	Tenderness, swelling, increased erythema, and decreased bowel sounds are signs of intra-abdominal infection.	Abdomen soft, active bowel sounds; no signs or symptoms of infection. Continue plan.

Problem Statement/Nursing Diagnosis

Potential for injury/*Risk for injury related to possibility of thrombophlebitis from bed rest and abdominopelvic surgery.*

Supporting Assessment Data

Objective: Abdominal hysterectomy and decreased activity level.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will not exhibit signs of thrombophlebitis at time of discharge.	Encourage ambulation as soon as it is ordered; explain benefits of walking. Assist with leg and ankle exercises q2h.	Range-of-motion exercise and early ambulation can prevent the development of thrombus formation. Leg exercises increase circulation and prevent blood pooling.	Leg and ankle exercises q2h while awake, and is tolerating ambulation.
	Monitor SCDS every shift.	SCDS prevent pooling.	SCDS functioning properly.
	Encourage added fluid intake as soon as diet order allows.	Extra liquids keeps blood more fluid and less likely to clot.	Presently NPO with IV fluids.
	Inspect lower legs every shift; check for positive Homans sign.	A positive Homans sign may indicate development of thrombophlebitis.	Homans sign negative. Continue plan.

Problem STATEMENT/Nursing Diagnosis

Altered body image/*Disturbed body image related to removal of uterus.*

Supporting Assessment Data

Subjective: "I wonder how this will affect my husband's view of me."

Objective: Abdominal hysterectomy.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will express her concerns over loss of uterus before discharge. Patient will accept new body image within 3 mo as evidenced by lack of depression and reinvestment in usual activities.	Provide openings for conversation regarding patient's concerns over loss of her uterus and its meaning to her. Explore her feelings regarding sexuality after hysterectomy. Encourage expression of positive aspects of having the hysterectomy and how she as a person is unchanged.	Enabling patient to verbalize and express concerns will make it possible to establish a patient-centered plan of care and teaching.	Patient is able to begin discussion about her concerns; will continue tomorrow. Continue plan.

Critical Thinking Questions

- After the abdominal hysterectomy, Mrs. Blair appears depressed and states she is worried her marital relations will "never be the same." What is the best response of the nurse?
- Aside from an abdominal hysterectomy, what other options for the treatment of uterine fibroids are available?

BP, Blood pressure; *IV*, intravenous; *NPO*, nothing by mouth; *P*, pulse; *R*, respirations; *SCD*, sequential compression device; *T*, temperature; *VS*, vital signs; *WBC*, white blood cell; *WNL*, within normal limits.

■ Implementation

The patient's needs must always be addressed when implementing various aspects of the plan of care. Table 38-4 contains detailed information on various types of surgical procedures that are used for different gynecologic problems. Education must be done in a manner appropriate to the patient's knowledge base and her ability to learn new information. Patient teaching should be an important aspect of each nursing contact.

Table 38-4
Gynecologic Surgical Procedures

REASONS FOR PERFORMING	DESCRIPTION	NURSING CARE AND TEACHING POINTS
Dilation and Evacuation (D&E)		
Excessive vaginal bleeding; incomplete abortion; removal of placental fragments; therapeutic abortion.	Scraping away the inner lining of the uterus (endometrium) via the cervix.	Observe for excessive bleeding postoperatively.
Conization or Conical Excision		
To remove abnormal or early cancerous tissue; biopsy.	Removal of cone of tissue with scalpel or electrical cutting wire.	Office procedure. May cause some bleeding.
Fistulectomy		
Presence of rectovaginal fistula (channel between rectum and vagina) or urethrovaginal fistula (channel between bladder and vagina).	Surgical excision of the fistula and repair of the tissue to prevent passage of urine or feces into the vagina.	Observe for excessive bleeding or for vaginal fecal drainage postoperatively.
Hysterectomy		
Prolapse of pelvic organs; pain associated with pelvic congestion; endometriosis; excessive/debilitating uterine bleeding; fibroids; noninvasive uterine or cervical cancer.	Removal of entire uterus, vaginally or abdominally (open, or robotic).	Observe for excessive bleeding; paralytic ileus can occur. Ends childbearing if premenopausal, which may have profound emotional effects.
Pan hysterectomy		
Cancer; pain associated with pelvic inflammatory disease; recurrent ovarian cysts.	Removal of entire uterus, fallopian tubes, and ovaries.	See hysterectomy. Removal of ovaries induces menopause in premenopausal women.
Radical Hysterectomy		
Invasive cancer.	Removal of uterus, tubes, ovaries, upper third of vagina, and lymph nodes.	See hysterectomy and panhysterectomy. Vaginal alteration may affect ability to have sexual intercourse. Possible lymphedema from removal of nodes.
Anterior and Posterior Colporrhaphy		
Presence of prolapse of bladder and rectum into the vagina; may accompany a uterine prolapse.	Repair of the anterior and posterior wall of the vagina.	Observe for excessive bleeding.
Salpingectomy		
Tubal pregnancy; tumor; traumatic injury.	Removal of a fallopian tube.	Will not cause infertility if other tube/ovary is intact.
Oophorectomy		
Tumor; cystic disease; endometriosis; traumatic injury; severe hormonal disorder.	Removal of an ovary.	See salpingectomy. Only a portion of one ovary is necessary to provide normal hormonal balance before menopause.
Vulvectomy/Endoscopic Laparoscopy		
Malignancy.	Radical vulvectomy: surgical excision of the labia, clitoris, perineal structures, femoral and inguinal lymphatic tissues.	Major disfigurement; extreme supportive measures, including professional counseling, often required.

■ Evaluation

Any nursing intervention requires evaluation of its effectiveness. This can be accomplished by asking the following questions: How effective were pain control measures? How is the patient tolerating the change in diet or new therapy? Have there been any adverse reactions to medications or treatments? A decision to continue the plan of care or revise the plan of care is the outcome of evaluation.

Disorders of the Female Reproductive Tract

Pelvic Relaxation Syndrome (Cystocele, Rectocele, Enterocoele, and Uterine Prolapse)

When the muscles, ligaments, and fascia that support the pelvic floor weaken, the pelvic organs may descend toward the vaginal orifice. It can affect the bladder (**cystocele**), rectum (**rectocele**), bowel (**enterocele**), or uterus (uterine prolapse).

Etiology and Pathophysiology

Because the lack of estrogen results in weakening of tissue structures, pelvic relaxation syndrome is more likely to occur as women age. The bladder protrudes through the vaginal wall, forming a cystocele, or into the rectum, forming a rectocele. As expected life span increases, these problems have increased in frequency. Heavy lifting, constipation, and obesity contribute to the weakening of the pelvic floor muscles and tissues. Pelvic surgery and the strain of vaginal childbirth may also contribute to the development of pelvic relaxation syndrome.

Signs and Symptoms

Symptoms relate to the specific organs involved. In a cystocele, urinary frequency or incontinence is most common. A rectocele may result in constipation, soiling, or painful defecation. A uterine prolapse may result in dyspareunia. The uterus may protrude from the vaginal orifice. The woman often complains of general symptoms that include a sense of fullness in the pelvis and backache. **Stress incontinence** (loss of small amount of urine during coughing, sneezing, or lifting objects) may occur.

Diagnosis

Diagnosis is confirmed by history and physical examination. Obtain an obstetric history concerning the number of vaginal deliveries and the size of the infants, which may have contributed to the problem. A history of stress incontinence or constipation may indicate how the problem may interfere with activities of daily living. A computed tomography scan may be required if other pelvic pathology is suspected. The patient and the health care provider determine whether a nonsurgical or surgical approach to management is most appropriate.

Treatment and Nursing Management

Nonsurgical management.

Nonsurgical management includes teaching the woman how to perform Kegel exercises to strengthen the pubococcygeal muscles that support the pelvic floor (refer to [Chapter 33 Patient Teaching on p. 780](#)).

Lifestyle changes include increasing fluid intake and a high-fiber diet to prevent constipation and heavy lifting and maintaining an optimal weight. Hormone therapy may be prescribed. A **pessary** (a hard rubber or plastic ring) can be fitted into the vagina by the health care provider to provide support to the pelvic structures.

Complementary and Alternative Therapies

Biofeedback and Transcutaneous Electrical Nerve Stimulation

Biofeedback and transcutaneous electrical nerve stimulation (TENS) may be performed by a licensed provider to help strengthen the pelvic floor muscles.

Surgical management.

The procedure to repair a cystocele or rectocele is called an *anteroposterior repair (colporrhaphy)*. A **hysterectomy** (removal of the uterus) may be indicated.

The management of pelvic prolapse includes minimally invasive surgery. Surgical repair may be accomplished laparoscopically, abdominally, or transvaginally. The use of some mesh materials such as vicryl or allogenic materials have not shown to improve the surgical outcome.

Research is continuing concerning the use of synthetic polypropylene mesh with large pore size that decreases the chance of complications such as mesh infection and erosion (Delroy, 2013). Decreased operation time and rapid recovery time have been noted with the use of collagen-coated transvaginal mesh (Rudnicki, 2014). Postoperatively monitor bowel and bladder patency. Residual urine may be measured via catheterization after voiding. Routine postoperative pain management is provided. Refer to Chapter 34 for treatments for urinary incontinence.

Polycystic Ovarian Syndrome

Polycystic ovarian syndrome is a congenital condition in which many cysts develop on one or both ovaries and produce excess estrogen. High levels of testosterone and LH and low levels of FSH occur. Signs and symptoms include irregular menstruation, infertility, hyperinsulinemia, and glucose tolerance problems. Excessive hair on the body (**hirsutism**) is common.

Treatment involves use of OCs to inhibit LH and testosterone production. Surgical removal of the cysts may be indicated. If pregnancy is desired, ovulation-stimulating medications are prescribed. Advise the patient concerning the importance of follow-up care to monitor the progress of this condition.

Dysfunctional Uterine Bleeding

Dysfunctional uterine bleeding is uterine bleeding that occurs at times other than the normal menstrual cycle or abnormal bleeding during menstruation. Uterine bleeding may be considered abnormal if the interval between menstruations is less than 21 days or more than 45 days, the duration of menstrual flow is more than 7 days, or the amount of blood loss exceeds 80 mL.

Oligomenorrhea (decreased menstruation) usually refers to menstrual periods that occur at an interval of 45 days or longer. The cause often involves a problem with the hypothalamus, the pituitary gland, or ovarian function. Hormone therapy is the treatment of choice, and the woman should be educated concerning advantages and disadvantages of hormone therapy. The use of OCs can decrease menstrual flow. Structural abnormalities can cause obstructions or destruction of the endometrium, resulting in oligomenorrhea. The woman should be taught to keep close records of her menstrual cycle and associated symptoms.

Amenorrhea means absent menstruation. *Primary amenorrhea* refers to women who have not had a normal onset of menstrual periods (they never started to menstruate). *Secondary amenorrhea* applies to women who began normal menses that later ceased. Some causes can include anatomic defects such as **imperforate** (closed) hymen, an endocrine dysfunction affecting female hormones, chronic disease, extreme weight loss or obesity, emotional disturbances, drug side effect, excessive exercise, or poor nutrition. Amenorrhea is a normal occurrence during pregnancy. Goals of treatment include progression of normal pubertal development; prevention of complications such as osteoporosis, endometrial hyperplasia, or heart disease; and promotion of fertility.

Metrorrhagia is bleeding between menstrual periods. Occasionally, a brief episode of "spotting" occurs 14 days before the expected menstrual period (corresponding to the time of ovulation). This is known as "mittle staining" and is considered normal. Women who take OCs or have an IUD may have bleeding between menstrual periods, which is termed *breakthrough bleeding*. The problem is usually resolved by adjustment of the medication or dosage. Causes of abnormal metrorrhagia include leiomyomas, uterine polyps, trauma, foreign body, malignancy, infection, or an interrupted pregnancy. The treatment depends on the cause. Nursing responsibilities include providing reassurance, support, and education.

Menorrhagia is excessive menstrual bleeding or duration of the menstrual period. There are many causes, including hormone imbalances, malignancies, fibroids, infections, and the use of some drugs. One cause of heavy menstrual bleeding is von Willebrand disease, which is caused by a chromosome factor VIII dysfunction. Symptoms often include frequent nosebleeds and delayed postpartum hemorrhage. Blood tests should be taken during menstruation for accurate diagnosis. Treatment of menorrhagia depends on the cause. The hemoglobin and hematocrit should always be assessed to determine the seriousness of the blood loss. In 2010 the FDA approved a nonhormonal treatment of menorrhagia with the drug tranexamic acid (Lysteda). This oral medication works by

reducing clot breakdown in the uterus. Tranexamic acid should not be used with oral contraceptives, because the risk for thrombus formation or stroke increases with the combination ([Drugs.com 2014](#)). Nursing interventions include education concerning follow-up care, an iron-rich diet, and information concerning treatment options available.

Abnormal Uterine Bleeding

Abnormal uterine bleeding is defined as uterine bleeding not related to the menstrual period. It is often caused by anovulation and a failure of hormonal changes during the menstrual cycle. It most often occurs at the beginning (menarche) or end (menopause) of the reproductive years. Bleeding from continuous estrogen production can also occur as a result of thyroid dysfunction, polycystic ovarian disease, infection, trauma, or neoplasm. Use of some herbal products that promote estrogen activity can also cause dysfunctional or abnormal uterine bleeding.

Older Adult Care Points

Vaginal bleeding in postmenopausal women is a possible warning sign of cervical or uterine cancer. An immediate pelvic examination to determine and treat the cause of such bleeding is advised. The incidence of these cancers increases with age.

Monitoring the hemoglobin and hematocrit is essential, and hospitalization may be required if the hemoglobin falls below 8 g/100 mL. Severe bleeding may be treated with intravenous conjugated estrogens (Premarin) until bleeding stops or slows significantly. A dilation and evacuation (formerly known as a *dilation and curettage*) and endometrial biopsy may be required. The woman may be given OCs for 3 to 6 months, after which the bleeding pattern will be reassessed.

Persistent **anovulation** (failure to ovulate) with continuous estrogen stimulation of the endometrium can cause abnormal tissue changes in the uterus. Nursing interventions include educating the patient concerning the use of unsupervised CAM therapies and proper use of OCs, providing support during treatments, and ensuring that the patient is aware of treatment options.

Leiomyoma

Commonly known as uterine **fibroids**, leiomyomas are benign tumors of the uterine muscle. Their growth is influenced by ovarian hormones, and they are common in women taking birth control pills. They spontaneously shrink during and after menopause. Common symptoms include backache, a sense of lower abdominal pressure, constipation, urinary frequency or incontinence, and abnormal uterine bleeding. A pelvic examination and ultrasound may help confirm the diagnosis.

Medical management depends on the size and location of the fibroids, the symptoms experienced, the desire for future pregnancies, and how near the woman is to natural menopause. In mild cases, monitoring and supportive care to relieve symptoms are indicated. Nonsteroidal anti-inflammatory drugs or OCs may be prescribed. In severe cases, leuprolide (Lupron) or nafarelin (Synarel), which are gonadotropin-releasing hormone (GnRH) agonists that shrink the fibroids, and other hormones may be prescribed to suppress estrogen. These drugs may cause menopausal symptoms and bone demineralization, and their use is limited to a 6-month period to reduce the fibroids and prepare for surgery.

Uterine artery embolization involves the injection of special pellets into selected blood vessels that supply the fibroid, resulting in shrinkage of the fibroid. It is performed under conscious sedation by an interventional radiologist (a radiologist who specializes in invasive procedures not requiring general anesthesia). Cramping, nausea, fever, and malaise (postembolic syndrome) may occur postoperatively as the fibroid degenerates. Postoperative pain may require an overnight hospitalization and treatment with fentanyl or hydromorphone (Dilaudid) by patient-controlled analgesia. Maintenance of hydration and ambulation to prevent complications are encouraged postoperatively. After 6 weeks, MRI confirms the effectiveness of the procedure. Postoperative teaching includes not using anticoagulant drugs, including aspirin; avoiding douches, sexual intercourse, and the use of tampons for 4 weeks postoperatively; monitoring urine output; preventing constipation; and returning for follow-up care.

Myomectomy is the removal of the tumor from the uterine wall and can be accomplished by use of an endoscope via an abdominal incision (**laparoscopy**) or vaginally (**hysteroscopy**). It is performed in the proliferative phase of the menstrual cycle and does minimal damage to the uterine lining, allowing for positive pregnancy outcomes in the future. Fibroids can eventually return.

Hysteroscopic endometrial ablation is a nonsurgical technique that involves resection of submucosal fibroids followed by scraping and burning of tissue. This procedure significantly reduces future fertility. **Myolysis**, laser or electrosurgical destruction of the fibroids, can also be done laparoscopically or vaginally and may preserve fertility. **Magnetic resonance-guided focused ultrasound surgery (MRgFUS)** is a safe way to significantly reduce symptoms of premenopausal uterine fibroids with a rapid return to quality of life (Abdullah et al, 2010).

A **hysterectomy** (removal of the uterus) may be performed if the woman does not wish future pregnancies. A laparoscopic supracervical hysterectomy preserves the cervix and is less invasive, with fewer complications. However, for benign disease, the robotic or vaginal route for hysterectomy is preferred. Of the 590,000 hysterectomies performed within the United States each year, approximately 40% are for fibroids, 17% for endometriosis, and 14% to treat vaginal prolapse. Many hysterectomies are performed unnecessarily, because there are commonly other alternatives. The medical necessity for a hysterectomy includes cancer, an unmanageable infection or bleeding, or a serious birth complication such as a ruptured uterus. Nursing responsibilities include providing education to understand options, clarify misconceptions, and reduce anxieties. The postoperative teaching plan should include current information concerning advantages and disadvantages of hormone therapy, comfort measures for pain relief, and when to resume normal activities. The use of lubricants for vaginal intercourse and a plan for follow-up care should also be provided. Danger signs to report to the health care provider include bleeding or abnormal vaginal discharge.

Endometriosis

Endometriosis is a common disorder in which endometrial tissue (the inner lining of the uterus) is found outside the uterus, particularly on the ovaries, in the rectovaginal septum (wall separating the rectum and the vagina), and in the pelvis and abdomen. It usually undergoes the same changes as the normal endometrium during the menstrual cycle and may bleed at the time of menses, which can cause irritation, pain, and the formation of adhesions. Other symptoms may include excessive menstrual flow, bleeding between periods, painful bowel movements, and painful coitus.

Continuous hormonal contraceptive therapy and drugs such as medroxyprogesterone acetate (Depo-Provera) or norethindrone (Ortho Micronor) suppress growth of the endometrial tissue. Danazol (Cyclomen, Danocrine) and GnRH agonists such as leuprolide or nafarelin create a "pseudomenopause" by interfering with hormones that stimulate ovulation and menstruation. Menopausal symptoms such as hot flashes, decreased **libido** (sexual drive), and reduced bone density may occur. Continuous hormonal contraceptive treatment may be continued for 3 to 6 months. Surgical treatment may include a laparoscopy to remove adhesions or laser ablation of the lesions, which may preserve fertility.

If the woman does not desire children in the future, a complete hysterectomy and removal of all endometrial lesions is the treatment of choice. Treatment for menopausal symptoms may be needed postoperatively.

Surgical Management

Robotic surgery is surgery performed by a surgeon's medical manipulation of robotic "hands" and electronic monitors. Robotic surgery has benefits such as shorter operative time, shorter hospitalization, more rapid recovery, and more sophisticated surgery. Robotic surgery is not indicated for very short procedures such as endoscopic sterilization. Urogynecologic reconstructive surgery, fistula repair, and hysterectomy are best accomplished by robotic approach. The application of robotic surgery to gynecologic cancer is growing. Robotic surgery may be preferred over minilaparotomy for tubal anastomosis or reproductive endocrinology.

Inflammations of the Lower Genital Tract

Etiology and Pathophysiology

Inflammations or infections of the vulva, vagina, or cervix most often occur when the acid environment of the vaginal secretions changes, enabling the survival of pathogenic organisms. The acid environment of the vaginal vault is maintained by estrogen levels and the presence of *Lactobacillus*. Risk factors that alter the bacterial flora and pH environment within the vagina include aging; poor nutrition; the use of medications such as steroids, OCs, or antibiotics; and douching.

Organisms can also gain entrance to the vagina through contaminated hands, clothing, loss of skin integrity from trauma or surgery, or sexual intercourse. Vulvar infections typically occur as a result of skin trauma caused by itching and scratching. Although *Candida albicans* is normally present in low levels in the vaginal area, a change in vaginal pH can lead to an overgrowth, resulting in vulvovaginitis (Table 38-5).

Table 38-5
Comparison of Two Types of Common Vaginal Infections

	BACTERIAL VAGINOSIS	YEAST INFECTION
Primary causative organism(s)	<i>Gardnerella</i> (most common).	<i>Candida</i> (formerly called <i>Monilia</i>).
Onset	May be asymptomatic.	Abrupt; preceding menstruation.
Odor	Fishy, most noticeable after intercourse.	None or mild "musty" odor.
Itching	Usually none (does not invade vaginal wall).	Severe; most prominent symptom.
Discharge	Thin, gray, may be frothy.	Thick, white, "cottage cheese" texture when colonization is heavy.
Sexually transmitted	Possibly; 70% of women have this organism present in vaginal flora.	Possibly. Associated with high estrogen levels; diabetes mellitus; tight underclothing that increases warmth and moisture.
Vulvar signs	Absent.	Redness; excoriation from scratching; may have edema of labia.
Vaginal signs	Vaginal pH above 4.6. Little redness; discharge adherent to vaginal wall, normal cervix.	Normal cervix, no discharge. Lesions and edema from scratching.
Treatment	Metronidazole orally, sometimes vaginally; clindamycin in second trimester if pregnant (metronidazole associated with adverse pregnancy outcomes).	Miconazole, clotrimazole, or nystatin vaginally as directed. Oral treatment: fluconazole (Diflucan) 150-mg single dose. Nonprescription treatment is available.

Signs, Symptoms, and Diagnosis

A history and physical examination usually reveal the nature of the problem. Lesions may be present, and **dysuria** (painful urination) commonly occurs because the acidic urine comes into contact with open lesions. An abnormal vaginal discharge may occur that causes **pruritus** (itching discomfort). Women with cervicitis may experience bloody spotting after intercourse.

The diagnosis of the specific condition may be accomplished by culturing vaginal discharge or lesions, blood tests for specific infections, or a colposcopy or biopsy of the lesion. Drug therapy is based on the diagnosis.

Treatment and Nursing Management

You can teach the woman about the risks and prevention of genital infections as well as the treatment protocol for the specific infection. Infections of the lower genital tract are typically treated with local creams, vaginal suppositories, or systemic antimicrobials. Hand hygiene; wearing loose cotton underwear; and the use of intermittent warm, local, moist heat provide comfort and decrease irritation. Genital infections can cause the woman embarrassment, impair her self-image, and negatively affect relationships. Providing psychological support is very important. Because many organisms that cause lower genital tract infections are spread by sexual intercourse, prompt treatment is essential to prevent the spread of infection to the upper genital tract. The importance of recognizing symptoms and seeking medical care should be stressed. A nonjudgmental attitude will empower the woman to ask questions and seek advice. Ensure that the woman fully understands directions for taking medication or applying creams, and visual aids should be used whenever possible to ensure clarity of directions. Infections of the lower genital tract that are also STIs, such as pelvic inflammatory disease, are discussed in Chapter 40.

Toxic Shock Syndrome

Toxic shock syndrome (TSS) is a rare and potentially fatal disorder caused by strains of *Staphylococcus aureus* that produce toxins that cause shock, coagulation defects, and tissue damage if they enter the bloodstream. It is associated with the trapping of bacteria within the reproductive tract for a prolonged time. Risk factors include the prolonged use of high-absorbency tampons, cervical caps, or diaphragms.

Symptoms of TSS include:

- Sudden spiking fever
- Flulike symptoms
- Hypotension
- Generalized rash resembling a sunburn
- Peeling skin on the palms or soles

Treatment includes hospitalization and intensive care with supportive treatments and intravenous antimicrobials. The nurse plays an important role in preventing TSS by teaching the woman hand hygiene when inserting tampons, and the importance of changing tampons every 4 hours. Tampons should not be used when sleeping, because they will likely remain in place longer than 4 hours. Diaphragms and cervical caps should not be left in place for a prolonged time or used during menstruation.

Cancer of the Reproductive Tract

Vulvar Cancer

Vulvar intraepithelial neoplasia (VIN) refers to the growth of abnormal tissue on the vulva that may be precancerous. Cancer of the vulva is rare and occurs most commonly in aging women. Symptoms include red, brown, or white patches on the skin of the vulva. Treatment includes surgical removal of the pathologic tissue. Some strains of VIN are associated with the HPV. The incorporation of the HPV vaccine (Gardasil) into the standard immunization regimen for all girls will further reduce the incidence of this condition. Melanoma may begin on the vulva as well, even though the vulva is not typically exposed to sunlight. Women should be encouraged to observe and report any changes in any moles or visible lesions in the vulvar area.

Cancer of the Cervix

The risk factors for cancer of the cervix include multiple sex partners, sexual intercourse with uncircumcised males, starting intercourse at a young age (younger than 20 years of age), multiple pregnancies, obesity, and history of HPV infection or an STI. An approved HPV vaccine given to girls at or before puberty may prevent the type of HPV infection that causes cervical cancer. Regular pelvic examinations and Pap smears may enable early diagnosis and provide an opportunity for early and more successful intervention. The HPV screening can be done during or instead of a Pap test in women older than 30 years ([Centers for Disease Control and Prevention, 2014](#)). The ACOG recommends Pap testing (without HPV testing) should begin at age 21 and be repeated every 3 years between ages 21 and 29 in asymptomatic women. Women with three consecutive negative screenings at age 30 years should have repeated testing, including HPV testing, every 5 years until age 65 years, when testing of asymptomatic women is no longer necessary. Women with cervical pathology or cancer should be screened annually for 20 years after treatment. Treatment of cervical neoplasia may include cryosurgery, electrosurgical excision, or surgical conization of the cervix. Cervical cancer requires a hysterectomy with possible bilateral salpingo-oophorectomy (removal of the uterus, including the fallopian tubes and ovaries) followed by radiation and chemotherapy. See [Chapter 8](#) for discussion of care of a patient receiving radiation or chemotherapy.

Cancer of the Uterus

The most common malignant tumor of the female reproductive tract is endometrial cancer. It is a slow-growing cancer that most commonly occurs after menopause. The treatment of choice is a hysterectomy with bilateral salpingo-oophorectomy. Treatment is often complicated by the fact that many women with cancer of the uterus may be elderly or have chronic conditions such as diabetes. Surgery is commonly followed by radiation and chemotherapy. Chemotherapy agents used are doxorubicin (Adriamycin), cisplatin (Platinol), 5-fluorouracil (5-FU), carboplatin (Paraplatin), and paclitaxel (Taxol). See [Chapter 8](#) for discussion concerning care of a patient receiving chemotherapy and radiation therapy.

Cancer of the Ovary

Approximately 70% of ovarian tumors are benign. Ovarian cancer is known as a "silent cancer" because signs and symptoms are often nonspecific or vague, such as fatigue or abdominal distention with no detectable precancerous changes in the ovary. An important risk factor for the development of ovarian cancer is having a sister or mother with the disease or inheriting the *BRCA1* or *BRCA2* gene, which is also associated with breast cancer. Exposure to asbestos, talc powder, pelvic irradiation, or mumps has also been linked to the development of ovarian cancer. Women on hormone therapy should be informed concerning the risks for ovarian cancer. Factors that may prevent ovarian cancer include one or more term pregnancies, breast-feeding, tubal sterilization, and possibly the use of OCs. Ovarian cancer is classified according to the type of tissue within the ovary that is involved. Diagnosis is commonly made during a routine pelvic examination. An ovarian cancer tumor marker (CA-125), assessed by a blood test, combined with pelvic ultrasound can detect ovarian cancer, but not at an early stage. In 85% of cases, diagnosis of ovarian cancer is

first established when the cancer is well beyond the ovary. Current research is focusing on the fallopian tube as the source of ovarian cancer. Researchers at Yale Medical School have a new test under development and trials that could detect ovarian cancer in the early stages. However, at this date, the CA-125 test is not covered by most insurance companies for routine screening. Once diagnosis is established, a **panhysterectomy** (removal of the uterus, the fallopian tubes, and the ovaries) is followed by chemotherapy and radiation. Newer drugs have improved the survival rate to 50%. Cisplatin and carboplatin are used for stage III and stage IV disease. Altretamine (Hexalen) is used for recurrent ovarian cancer. Paclitaxel and topotecan (Hycamtin) are used to treat metastatic ovarian cancer. CAM is helpful in managing the side effects of the cancer and the medications used to treat the cancer.

Health Promotion

Symptoms of Ovarian Cancer

The American Cancer Society identified possible warning signs of ovarian cancer as:

- Abdominal, pelvic pain
- Feeling full quickly when eating
- Feeling a frequent or urgent need to urinate
- Increased abdominal girth

Disorders of the Breast

Although the breast is not a reproductive organ, it is affected by hormonal changes related to the menstrual cycle and after pregnancy; therefore, it is discussed in this chapter.

Benign Disorders of the Breast

Fibroadenoma

Fibroadenomas are commonly found in teenagers and young adults. Fibroadenomas are firm, rubbery, mobile nodules of fibrous and glandular tissue that may or may not be tender on palpation. They typically occur in the upper outer quadrant of the breast and do not change during the menstrual cycle. A fine needle aspiration or biopsy may be performed to determine the presence of cancerous cells.

Fibrocystic Breast Changes

Fibrocystic breast changes (FBCs) are common during the reproductive years. An FBC is a palpable thickening of portions of the breast tissue associated with pain and tenderness. Multiple smooth, well-delineated cysts may form that are most painful during the premenstrual phase of the menstrual cycle. The “lumps” make BSE more difficult and are commonly a source of anxiety. Women with FBC can learn to recognize the size and shape of their normal lumps and should report any change in these findings as well as other changes to their health care provider. Treatment of fibrocystic changes is conservative and based on supportive care. Vitamin E supplements, the elimination of caffeine and alcohol, reduction of fat in the diet, and the use of NSAIDs such as ibuprofen help control discomforts associated with FBC. Wearing a supportive bra and the use of heat are also helpful.

Complementary and Alternative Therapies

Alternative Therapy for Fibrocystic Breast Changes

Relaxation techniques and herbal therapy with angelica, lady's mantle, or evening primrose oil may be helpful in FBC.

Intraductal Papilloma

Intraductal papilloma is the development of small elevations in the epithelium of the ducts of the breasts under the areola. The ducts erode, causing a serosanguineous discharge from the nipple. Treatment includes excision of the mass and analysis of the discharge to determine whether cancer cells are present.

Clarify and reinforce the explanations of diagnostic procedures to be performed and recognize the anxiety and apprehension that the woman feels until the final diagnosis is confirmed. The woman should be encouraged to express her concerns, and supportive care should be provided.

Breast Cancer

In the United States approximately one in eight women (12%) will develop breast cancer in her lifetime. In 2013 more than 230,000 cases were diagnosed, 10% of which were caused by gene mutations and 85% of which were women with no family history of breast cancer ([American Cancer Society, 2014](#)). Gender and aging are the highest risk factors. The incidence of breast cancer dropped by 7% in 2003, possibly because of the decreased use of routine hormonal therapy. Early awareness via education, early detection available with new technology, and treatment advances have reduced the death rate of breast cancer. Although the risk of developing breast cancer increases with the woman's age, many other factors contribute to the risk ([Box 38-5](#)). Breast cancer is identified according to the structure affected and staged according to the size and degree of invasiveness ([Table 38-6](#)).

Box 38-5**Risk Factors for Breast Cancer**

1. Family history of relative with breast cancer
2. Early menarche, late menopause
3. Late first pregnancy or no children
4. Previous breast biopsy
5. Obesity
6. Environmental exposure to hormone-modulating chemicals such as pesticides and polycyclic aromatic hydrocarbons found in meat barbequed or grilled at high temperatures.
7. Consumption of alcohol

Note that the specific cause of breast cancer has not been established. It is most likely due to genetic factors combined with environmental factors resulting in a cumulative risk level. Risk factors 1 to 4 are included on the National Cancer Institute (NCI) risk assessment tool. This can be accessed on www.cancer.org.

Table 38-6
Stages of Breast Cancer

CANCER STAGE	LOCATION	DESCRIPTION	5-YEAR SURVIVAL RATE
Stage 0	Carcinoma in situ	Lobular carcinoma in situ (LCIS)—cancer cells in lining of a lobule. Ductal carcinoma in situ (DCIS)—cancer cells in lining of a duct.	100%
Stage I	Early stage of invasive cancer	Tumor is <2 cm in diameter. Cancer cells have not spread beyond the breast.	100%
Stage II	Invasive	Any one of the following: Tumor is <2 cm across. Cancer has spread to lymph nodes under the arm. Tumor is between 2 and 5 cm. Cancer may have spread to lymph nodes under the arm. Tumor is >5 cm. Cancer has not spread to lymph nodes under arm.	92%-81%
Stage III	Locally advanced	Large tumor, but cancer has not spread beyond the breast and nearby lymph nodes.	
Stage IIIA		Any one of the following: Tumor is <5 cm. Cancer has spread to underarm lymph nodes attached to each other or to other structures. Tumor is >5 cm. Cancer has spread to underarm lymph nodes.	67%
Stage IIIB		Any one of the following: Tumor has grown into chest wall or skin of the breast. Cancer has spread to lymph nodes behind the breastbone.	54%
		Inflammatory breast cancer is a rare type of Stage IIIB in which the breast looks red and swollen because cancer cells block the lymph vessels in the skin of the breast.	
Stage IIIC		Any size tumor that has: Spread to lymph nodes behind the breastbone and under the arm. Spread to lymph nodes under or above the collarbone.	This was defined only recently, so survival rate not yet available
Stage IV	Distant metastatic	Distant metastatic cancer. Cancer has spread to other parts of the body.	20%

Etiology and Diagnosis

The development of breast cancer is believed to be related to the hormones estrogen and progesterone. For example, women who start to menstruate at an early age (early menarche) and have late menopause are exposed to more estrogen spikes during monthly ovulation and are at higher risk of developing breast cancer. Conversely, women who have had multiple pregnancies have fewer monthly ovulating cycles and hormonal spikes and thus are at lower risk.

Genetic testing for *BRCA1* and *BRCA2* gene mutations continue, because identifying high-risk women can result in specific interventions to prevent development of cancer such as preventive mastectomy and reconstructive surgery. The current breast cancer risk assessment tool developed by the National Cancer Institute (NCI) is available on the website www.cancer.gov.

Legal and Ethical Considerations***BRCA1* and *BRCA2* Genes**

If all women are tested for the presence of the *BRCA1* or *BRCA2* gene, an ethical problem is raised regarding the action to take if the gene is present. Should the young woman have a prophylactic mastectomy? Should the woman be given prophylactic treatment with tamoxifen? Does the knowledge of the potential risk for cancer produce anxiety that may result in life changes that can have a negative outcome? Would there be health insurance implications?

In 2013 the U.S. Preventive Services Task Force (USPSTF) did not recommend that routine genetic testing be done. *BRCA* testing can be expensive and may not be covered by insurance. Instead, the USPSTF recommends that women who have at least one family member with *BRCA1*- or *BRCA2*-related cancers be screened for genetic testing using one of the following models:

- Ontario Family History Assessment Tool
- Manchester Scoring System
- Referral Screening Tool
- Pedigree Assessment Tool
- FHS-7

The Referral Screening Tool (which can be found at www.breastcancergenescreen.org) and FHS-7 are the simplest and easiest to use. The USPSTF reports that no one tool is better than another and makes no recommendation as to which tool to use.

Signs, Symptoms, and Diagnosis

Although 90% of breast lumps are detected by the woman during a BSE, most early breast cancer can be detected by mammography (x-ray examination of the breast) before it can be clinically palpated. A nipple discharge or change in the skin pattern such as “dimpled skin” on the breast may also be a sign of breast cancer. Any unilateral breast change should be immediately reported to a health care provider. Even a short delay in diagnosis can result in invasion of surrounding tissue and metastasis to other parts of the body. Fenretinide, a retinoid, is being studied as a way to reduce the risk of breast cancer, along with other drugs such as aromatase inhibitors ([American Cancer Society, 2014](#)). Scintimammography (molecular breast imaging) involves injecting a radioactive tracer into a vein that attaches to a breast cancer cell and is detected by a camera for more accurate diagnosis than an MRI scan. This new technology does not replace routine screening tests such as mammography. Refer to [Table 38-3](#) for details on the role of routine ultrasound or MRI diagnostic tests in confirming diagnosis.

Prevention

A healthy lifestyle that includes exercise and a diet rich in antioxidants and phytoestrogens, such as vegetables, fruits, whole grains, and soy products, may protect against the development of many cancers. Monthly BSE ([Figure 38-5](#)) and regularly scheduled mammograms between the ages of 50 and 85 years have been recommended by the ACOG, but research concerning a needs-based or individual risk screening plan is ongoing. At present, the drug tamoxifen is used to prevent recurrent breast cancer and is also recommended for women at high risk of developing breast cancer, because it may reduce breast cancer risk by half ([M.D. Anderson, 2015](#)). However, this drug is not recommended for the general population because of potential side effects such as increased bone pain, photosensitivity, headache, and increased risk for pulmonary embolism or uterine malignancies. Fenretinide, a retinoid, is being studied as a way to reduce the risk of breast cancer. Aromatase inhibitors such as anastrozole (Arimidex) or exemestane (Aromasin) may be more effective than tamoxifen and are under continued study.

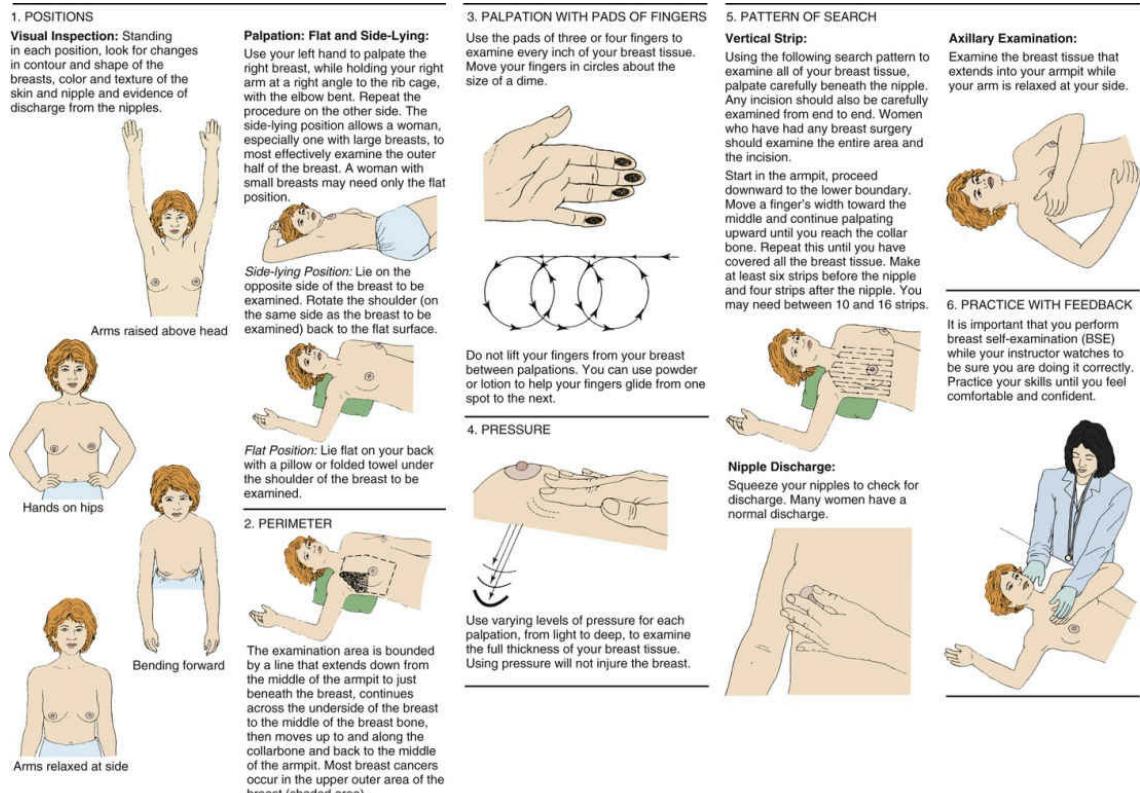

FIGURE 38-5 Recommended breast self-examination procedure. (From Lewis SL, Heitkemper MM, Dirksen SR, et al: *Medical-surgical nursing: Assessment and management of clinical problems*, ed. 7, St. Louis, 2007, Mosby.)

Some women who have known genetic *BRCA1* or *BRCA2* predispositions have elected to have prophylactic bilateral mastectomies. The psychological implications and effect on self-image should be carefully measured against the preventive benefits. The decision is between the woman and her health care provider.

Treatment

Treatment options are based on the type of breast cancer, stage of the disease, patient's age, physical and menopausal status, and other health factors that may affect the woman's ability to undergo the specific treatment. In general, the primary treatment depends on the size of the cancer and can be initial chemotherapy to shrink the tumor followed by surgical removal, or simply surgical removal of a smaller tumor and varying amounts of surrounding tissue. The types of surgery include:

- **Lumpectomy** (removal of tumor only).
- Partial or **segmental mastectomy** (removal of tumor and a portion of the surrounding breast tissue and axillary lymph nodes).
- Simple or **total mastectomy** (removal of entire breast and axillary lymph nodes).
- **Modified radical mastectomy** (removal of breast, axillary lymph nodes, and lining over the chest wall muscles).
- **Radical mastectomy** (removal of breast, axillary lymph nodes, and chest wall muscles under the breast). Radical mastectomy was once very common, but high success rates with a reduction in disfigurement are now made possible by using appropriate staging of the disease when making treatment decisions.

A suggested nursing care plan for a woman undergoing a lumpectomy in a same-day surgery unit is presented in [Nursing Care Plan 38-2](#).

Nursing Care Plan 38-2

Care of a Patient After Breast Lumpectomy

Scenario

A 24-year-old woman is ready for discharge from the same-day surgery unit after undergoing a breast lumpectomy for a suspicious breast lesion. She expresses concern about the amount of scar tissue that will form and that her breasts may no longer be the same size after the lumpectomy.

Problem Statement/Nursing Diagnosis

Altered body image/*Disturbed body image related to asymmetric breasts and scar tissue as a result of undergoing a breast lumpectomy.*

Supporting Assessment Data

Subjective: Concern about scar tissue and that breasts will no longer be the same size.

Objective: Lumpectomy.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will use positive coping strategies to adjust to changes in body image as evidenced by use of support system and available resources.	Assess for previous problem with self-esteem.	Previous coping strategies can be revealed by discussing previous experiences.	Patient discussed previous experiences and recognizes the stages of loss she experienced.
	Assess for signs of anxiety or inability to focus.	Anxiety can be an expected result of a diagnosis that may involve a possible cancer.	Patient expressed understanding of prognosis as explained by physician.
	Encourage verbalization of feelings.	Verbalization can reduce anxiety and focus on the problem of altered body image.	Patient expressed her concerns about scar tissue and alteration in breast symmetry.
	Involve family and multidisciplinary health care team in offering support.	Providing patient with broad support base and resources assists in adjustment.	Patient expressed understanding of healing process and resources available for assistance after discharge.
	Provide accurate information concerning prognosis.	Provides an opportunity to correct misinformation.	Patient expressed understanding of need for follow-up care.
	Encourage her to help care for wound.	Looking at and touching wound indicates readiness to participate in self-care to achieve optimal wound healing.	Patient states will actively participate in wound dressing changes.

Critical Thinking Questions

1. What factors influence a woman's perception of the importance of body image?
2. What other problems or issues might there be for a woman sent home the same day after a breast lumpectomy?

If there is concern that cancer cells have invaded the lymph nodes, **sentinel node biopsy** may be performed, wherein the primary node is removed and, if laboratory results show no evidence of cancer, the remaining nodes are left intact. Alternatively, an axillary node dissection may be performed during breast surgery, in which the lymph nodes under the affected arm are removed and sent to the laboratory. This procedure may result in swelling of the affected arm.

Tamoxifen blocks estrogen by binding with the estrogen receptors. This drug is usually prescribed for 5 years. Nausea and anorexia may occur, and cholesterol and triglyceride levels should be monitored. Certain drugs interfere with the metabolism of tamoxifen and should be avoided, including some selective serotonin reuptake inhibitor (SSRI) and selective serotonin-norepinephrine reuptake inhibitor (SNRI) antidepressants such as paroxetine; fluoxetine; and duloxetine; some antipsychotics such as pimozide, perphenazine, and thioridazine; some cardiac drugs such as quinidine or ticlopidine; some medications for infectious diseases such as terfenadine; and histamine (H_2)-blockers such as cimetidine.

Approximately 25% of women have a type of breast cancer tumor that manifests the human epidermal growth factor receptor-2 protein (*HER2*-positive breast cancer). Studies have shown that the monoclonal antibody trastuzumab (Herceptin) added to chemotherapy is very effective at reducing the risk of tumor recurrence. A new class of drugs called *Poly ADP ribose polymerase (PARP) inhibitors* show promise in treating breast, ovarian, and prostate cancer in patients resistant to other drugs (American Cancer Society, 2014).

Research is ongoing concerning the customization of treatment options for women with breast cancer. The National Institutes of Health and the NCI are researching a treatment trial called TAILORx (Trial Assigning Individual Options for Treatment). Women are assigned to treatment regimens based on genetic findings. The results of these trials may enable a change from standardized treatment to customized treatment protocols.

Radiation therapy commonly is performed after lumpectomy or segmented mastectomy to destroy micrometastases and decrease cancer recurrence rates. Radiation therapy options include

whole-breast radiotherapy using external beam radiation weekly for 7 weeks; intensity-modulated radiation therapy (IMRT), which minimizes damage to surrounding tissue; accelerated partial breast irradiation (APBI), using a balloon catheter in the local tumor site; interstitial brachytherapy, with pellets inserted around the tumor site; or external beam radiation (EBRT) after healing occurs (Figure 38-6). Chemotherapy also may be considered as part of treatment, in combination with surgery and radiation. Aromatase inhibitors such as anastrozole, letrozole (Femara), or exemestane reduce the risk of recurrence by inhibiting the enzyme aromatase, which results in decreased estrogen production. Aromatase inhibitors are not used in premenopausal women with functioning ovaries (see Safety Note). An estrogen receptor agonist such as fulvestrant (Faslodex) binds with estrogen receptors and can be used when tamoxifen fails. Ovarian ablation is the surgical removal or irradiation of the ovary to stop estrogen production. The use of goserelin (Zoladex) may be an alternative to chemotherapy. See Chapter 8 concerning care of a patient receiving chemotherapy or radiation therapy.

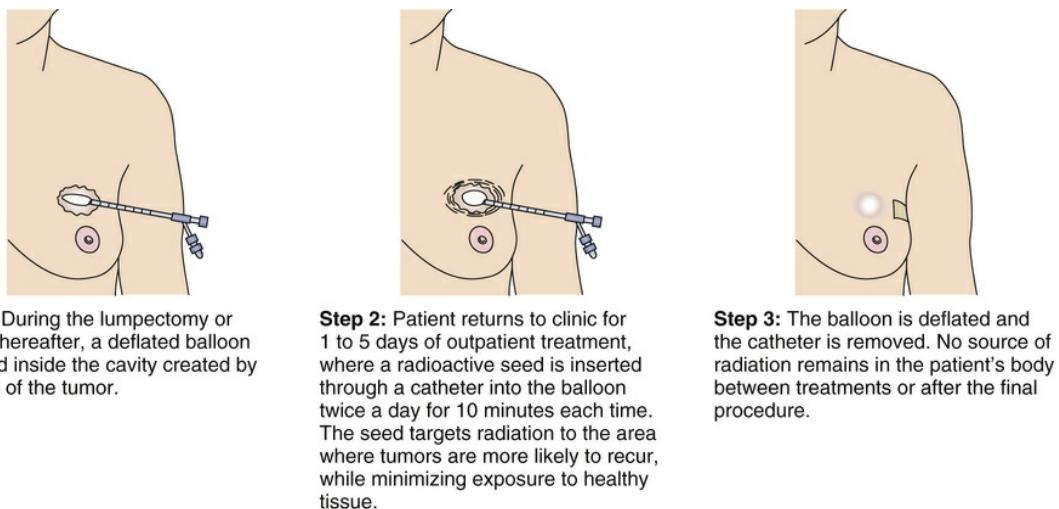

FIGURE 38-6 Brachytherapy. (From Lewis SL, Heitkemper MM, Dirksen SR, et al: *Medical-surgical nursing: Assessment and management of clinical problems*, ed. 7, St. Louis, 2007, Mosby.)

Safety Note: Skin moisturizers and some vaginal creams that contain estrogens used on a regular basis can be dangerous to estrogen-receptor-positive cancer in women, especially if they are taking aromatase inhibitors (Olson et al, 2009).

Breast Reconstructive Surgery

Plastic surgery of the breast may be performed to reduce breast size (reduction mammoplasty), enlarge breast size (augmentation mammoplasty), or reconstruct (reconstruction mammoplasty) the breast after breast cancer surgery.

Reduction mammoplasty.

Problems related to an excessively large breast include back and shoulder pain, pressure on nerves from brassiere straps, inability to buy clothing that fits, and psychological problems related to fear of ridicule or unwelcome sexual advances.

A mammogram may be necessary before surgery in women older than 40 years of age. The amount and degree of scarring should be discussed with the woman, because the scar is determined by the technique of surgery. Although data suggest that breast reduction surgery does not interfere with successful breast-feeding, it is possible milk production may be affected. Decreased nipple sensation or loss of part of the areola may also be a side effect of surgery that the woman should be aware of preoperatively. Information concerning successful breast-feeding after breast reduction surgery may be obtained from the La Leche League International.

Augmentation mammoplasty.

Breast augmentation is usually initiated by patients who wishes to improve self-image and attain a

sense of increased femininity. Breast augmentation can be accomplished by insertion of a saline implant under the pectoralis muscle.

Reconstructive mammoplasty.

Reconstructive mammoplasty creates a new breast when the natural tissue has been removed during mastectomy. A nipple/areola reconstruction provides a more natural appearance. Saline implants can be used, or skin and tissue may be taken from other parts of the body (autologous reconstruction), and tattooing of the nipple area provides natural-looking coloring. A pedicle flap tunnels body tissue to the breast area, keeping the blood vessels intact so that a microvascular surgeon is not needed. A free flap or muscle-sparing flap is another technique of reconstructive breast surgery in which blood vessels are harvested along with tissue and a microvascular surgeon reimplants the vessels. Perforator flap surgery is a technique that spares muscle tissue but requires detailed surgical skill ([Dellacroce, 2015](#)). Nursing responsibilities include frequent checking of the flaps for adequate perfusion, maintaining hydration to support flap perfusion, and proper patient positioning as prescribed. Pain management is essential to encourage deep breathing post-operatively. Range-of-motion exercises typically begin 1 week after surgery, and 5-lb weight lifting is prescribed for 6 to 8 weeks. The nipple is reconstructed 3 to 4 months after breast reconstruction surgery to be sure swelling is minimal. Tattoo of the nipple is a popular option rather than reconstruction of a new nipple.

Nursing Management for Breast Cancer Surgery

Preoperative care.

Most women need extensive education before breast surgery. Many surgeons now provide educational programs for their patients, but it is important for you to determine whether, in fact, the patient did receive adequate information and whether she has a good understanding of what was taught. Women commonly are particularly concerned about the change in their appearance after breast surgery. Talking with a Reach to Recovery volunteer or a nurse with extensive professional or personal knowledge before surgery can be very helpful. Teaching points will vary depending on the amount of tissue to be surgically removed and whether or not a prosthesis will be implanted either during the initial surgery or at a later date ([Figure 38-7](#)).

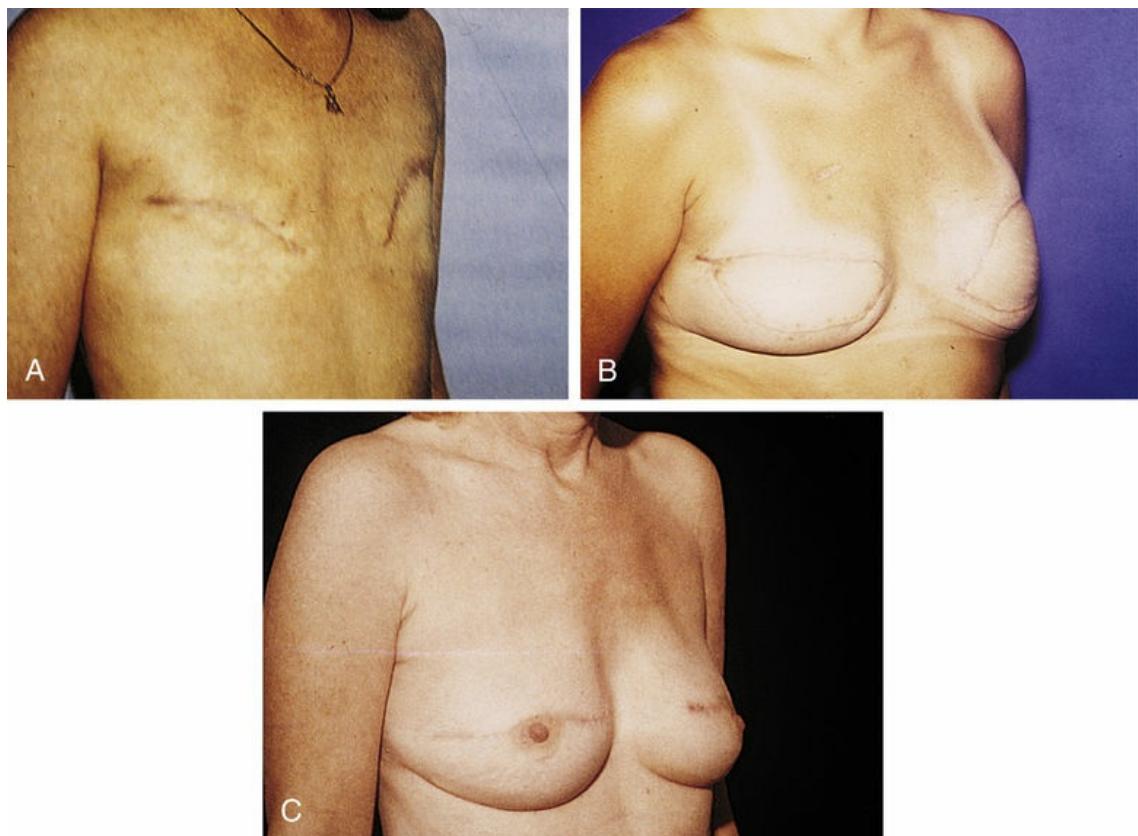

FIGURE 38-7 Reconstructive breast surgery. **A**, Appearance of the chest after bilateral mastectomy. **B**, Postoperative breast reconstruction before nipple reconstruction. **C**, Postoperative breast reconstruction after nipple and areolar reconstruction.

Postoperative care.

Postoperative care includes pain management, observation for signs of infection, and continued supportive and educational measures. Because breast tissue is very vascular, bleeding may be a problem. Surgical dressings should be observed frequently during the first 48 hours after the procedure.

Body image and disfigurement issues, as well as the focus in our society on the breast as a marker of femininity or sexual attractiveness, make treatment for breast cancer a highly emotionally charged experience. Women require ongoing supportive care, and most will benefit greatly from participating in a support group and from visits by American Cancer Society Reach to Recovery volunteers. These women have all undergone treatment for breast cancer and have been trained to do peer counseling. The local chapter of the American Cancer Society can be contacted regarding Reach to Recovery visits.

Collaborative care.

Collaborative care is essential to reduce anxiety and stress in the patient. Emotional support and accurate information are essential. The woman and her partner may differ in how much information they want to discuss. Issues concerning self-image and loss of control should be addressed.

Complications

Lymphedema.

Lymphedema is swelling of the arm that sometimes occurs after breast cancer surgery because of the damage to and resulting congestion of the lymphatic tract. (It can also be idiopathic, or of unknown origin, or a congenital problem.) Upper body symptoms usually occur within 6 months to 3 years of treatment in 10% to 64% of women who undergo breast node biopsy or cancer surgery,

and about 20% develop lymphedema (Hayes et al, 2012). Lymphedema can become a chronic condition. The use of sentinel node biopsy, with removal of additional lymph nodes only if the sentinel lymph node is positive for cancer, has reduced the occurrence of lymphedema because of less damage to the lymph tissue and thus less chance of developing lymphedema. Nursing interventions during the postoperative nursing care of a patient with a breast node biopsy or breast cancer surgery that can reduce the risk of development of lymphedema include:

- Do not assess blood pressure in the affected arm.
- Do not give injections or do venipuncture in the affected arm.
- Provide meticulous skin care.
- Teach the patient to wear gloves in the kitchen and when gardening to prevent skin irritation or injury.
- Teach the patient to avoid heavy lifting.
- Advise the patient to wear a compression garment during strenuous activities.
- Advise the patient to elevate and exercise the arm daily.

Patient Teaching

Measures to Prevent or Decrease Lymphedema

Teach the patient to:

- Elevate the extremity to the level of the heart. This reduces hydrostatic pressure within the veins.
- Apply elasticized stockings or gloves that do not have tight bands when up and active. This increases pressure on vessels and encourages venous return. (Garments may be removed when the extremity can be elevated.)
- Do not wear constrictive clothing.
- Do not cross your legs when sitting; do not carry a heavy bag if an arm is affected.
- Perform active exercise of the skeletal muscles. This promotes massage of the lymph vessels and the movement of lymph.
- Cleanse and dry the skin thoroughly and regularly, applying mild skin moisturizers to prevent cracking.
- Try to prevent any minor trauma to the area (e.g., no blood pressure cuffs or blood draws on the affected extremity) and do not use a heating pad.
- Wear gloves and sunscreen when gardening.

Review exercises that may be helpful (Figure 38-8). Discharge teaching should focus on the need for follow-up care, exercises to improve range of motion, prevention of infection, side effects of medical therapy, and community resources available.

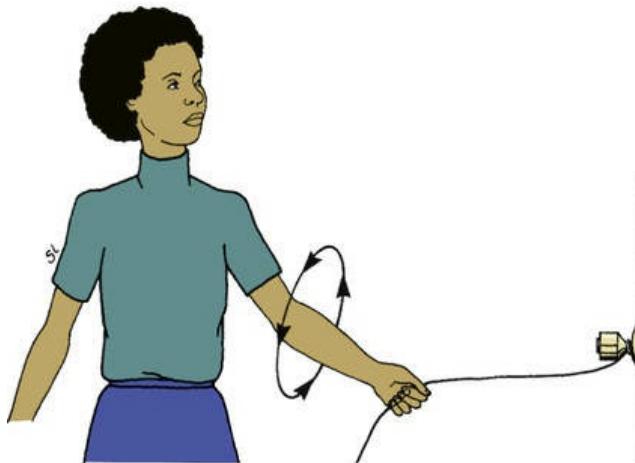

FRONT WALL CLIMBING

Patient stands facing the wall, elbows slightly bent. Palms are placed at shoulder level and fingers are flexed and unflexed as hands "walk" up the wall as high as possible. Hands are then walked back down to shoulder level. Patient moves toward wall as fingers climb higher and then away from wall as fingers move downward.

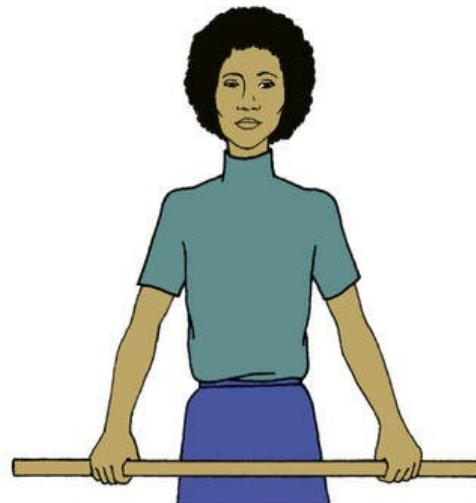

SIDE WALL CLIMBING

With operative side to wall, arm is extended until fingers touch wall. Patient moves toward the wall as fingers climb higher until body touches it. Maneuver is reversed as fingers climb back down wall.

ROPE TURNING

One end of rope is tied to door knob. Patient holds other end of rope and swings it in a circular motion, being sure entire arm and not the wrist is in motion.

YARDSTICK OR BROOM LIFT

Holding a yardstick or broom handle with both hands, the back is placed against a wall. Arms are extended straight downward and, with elbows straight, the stick is raised by the straightened arms until knuckles touch the wall over the head.

FIGURE 38-8 Postmastectomy exercises.

Clinics that specialize in the care of patients with lymphedema are available in some states. The standard of care is complex physical therapy, which involves techniques that provide lymphatic drainage, specialized pressure bandaging, application of a compression garment, exercising, and

skin care. More information can be obtained from the National Lymphedema Network website at www.lymphnet.org.

The diagnosis and treatment of breast cancer in women can be a direct threat to the sense of femininity and body image. Anxiety, denial, anger, and depression are common reactions. Many women fear they will no longer be attractive to their peers. A combination of peer support and psychotherapeutic, spiritual, and educational guidance can help the woman cope with the diagnosis and treatment. Nurses play a key role in education and referral.

Home Care

Home health nursing is a standard of care in the United States. Hospital stays are becoming progressively shorter, and women typically go home very quickly after illness, surgery, or childbirth. Intravenous antibiotic therapy is increasingly occurring in the home setting; many health problems are treated outside the hospital setting.

Many women recover at home after a surgical procedure. Home health nursing responsibilities include pain management, observation of the surgical site for signs of infection (redness, swelling, pain, presence of exudate, foul odor, fever), or reopening of the surgical wound because of trauma or a poor healing response. If the procedure involves the pelvic reproductive organs, the nurse must also assess the amount and duration of bleeding, any increase in the volume of flow, and any change (e.g., purulence or foul odor) that indicates the presence of infection.

Patient teaching typically becomes the responsibility of the home health nurse. Even conscientious teaching by the hospital nurse commonly needs extensive follow-up, because the patient's learning ability was impaired by immediate concerns such as acute pain, recovery from anesthesia, or emotional stresses associated with the diagnosis and the potential effects on daily living. The home health nurse must be prepared to give accurate, detailed information as part of home care. The nurse also should assess the patient's need for more general education regarding reproductive health, such as regular clinical breast examinations (CBEs), Pap smears, and need for information regarding contraception or STIs.

The home health nurse must be able to function independently and needs to communicate with the other members of the care team by phone, written documentation, and group conferences. The nurse also is commonly the primary source of information about appropriate support groups and informational programs that would be of assistance to the patient and her family.

Patient Teaching

Teaching Older Adults

Advanced age can inhibit ability to learn at a time when information concerning comfort and health is vital. In any teaching plan, the nurse should:

- Promote readiness and motivation to learn. The woman must sense that the information applies to her and is important.
- Provide brochures; reliable sources confer credibility of information.
- Include the woman's experiences and interests; personalizing teaching makes it more meaningful.
- Ask questions to confirm understanding.
- Provide socialization and opportunity to share. Use group sessions when possible.
- Provide short teaching sessions.
- Face the patient, and talk loudly and clearly.
- Use a quiet, adequately lit environment.

Community Care

Community care can take many forms. In the area of general reproductive health, low-cost women's health care clinics and organizations such as Planned Parenthood offer pregnancy testing, counseling and instruction on contraception and prevention of STIs, programs concerning BSE and VSE, and screening procedures such as pelvic examinations and mammograms. Instruction and low-cost screening may also be made available by local chapters of organizations such as the American Cancer Society. These outreach programs seek to make information and services available to all women at a reasonable cost. Such programs assist in the prevention and early detection of disease, reducing the long-term effects of potentially serious illness and the cost of intrusive health care.

Community care also takes the form of educational public service announcements on radio and television and in newspapers and magazines. These give the public valuable information on sexual health and disease prevention and treatment.

School nurses can and should play a major role in reproductive education and health maintenance. Drugs, alcohol, and early sexual activity are major health care concerns for adolescents. The school nurse is in a position to become a trusted source of accurate, nonjudgmental information for young people who are confused and lack education in the realities of reproductive health.

In recent years, a variety of programs have been developed for women at risk for serious diseases of the breast or reproductive organs. They may be sponsored by national organizations such as the American Cancer Society or by local groups or health care facilities and organizations. These programs provide both education and support groups for women undergoing treatment of serious health problems such as breast or uterine cancer, infertility, fetal loss, and other health concerns of women. The nurse can be very helpful in referring women to these community programs or by volunteering as a group facilitator or resource person.

Get Ready for the NCLEX® Examination

Key Points

- Reproductive health can be disrupted by many physical disorders. Alterations in reproductive health can affect other body systems.
- Women should keep a calendar of their individual menstrual cycles to determine regularity and recognize deviations from their normal cycle.
- PMS, also known as *ovarian cycle syndrome*, is the presence of physical, psychological, or behavioral symptoms that regularly occur in the luteal phase of the menstrual cycle.
- PMDD is a more severe type of PMS described officially in the DSM-5, a classification of disorders published by the American Psychological Association.
- Personal contraceptive techniques include fertility awareness methods, BBT, calendar and rhythm methods, ovulation or Billings method, and symptothermal method.
- Mechanical contraception methods include the use of a male condom, female condom, diaphragm, spermicide, cervical cap, or IUD.
- Hormonal contraception methods include the use of OCs, injectable contraceptives, transcutaneous patches, intrauterine and vaginal inserts, and sustained-release implants.
- Permanent contraception includes tubal ligation (female) and vasectomy (male).
- Emergency contraception may be indicated after unprotected intercourse but is not meant for regular use.
- Menopause is described as cessation of menses for a 12-month period because of decreased estrogen production. The perimenopausal or climacteric period is the period around the actual cessation of the menstrual period. Common symptoms include irregular menstruation, hot flashes or hot flushes, fatigue, insomnia, emotional swings, depression, back pain, headache, irritability, and decreased libido.
- A decrease in estrogen can increase the risk for the development of osteoporosis and increased blood cholesterol levels.
- Osteoporosis is a decrease in bone mass that increases the risk for bone fractures.
- BSE should be performed monthly 1 week after menstruation begins or on a specific date each month after menopause.
- Risk factors for cancer of the cervix include multiple sex partners, early sexual activity, multiple pregnancies, infection with HPV, and smoking.
- Leiomyomas (fibroids) of the uterus are common among women between 25 and 40 years of age and may cause vaginal bleeding between menstrual periods.
- Endometriosis is a condition in which endometrial tissue is found outside the uterus.
- Pelvic relaxation syndrome can affect the bladder (cystocele), the rectum (rectocele), or the uterus (uterine prolapse).
- Robotic gynecologic surgery is an effective alternative to open surgery.
- Exercise to restore arm function is very important after mastectomy.
- School nurses can and should be a valuable resource to young women regarding issues of sexuality, reproduction, and disease.
- Disorders of the female reproductive system can affect the woman's self-image.
- Specific genes have been identified that can predict the risk of specific types of breast cancer.
- Screening measures such as mammography, BSE, VSE, and Pap smears allow early detection and treatment of cancer of the reproductive tract and accessory organs.
- Modern technology can assist women who have fertility problems.
- Nurses must understand the perceptions of the woman and family before designing a teaching plan.

Review Questions for the NCLEX® Examination

1. A female patient complains of irritability, fatigue, mood swings, and fear of losing control days before menstruation. The initial assessment suggests a nursing problem of altered coping due to cyclic hormonal changes. Which of the following instructions given by the nurse would likely promote patient coping?

1. "Avoid calcium-containing foods."
2. "Exercise regularly."
3. "Have occasional alcohol."
4. "Consider a sodium-rich diet."

NCLEX Client Need: Physiological Integrity: Reduction of Risk Potential

2. Which of the following nursing interventions would help relieve symptoms of dysmenorrhea? (*Select all that apply.*)

1. Pelvic rocking exercises
2. Cold compresses
3. Effleurage
4. Low-fat diet
5. NSAIDs

NCLEX Client Need: Health Promotion and Maintenance

3. A 44-year-old patient complains of irregular menses with hot flashes. She is informed that she is approaching the climacteric period. Her nurse finds her withdrawn and crying. An appropriate statement by the nurse would be:

1. "It is not the end of the world."

2. "You seem upset. I am here to listen."
3. "Everything will be all right."
4. "Aging is not for the faint of heart."

NCLEX Client Need: Psychosocial Integrity

4. Metrorrhagia is associated with which of the following?

1. Uterine polyps and leiomyomas
2. Trauma and foreign body in the vagina
3. Cervical cancer
4. All of these

NCLEX Client Need: Health Promotion and Maintenance

5. A 65-year-old patient complains of vaginal bleeding. She has been menopausal for 11 years. Which of the following are possible causes? (*Select all that apply.*)

1. Postcoital bleeding from atrophic vaginitis
2. Endometrial cancer
3. Endometriosis
4. Cervical polyp

NCLEX Client Need: Safe and Effective Care Environment

6. A nurse is discussing healthy lifestyle activities with a woman. Which of the following statements by the woman indicates a need for follow-up teaching? (*Select all that apply.*)

1. "I can use herbals such as Angelica or evening primrose oil during menstruation to decrease breast tenderness."
2. "I will focus on drinking caffeine-free colas to keep my fluid intake adequate."
3. "I will douche regularly with an alkaline solution to maintain vaginal health."

4. "I will wear form-fitting, nylon clothing and underwear for warmth and to prevent infections."
5. "As I approach menopause, I can eat wild yams, cherries, and alfalfa sprouts as a source of phytoestrogens."

NCLEX Client Need: Physiological Integrity: Reduction of Risk Potential

7. A nurse is discussing various methods of contraception with a woman. When discussing mechanical methods of contraception that do not provide any protection from STIs, the nurse would specifically include:

1. The symptothermal method
2. The Billings method
3. The use of water-soluble spermicidal lubricants during sexual activity
4. The use of IUDs
5. OCs

NCLEX Client Need: Physiological Integrity: Reduction of Risk Potential

8. A nurse empowers a patient who had a right radical mastectomy by providing specific instructions regarding postoperative care of the surgical site and surgical complications. Which of the following statements by the patient would indicate a need for more teaching?

1. "Blood pressure cannot be taken on the right arm."
2. "I can resume intense weight training immediately after discharge."
3. "No injections must be given in the right arm."
4. "When gardening, I need to wear gloves."

NCLEX Client Need: Safe and Effective Care Environment

9. A 44-year-old patient who had a right radical mastectomy expresses concerns regarding her physical appearance. Further assessment indicates a nursing problem of altered body image. An important goal for this patient would be to:

1. participate in activities of daily living.

2. demonstrate acceptance of change in appearance.
3. perform aseptic wound care.
4. state signs and symptoms of infection.

NCLEX Client Need: Safe and Effective Care Environment

10. A nurse is taking the gynecologic history of a postmenopausal Mexican American patient. Which strategies would help develop rapport with the patient? (*Select all that apply.*)

1. Establish direct eye contact.
2. Involve family members.
3. Touch the patient.
4. Use a polite tone of voice.
5. Respect privacy.

NCLEX Client Need: Psychosocial Integrity

Critical Thinking Questions

Scenario

Mrs. Long is a 45-year-old college instructor, married with two teenage children. She found a lump during BSE that was diagnosed as malignant. Mrs. Long does not want to have the radical mastectomy recommended by her surgeon.

1. What are some possible reasons for Mrs. Long's hesitation about having a radical mastectomy?
2. What alternative surgical procedures are available to Mrs. Long?
3. What types of resources are available to help Mrs. Long make this decision?

CHAPTER 39

Care of Men With Reproductive Disorders

Objectives

Theory

1. Review the effects of aging on the male reproductive system.
2. Summarize the medical and nursing management of erectile dysfunction.
3. Recognize factors involved in fertility, infertility, and contraception in men.
4. Present the most common diagnostic tests and examinations of the male reproductive system.
5. Explain the assessment of the male reproductive system.
6. Outline the pathophysiology and manifestations of common disorders of the male reproductive tract.
7. Evaluate the plan of care for a male patient with a disorder of the reproductive tract.
8. Explain the psychological and emotional effects of disorders of the male reproductive tract.
9. Analyze the role of drug therapy in disorders of the male reproductive tract.
10. Compare and contrast four types of surgical treatments for benign prostatic hyperplasia (BPH).
11. Diagram the preoperative and postoperative nursing care of a patient with BPH.
12. Discuss inflammations of the male reproductive system and their treatments.
13. Illustrate the patient teaching involved for early detection of testicular and prostate tumors.

Clinical Practice

14. Teach a patient about the procedure for a prostate biopsy.
15. Create a nursing care plan for a patient with prostate cancer.
16. Devise a teaching plan for testicular examination for young adult men.
17. Prepare materials describing treatment to a patient experiencing erectile dysfunction.

urodynamics (ū-rō-dī-NĀM-īks, p. 931)
vasectomy (vă-SĒK-tō-mē, p. 924)

Many diseases and disorders, and many medications, can affect the male reproductive system. The urinary system and reproductive system are so closely linked in the male that a disorder in one system typically affects the other. Assessment of the reproductive system is an essential part of any comprehensive health history. Nurses need to be comfortable with their own sexuality and knowledgeable about the male reproductive system to be helpful to patients.

Anatomy and Physiology of the Male Reproductive System

Structures

- The male **gonads** (sex glands) are the testes; they are oval shaped and are encased in the scrotum along with the epididymis, seminal vesicles, and vas deferens (Figure 39-1).

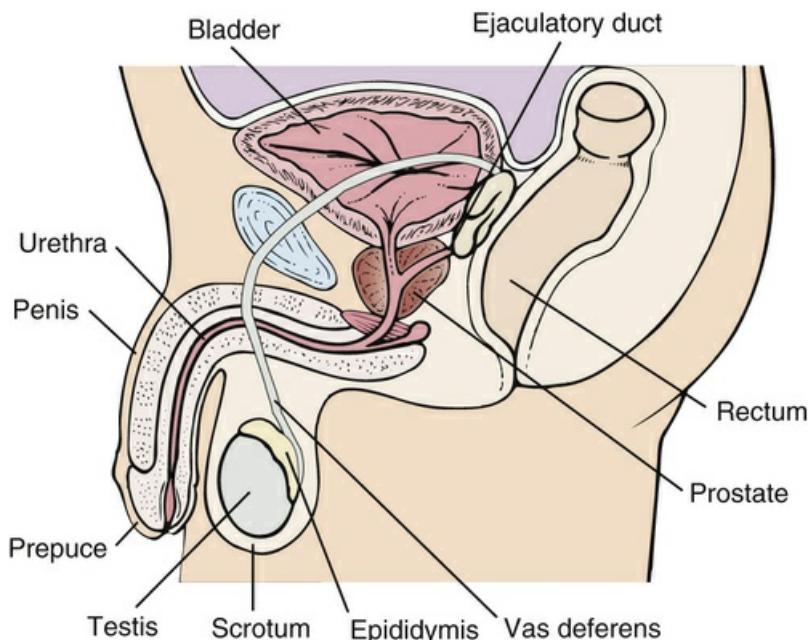

FIGURE 39-1 Structures of the male reproductive system. (From Lewis SL, Heitkemper MM, Dirksen SR, Bucher L: *Medical-surgical nursing: Assessment and management of clinical problems*, ed. 9, St. Louis, 2014, Mosby.)

- The scrotum is covered with wrinkled skin (**rugae**) and is very sensitive to temperature, pressure, touch, and pain.
- The penis is a cylindrical, erectile organ that hangs in front of the scrotum. It contains three columns of erectile tissue that can cause it to extend and enlarge in circumference, becoming stiff. The penis is covered with skin and includes a foreskin (unless circumcision has been performed). The scrotum and penis make up the external genitalia of the male.
- The prostate gland is shaped like a walnut, encircles the urethra, and is located below and to the rear of the bladder.
- The bulbourethral (Cowper) glands are small pea-sized glands located in the urethral sphincter, posterior to the urethra.

Functions of the Organs of the Male Reproductive System

- The scrotum—a thin-walled, muscular sac—holds the testes, the epididymis, and the vas deferens. The scrotum hangs from the pubic bone and suspends the testes outside the body, where they remain several degrees cooler than the body; the cooler temperature is needed for the production of viable sperm.
- The spermatic cord attaches the testes to the body. It contains the blood vessels and nerves that supply the testes.
- The seminiferous tubules within the testes produce sperm (**spermatogenesis**). These tubules collect and transport the sperm to the epididymis. Testosterone also is produced in the testes.
- The epididymis is a long tube (almost 6 m if uncoiled) that conducts sperm from the testes to the

vas deferens. Immature sperm mature as they travel through this tube. Mature sperm are stored in the lower portion of the epididymis.

- The vas deferens is a muscular tube that connects to the epididymis. It stores sperm and then carries it to the ejaculatory duct by peristaltic movements.
- The prostatic section of the urethra receives the sperm and carries it to the penile portion of the urethra for ejaculation. Secretions from the seminal vesicles and ducts of the prostate gland are mixed with the sperm in an alkaline solution that assists in neutralizing the acidity of the vaginal tract.
- The seminal vesicles produce a fluid that is thick and contains fructose to nourish the sperm and provide energy. The fluid also contains prostaglandins, which contribute to the motility of the sperm. This fluid mixes with the sperm to form seminal fluid, or **semen**. The average volume of semen ejaculated is 2.5 to 4 mL but may vary from 1 to 10 mL.
- The prostate gland produces thin, milky, alkaline secretions that contribute to the seminal fluid and enhance the motility of the sperm.
- The bulbourethral glands secrete an alkaline mucuslike fluid in response to sexual stimulation.
- The secretions of the bulbourethral glands neutralize the acid of residual urine in the urethra and provide some lubrication at the tip of the penis for intercourse.
- The penis is flaccid until sexual arousal causes the arterioles to the erectile tissue to dilate and the veins to constrict, engorging the penis with blood until it is enlarged and rigid. This is an **erection**. Erections are stimulated by anticipation, memory, visual sensations, or touch on the glans penis and skin of the genital area. If stimulation continues, **ejaculation** will occur. This is the forceful expulsion of semen from the urethra. Thoughts, emotions, some medications, or medical disorders can sometimes inhibit erection. The penis transfers semen to the vagina. It also carries urine through the urethra to be excreted.

Control of Sperm Production

- The hypothalamus, the anterior pituitary, and the testes secrete hormones that control male reproduction.
- The hypothalamus secretes gonadotropin-releasing hormone (GnRH) in response to an unknown stimulus.
- GnRH stimulates the anterior pituitary to release luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH stimulates the testes to produce testosterone. FSH binds with cells in the seminiferous tubules, making them respond to testosterone. Testosterone and FSH stimulate the formation of sperm (spermatogenesis).
- The male sex hormones are called **androgens**.
- At puberty, testosterone levels rise and cause maturation of the male reproductive organs. Sperm take 70 days to mature and are constantly being produced once puberty has occurred.
- Normal sperm count is 100 million/mL. Sterility occurs when the sperm count drops to less than 20 million/mL.

Age-Related Changes

- The scrotum becomes more pendulous, and there are fewer rugae.
- Prostate enlargement may occur, with risk of urethral obstruction.
- Plasma testosterone and progesterone levels decrease.
- There is decreased sperm production, but fertility remains intact. Ejaculate volume decreases.
- After age 60 years, the cycle of sexual response lengthens. Arousal takes longer and more direct penile stimulation may be needed; the firmness of the erection may be decreased.
- Sexual activity in older men is closely related to their sexual activity in earlier years.
- Vascular problems are the major causes of impotence.
- Certain medical disorders, or the use of various medications, may have side effects that can affect sexual function.

The Male Reproductive System

The male reproductive organs are shared with the urinary tract, and disorders in functioning of one system typically affect the other. For this reason, men who have a disorder or dysfunction of the reproductive tract are commonly treated by a urologist.

Fertility

If the anatomy and physiology of the male reproductive tract are intact, sexual function is influenced by the functioning of the hypothalamus, pituitary, and testes; the metabolism and transport of sex hormones (such as GnRH and others); and the cognitive and sensory centers in the brain. A sexual desire (**libido**), the ability to respond to sexual stimulation with a penile erection, and the ejaculation of semen containing live sperm are necessary for fertility. Both the parasympathetic and sympathetic nervous systems influence the normal sexual response cycle.

Older Adult Care Points

The decrease in testosterone with age decreases muscle strength, bone mass, libido, and erectile function, and affects the psychological sense of well-being. Testosterone replacement therapy is thought to decrease visceral fat and improve bone density, muscle strength, libido, and energy, but it may not improve erectile function of the penis. There is no evidence that dehydroepiandrosterone (DHEA) supplements, available over the counter, benefit older men. Studies are ongoing concerning the benefits of testosterone therapy in older adults.

As a man ages, there is no abrupt cessation of gonadal hormone activity as there is in a woman. In the man, there is a gradual decrease in testosterone and other anabolic hormones, such as growth hormone and DHEA.

Contraception

Contraception is a method of preventing unwanted pregnancy. The only 100% effective method of contraception is abstinence. Abstinence is encouraged for adolescents and young adults and is taught in many school programs. However, nurses must be able to provide contraceptive options for the many couples who prefer not to have additional children. Contraception is the responsibility of **both** the man and the woman. Female contraception is discussed in [Table 38-2](#).

Reversible Contraception

Reversible contraception involves the use of spermicidal creams, gels, or foams applied before intercourse to kill sperm in the vagina. These are more effective if used in conjunction with a condom. A male condom is an effective reversible contraceptive technique if it is applied and used properly. The condom sheath is typically made of latex. Proper application includes timing of application and removal and providing a space at the tip for semen to collect. Oil-based lubricants such as petroleum jelly can cause latex to deteriorate, so these lubricants reduce the reliability of latex condoms. It is important to suggest the use of water-soluble lubricants such as jellies made for this purpose. Condoms made of polyurethane are compatible with oil-based lubricants. Latex condoms provide some protection against sexually transmitted infections (STIs).

Permanent Contraception: Vasectomy

Male sterilization by vasectomy is a popular method of permanent contraception. The term **vasectomy** refers to a surgical procedure performed on the vas deferens for the purpose of interrupting the continuity of this duct, which conveys the sperm at the time of ejaculation. This is considered a permanent procedure, but occasionally a vasectomy can be successfully reversed by vasovasotomy (microsurgery) at a later time if a man's life circumstances change.

A vasectomy is done on an outpatient basis in a clinic or provider's office, with a local anesthetic. An incision is made into the scrotal sac on each side, and the vas is lifted out. A segment of the vas is cut out, the ends are bound, and the incision is closed.

The patient should be instructed to use ice applications and acetaminophen or ibuprofen for

scrotal pain and swelling the first 12 to 24 hours postoperatively. The patient should wear jockey shorts or a scrotal support for comfort. Sexual intercourse may be resumed in about 1 week or whenever the patient finds it comfortable. Two negative sperm counts are needed after vasectomy before the patient can be considered infertile, and some form of contraception should be used until then.

Because seminal fluid is manufactured in seminal vesicles and the prostate gland, there is no decrease in semen ejaculation after a vasectomy. However, the semen does not contain sperm. After vasectomy, the sperm cells produced by the vas deferens are reabsorbed by the body. Vasectomy has no effect on libido or sexual performance and provides no protection from STIs. Some patients consider storing fertile sperm in a sperm bank before a vasectomy. Because reversal of a vasectomy may or may not be successful, using frozen sperm at a later date to father a child thus remains an option.

Clinical Cues

After the vasectomy, instruct the patient to use another method of birth control until sperm counts are negative, because active sperm are still present in the vas. Another sperm count should be done 1 year later to verify that the vas deferens is not intact.

❖Nursing Management

■ Assessment (Data Collection)

Because particular kinds of male reproductive disorders predominate in certain age groups, the age of the patient is relevant to nursing assessment. In men older than 50 years, the assessment is directed more toward detecting prostate problems, whereas younger men are carefully assessed for STIs and testicular cancer.

It may be awkward for new nurses to obtain a sexual and reproductive history, but with experience in interviewing male patients of all ages, they will soon become more comfortable and adept at obtaining necessary data. Because questions about urinary problems are usually less sensitive than those dealing with sexual dysfunction, it is best to begin with questions of this kind and then lead into more sensitive ones.

Open-ended questions that start out with "Tell me about..." or "When did you first notice..." give the patient room to discuss only those things he is comfortable talking about. It also is helpful to relate his problem to the inconvenience it has caused in his daily life. For example, tenderness and discomfort in the scrotal area could make sitting at a desk or walking very difficult and interfere with getting assigned work done. Frequent urination can cause distracting and sometimes embarrassing interruptions in his work schedule or recreational activities.

Good communication depends on the sender and receiver of messages using mutually understood language. Many people do not know the medical names of their sex organs. If you suspect that the patient does not understand what particular part of the body is being discussed, or if you are not familiar with the term the patient is using, it is important to phrase questions differently or ask for clarification from the patient.

Focused Assessment

Data Collection for the Male Reproductive System

Ask the following questions:

- Have you noticed any changes in patterns of urination? Any differences in the stream of urine?
- Do you ever have any discharge coming from the penis?
- Have you felt any masses or bumps in the scrotum or groin?
- Do you have any tenderness or pain in the scrotum or penis?
- Do you have any rectal or perineal pain?

- Do you perform regular testicular examinations?
- Have you had past infections of the reproductive system?
- What drugs do you take regularly?
- Do you have difficulty obtaining or maintaining an erection?

Health Promotion

Health Screening and Assessments

Regular self-evaluation of the testes is encouraged, such as testicular self-examination for early detection of cancer. You can encourage the patient to perform self-examination and teach proper techniques and follow-up care ([Figure 39-2](#)). (Privacy should be provided during examination and obtaining specimens.)

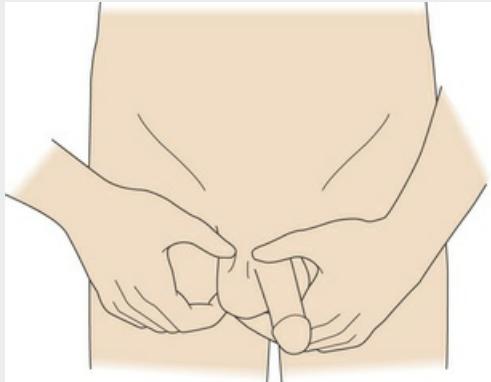

FIGURE 39-2 Testicular self-examination. (Courtesy Coloplast Surgical Marketing, Minneapolis, Minnesota.)

Think Critically

Can you think of five relatives or friends for whom you could provide information on testicular self-examination? How would you approach them on this subject?

Diagnostic Tests

Tests for general state of health, such as complete blood cell count, urinalysis, chemistry profile, and thyroid tests, are done initially for problems concerning the male reproductive tract. Serum acid phosphatase is usually elevated in patients with prostate cancer. Serum alkaline phosphatase is elevated if malignancy of the prostate has metastasized to the bone. A kidney-ureters-bladder (KUB) x-ray, an intravenous pyelogram, and cystoscopy with uroflowmetry studies also may be performed (see [Chapter 34](#) for more information on these tests). Blood tests are performed to detect specific UTIs.

Tumor protein marker studies are performed for patients with testicular cancer for follow-up to determine the success of treatment or recurrence of the disease. The primary tumor markers are alpha-fetoprotein (AFP) and the beta subunit of human chorionic gonadotropin (beta-HCG). A **prostate-specific antigen (PSA)** test detects levels of a glycoprotein produced by the prostate that is elevated in prostate cancer. Diagnostic tests that relate to the male reproductive organs are summarized in [Table 39-1](#).

Think Critically

How would you begin your assessment interview with a 52-year-old man? Would you have any difficulty asking the questions necessary to obtain a good reproductive system history and

information about present problems?

Table 39-1
Diagnostic Tests for the Male Reproductive System

TEST	COMMENTS
Digital rectal examination	A lubricated, gloved finger is inserted into the rectum to evaluate the consistency and size of the prostate and detect any nodules.
Semen analysis	Through masturbation, the patient provides a specimen of semen, which is analyzed for volume and for sperm content and motility.
Testicular self-examination (TSE)	Monthly self-examination is encouraged (see Figure 39-2).
Prostate-specific antigen (PSA) level	A sample of blood is examined for the level of glycoprotein produced only by the prostate. An elevated level is found in benign prostatic hyperplasia, and levels above 10 mg/mL may be indicative of prostate cancer. However, abnormal levels do not indicate a positive diagnosis. The United States Preventative Services Task Force recommends against routine screening for prostate cancer. The National Comprehensive Cancer Network recommends risk-stratified screening. The American Cancer Society recommends that men should make an informed choice.
Transrectal ultrasound	Recommended when PSA and/or digital rectal examination results are abnormal. May also be used to guide needle biopsies of the prostate.
Urography	Radiologically detects changes caused by ureter abnormalities and follows urine excretion pathway.
Uroflowmetry	Measures the volume of urine expelled from the bladder per second. Detects outflow tract obstruction. Patient voids into a urine flowmeter. Privacy is provided.
Prostate tissue analysis (biopsy)	Specimens of prostate tissue or fluids can be obtained by perineal or transrectal needle aspiration. If procedure is outpatient based, the patient is taught to report hematuria or change in urine flow after the procedure.
Cystoscopy	A lighted instrument is inserted through the urethra into the bladder. Used to detect prostate hypertrophy and bladder tumors. This is done as a sterile procedure.
Urethral smears	Used for laboratory microscopy study to identify pathogens. Prostate massage increases secretions in the urethra. A sterile swab is inserted into the urethra to obtain the specimen. Often used to diagnose some sexually transmitted infections.
Endocrine Studies	
Luteinizing hormone (LH) level	LH secreted by the pituitary stimulates Leydig cells in the testes to produce testosterone. High levels may indicate testicular failure.
Prolactin level	Prolactin, a hormone secreted by the pituitary, potentiates testosterone production.
Follicle-stimulating hormone (FSH) level	FSH is secreted by the anterior pituitary gland and stimulates the Sertoli cells in the seminiferous tubules to complete formation of mature sperm. Increased FSH levels indicate decreased spermatogenesis.
Testosterone level	Testosterone is secreted by the Leydig cells of the testes. High levels may indicate a testicular tumor. Low levels may occur in older men. Because testosterone levels are highest in the morning and lowest in the evening, it is important to obtain a morning sample.

■ Nursing Diagnosis

Examples of problem statements frequently associated with the male reproductive system may include:

- Altered elimination due to urinary blockage.
- Anxiety due to failure to empty bladder totally or due to leakage of urine.
- Pain due to pressure within the pelvis, bladder distension, surgical incisions, or bladder spasms.
- Altered sexual function due to failed erection or decreased libido.
- Decreased self-image due to changes in sexual function.
- Potential for infection due to urine stasis.

Additional problem statements may be appropriate for patients undergoing surgery or who have cancer (see Chapters 4, 5, and 8).

Specific NANDA-I diagnoses can be chosen from the NANDA-I list (see inside back cover).

■ Planning

Expected outcomes are written for individual patients based on the problem statements chosen. Interventions are planned to help the patient meet the expected outcomes. Plan interaction with the patient based on his age, educational level, degree of comfort in discussing reproductive problems, and culture.

Expected outcomes for a patient with problems of the male reproductive system are:

- Patient will have normal urinary flow without obstruction.
- Patient will have normal urinary elimination after surgery.
- Patient will have bladder spasms controlled with medication.
- Pain will be resolved after surgical recovery.
- Patient will have increased self-esteem 3 months after surgery.
- Patient will explore avenues for achieving sexual satisfaction.
- Patient will focus on positive traits and capabilities to increase a positive body image.
- Patient will not experience any infection from stasis of urine or from surgery.

■ Implementation

Nursing actions for selected problems of the male reproductive system are found within the sections on specific diseases that follow. Privacy should always be provided when assessing the genitals, performing catheter care, or doing dressing changes. There are wide variances in the degree of modesty in men. Female nurses must be especially cautious and display a matter-of-fact, respectful manner when providing care. Sensitivity to embarrassment is necessary. Rather than stating "Don't worry; I'm used to this," it might be better to state, "I understand that this may be embarrassing for you; I will try to be as quick about it as I can."

Some patients make inappropriate comments when they feel that their sexuality is threatened. A male patient with sexual dysfunction, or one about to undergo surgery that may affect his sexuality, might make sexual comments or advances to a female nurse; she should be tactful and matter-of-fact in setting limits on such behavior, without taking the patient's inappropriateness personally.

■ Evaluation

Evaluation assesses how effective the nursing actions are in helping the patient achieve the expected outcomes. If the actions and treatments are not achieving the desired effect, a revision in the plan of care is necessary.

Disorders of the Male Reproductive System

Erectile Dysfunction

Erectile dysfunction (ED), also known as **impotence**, is the inability to achieve or maintain an erection that is firm enough for sexual intercourse more than 25% of the time. Impotence can also involve ejaculation problems. ED has both psychological and organic causes.

Clinical Cues

Sexual Activity Among Older Adult Men

Cultural factors can affect erectile function in older men. Some cultures may disapprove of sexual activity among older adults, and some older men may not seek guidance for ED.

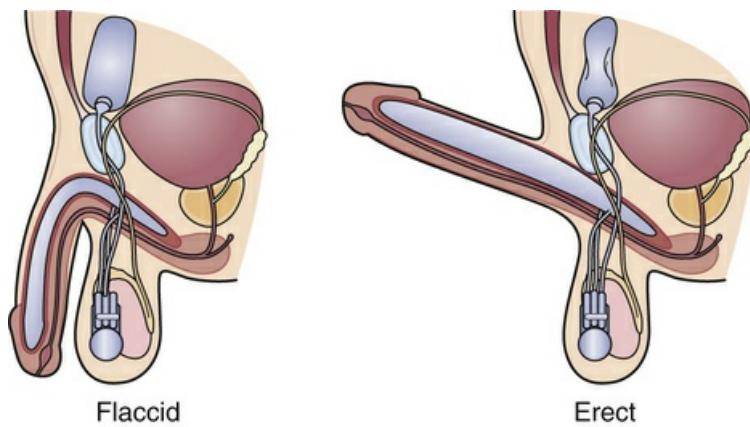

Factors that interfere with the mechanisms of penile erection will cause ED. Any condition that impairs the blood supply to the penis, impairs pathology of the nervous system or hormonal supply, or impairs psychosocial responses can interrupt the process of penile erection. Anxiety and depression can affect achieving or maintaining an erection. Organic causes can include diabetes mellitus and other endocrine disorders, disorders of the urinary tract, neurologic disorders, and chronic illness (such as sickle cell anemia, hypertension, cardiovascular disease, liver disease, and cancer). Medications and drug and alcohol abuse can interfere with sexual performance. Some antihypertensive drugs, diuretics, tranquilizers, and medications used to prevent gastroesophageal reflux disease (GERD) can cause sexual problems. Antiparkinson medications can enhance sexual desire but not the ability to perform (Wold, 2008).

A complete history and physical examination are needed to rule out any physical illness that may affect sexual performance. Sleep laboratories can monitor nighttime penile erections to detect organic causes of impotence. A Doppler probe can measure arterial flow in the penis essential for erections, and nerve conduction tests can rule out neurologic pathology related to impotence. Review the patient's medications for side effects affecting erectile function and conduct a complete evaluation for psychological causes of impotence before devising an individualized treatment plan. Studies have shown that among patients who seek help for ED, nearly 30% have undiagnosed hypertension, 15% have diabetes mellitus, and 5% have significant coronary artery disease (Jackson et al, 2006).

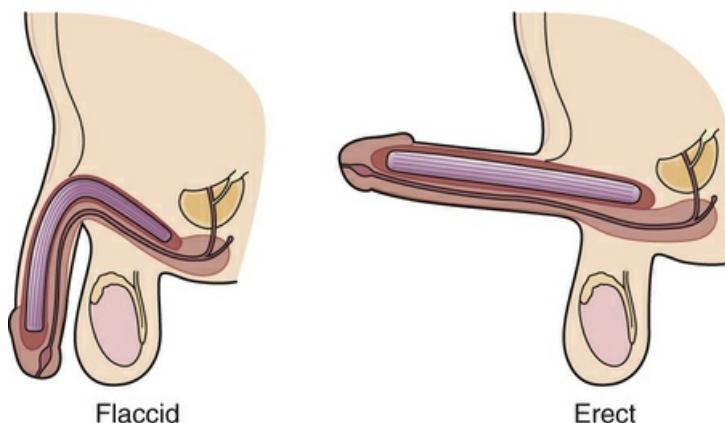

Treatment

Medical treatment depends on the cause of ED. Medical conditions are treated, the medications prescribed are reviewed and adjusted, hormone therapy may be prescribed for hypothalamic-pituitary disorders, and vascular surgery may be indicated for penile blood flow obstruction.

The primary intervention for ED is modifying reversible causes of the problem. Drug therapy includes phosphodiesterase (PDE-5) inhibitors, taken an hour before sexual activity. These drugs should not be taken with nitrate-based drugs used for heart problems, because a serious drop in blood pressure can occur from the combination. If these methods fail to resolve ED, surgical interventions include inserting a penile implant that can be rigid or flexible. One type of implant includes a pump, inflatable cylinders, and a reservoir for emptying after erection. The erection produced is usually firm enough to enable intercourse (Figure 39-3). Complications of oral medication therapy include **priapism**, a persistent abnormal erection that can develop into a urologic emergency. Treatment options are presented in Table 39-2.

INFLATABLE PENILE IMPLANT

FLEXIBLE ROD PENILE IMPLANT

FIGURE 39-3 Penile implants.

Table 39-2

Treatment Options for Erectile Dysfunction

OPTION	COMMENT
Medications Taken About 1 Hour Before Intercourse	
PDE-5 Inhibitors	Side effects can include headache, dyspepsia, and nasal congestion.
Sildenafil (Viagra)	Contraindicated in patients taking nitrates and patients with hypertension or retinopathy. Usually taken $\frac{1}{2}$ to 4 hr before sexual stimulation. Viagra
Vardenafil (Levitra): rapid onset	
Tadalafil (Cialis): longer lasting	can cause color vision disturbances and should not be taken more than once per day.
Yohimbine	Useful if organic disease is cause of ED.
Trazodone	Has sedation as side effect.
Intraurethral prostaglandin E ₁ suppository (alprostadil)	Works locally on corpora cavernosa as a vasodilator.
Intracavernosal injections of vasodilating drugs	Currently replaced by oral sildenafil therapy. May cause priapism.
Vasoactive drugs	Can be administered by topical gel, local self-injection, or insertion of medication pellet (alprostadil) into the urethra. Side effects can include pain, fibrotic nodules, and hypotension.
Papaverine gel	
Alprostadil (Caverject)	
Phentolamine (Vasomax)	
Complementary and Alternative Therapies	
Siberian ginseng	Believed to increase penile blood flow, but research-based evidence is lacking.
Ginkgo biloba	These therapies may be used in conjunction with other options. Research-based evidence of effectiveness is lacking, but research is ongoing.
Acupuncture	
Aromatherapy	
Sandalwood	
Rose	
Jasmine	
Ylang ylang oil	
Imagery	
Biofeedback	
Relaxation	
Other	
Sexual therapy	The psychosocial factors that may be causing ED are discussed with a qualified sexual therapist. Counseling should include the partner.
Penile implants	Can be a semirigid rod or an inflatable prosthesis.
Negative pressure (vacuum constrictive devices)	Used to induce erection by suction. A band is placed at base of penis to maintain erection. May be cumbersome to use. Injury can occur if constriction band is left in place longer than 1 hr.

ED, Erectile dysfunction; *PDE-5*, phosphodiesterase.

Be aware of relationship problems within the family unit. Asking open-ended questions concerning sexual function or problems can provide information that will be helpful to the plan of care. Referral to a sex therapist may be indicated to help the patient integrate his sexual belief, practices, and abilities into a healthy lifestyle. Community support groups for patients with ED and their partners may be available, such as Impotence Anonymous (I-Anon).

Older Adult Care Points

Older men who have been consistently participating in intercourse throughout adult life have the best chance of maintaining this capability. When abstinence has occurred over a considerable time, ED may become a problem. With patience and treatment, this problem may be overcome. Men can reproduce as long as they can participate in intercourse.

Ejaculation Disorders

Spinal cord injuries, neurologic disorders such as multiple sclerosis, diabetes mellitus, urologic surgery, or the side effects of various medications can cause problems with ejaculation. **Premature ejaculation** is the most common ejaculation problem in men; it occurs when the ejaculation reflex is not controlled, and the release of semen occurs before release is desired. Chemical, vibratory, and electrical stimulation can be used to treat premature ejaculation.

Retrograde ejaculation occurs when the semen travels toward the bladder rather than exiting the penis. Determining the physical and psychological factors causing the retrograde problem is the priority for selecting appropriate treatment and planning care. Retrograde ejaculation may occur after prostatectomy.

If fertilization is desired, men with retrograde ejaculation may have sperm harvested from their urine for artificial insemination. When spinal injury is the problem, an electro-ejaculation device inserted into the rectum stimulates the prostate and enables sperm collection for artificial insemination.

Infertility

Infertility is defined as failure of a couple to achieve a pregnancy after at least 1 year of frequent, unprotected intercourse. Approximately 25% to 30% of infertility may result from factors in the male partner.

Hypothalamic-pituitary disorders and ED contribute to infertility, but testicular disorders are the most common organic cause of male infertility. Drugs, infections, systemic disease, and congenital disorders can cause testicular failure.

A semen analysis with sperm count and activity is performed. Laboratory tests performed include FSH, LH, and testosterone levels to determine whether hormone therapy is indicated. A postejaculation urine specimen may be examined to diagnose retrograde ejaculation of semen into the bladder. An ultrasound of the seminal vesicles may reveal dilated vesicles and obstruction of the vas deferens near the ejaculatory duct. Surgical resection of the ejaculatory duct may be indicated. A fine-needle aspiration or biopsy of the testicles may reveal pathology that can be treated. Discussion with both partners concerning technique and timing of intercourse is indicated.

Pathology may be corrected with medications, hormone therapy, or surgery. In vitro fertilization or intracytoplasmic sperm injection (ICSI) after sperm extraction is often successful in treating male infertility.

The environment should be evaluated for toxins such as pesticides, lead, mercury, or radiation exposure—all of which can affect fertility. Occupational influences on fertility include exposure to heavy metals, solvents, fumes, or polycyclic aromatic hydrocarbons (DeFleurian, 2009). Patients seeking fertility should be instructed to prevent excessive heat around the scrotal area, which could decrease sperm development. Hot tubs, using a laptop on the lap, and tight underwear should be avoided. Stress reduction techniques, information concerning timing and technique of intercourse, optimum nutrition, and health practices should be reviewed with both partners. When infertility is attributable to the man, his self-image may be affected; therefore diplomatic, caring, and considerate family interactions are essential.

Hydrocele

There is normally a small quantity of fluid in the space between the testis and tunica vaginalis within the scrotum (Figure 39-4). A larger-than-normal amount of fluid accumulating in this space is known as *hydrocele*. The fluid accumulation may be caused by infection, such as epididymitis or orchitis, or accumulation may occur after trauma; hydrocele involves interference with lymphatic drainage of the scrotum. In many cases the cause is unknown. Hydrocele causes enlargement of the scrotum and usually is painless, but the weight and added bulk of the fluid can cause discomfort.

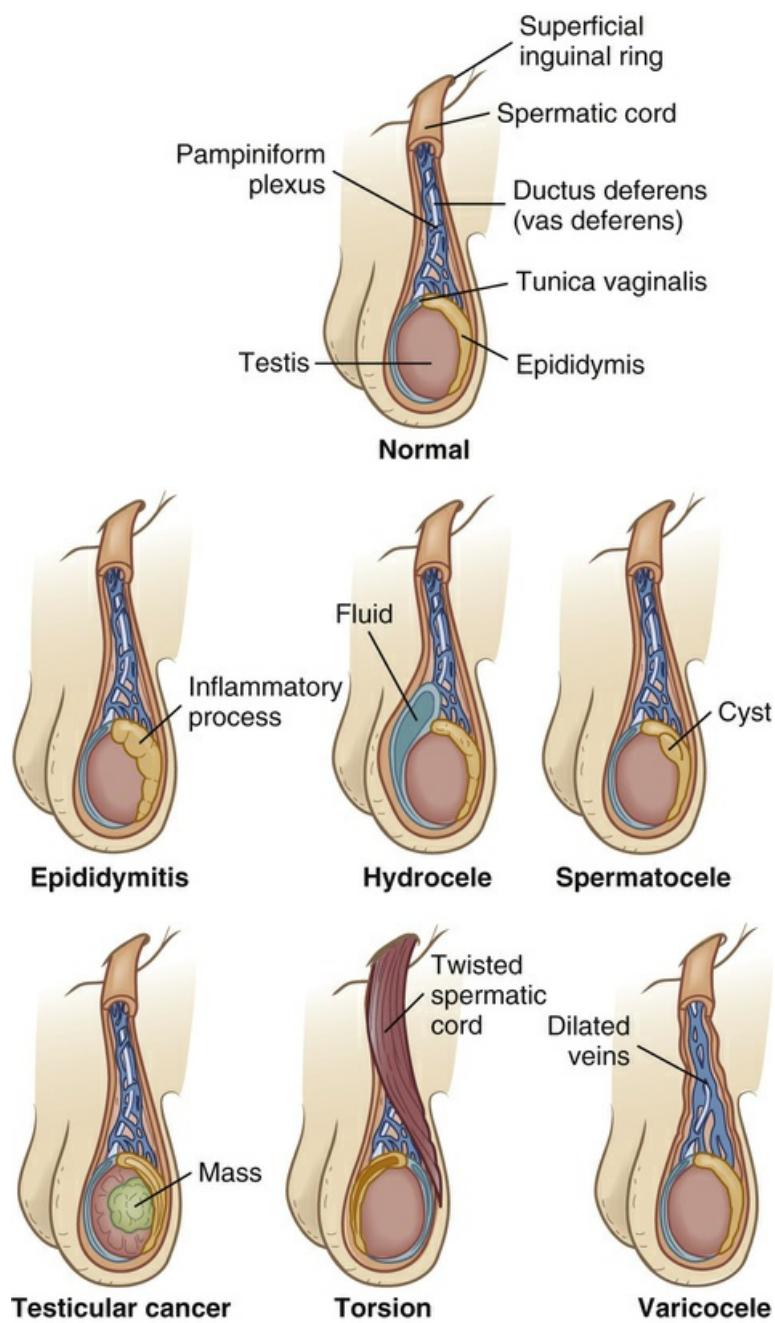

FIGURE 39-4 Scrotal masses. (From Lewis SL, Heitkemper MM, Dirksen SR, Bucher L: *Medical-surgical nursing: Assessment and management of clinical problems*, ed. 9, St. Louis, 2014, Mosby.)

Treatment, when indicated, is aspiration or surgical incision and drainage of the sac. A pressure dressing and a drain are left in place postoperatively. The patient will need to wear an athletic supporter for several weeks.

Varicocele

Dilation and clumping of the tributary vessels of the spermatic vein cause a painful swelling called *varicocele* (see [Figure 39-4](#)). Varicocele typically occurs on the left side of the scrotum from retrograde blood flow from the left renal vein. The discomfort is rarely enough to warrant surgery. If infertility has been a problem, surgical correction via injection of a sclerosing agent or ligation of the spermatic vein may improve fertility.

Nursing measures to help the patient cope with fatigue, weakness, and fever are appropriate, because these problems are commonly associated with urogenital infections and surgical procedures. Fluid intake should be increased to help prevent fluid deficit, reduce fever, increase urinary flow, and remove debris and bacteria. The patient is advised to wear scrotal support after any intervention.

Testicular Torsion

Testicular torsion is a twisting of the testes and spermatic cord (see [Figure 39-4](#)). It is commonly caused by elevated hormone levels in young adult men but can also be the result of scrotal trauma. Signs include sudden acute scrotal pain and an absence of the **cremasteric reflex** (retraction of the testicles when the inner thigh is stroked). Nausea and vomiting may also occur. A Doppler ultrasound scan may reveal diminished blood flow and confirm the diagnosis. To prevent testicular ischemia and necrosis, emergency surgery secures the testicle within the scrotum or possibly removes the testicle. Provide routine postoperative wound care, with emphasis on providing support and relieving anxieties concerning the patient's sexual self-image and future sexual performance.

Priapism

Priapism is a prolonged penile erection resulting in a large, hard, and painful penis, unrelated to sexual desire or activity. The cause can be neurologic, vascular, or the result of medications such as those designed to increase sexual performance. The most common disease that causes priapism is sickle cell disease, which causes a local accumulation of erythrocytes that result in engorgement of the corporal bodies. Circulation to the penis may be compromised, and voiding may be impaired while the penis remains erect, so prompt treatment is essential.

Treatment can be conservative, to promote dilation of vessels and relieve pressure. Sedation, bed rest, warm baths or enemas, and urinary catheterization may be prescribed. Aspiration of the corpora cavernosa with a large-bore needle or a shunting procedure to divert blood may be necessary to prevent ischemia of the penis. Provide supportive care to the patient, who not only may be in pain, but may be embarrassed by the loss of erectile control and fearful of the effect of this condition on future sexuality.

Peyronie Disease

Peyronie disease is a condition in which a plaque of nonelastic fibrous tissue develops in the tunica portion of the dorsal corpus cavernosa of the penis. The loss of elasticity in that section of the penis results in the inability to have a uniform erection of the penis. The penis will curve upward when erection occurs. Inability to penetrate the vagina may result, and the erection may become painful as well as embarrassing.

Treatment may include conservative measures such as local injections to dissolve the plaque. The size of the lesion and the level of ED may indicate a need for surgical intervention.

Benign Prostatic Hyperplasia

Etiology and Pathophysiology

Enlargement of the prostate, also known as benign prostatic hyperplasia (BPH), occurs when the prostate gland enlarges and extends into the bladder neck, causing obstruction of urine flow. An enlargement of the prostate often begins to develop before age 30 years. Fifty percent of men show evidence of enlargement by age 60 years, and 80% of men in their eighth decade develop BPH ([American Urological Association, 2010](#)).

Signs and Symptoms

BPH produces no symptoms until the growth becomes large enough to press against the urethra ([Figure 39-5](#)). Then the patient begins to experience difficulty in urinating, evidenced by a decrease in the caliber of the stream of urine, hesitancy, and dribbling after voiding. There may be frequency, nocturia, and urgency resulting from irritation of the distended bladder wall. In the later stages there may be complete obstruction of the urinary flow. Retention of urine (urinary stasis) is defined as more than 60 mL of residual urine after a void. Urinary tract infections can result from urinary stasis, because the retained urine acts as a medium for organism growth. Gradual dilation of the ureter (**hydroureter**) and kidneys (**hydronephrosis**) can occur. Nitrogen products can accumulate in the blood (**azotemia**) and cause renal failure if the urinary obstruction is not relieved. The American Urological Association has developed a tool to assess symptoms related to urinary obstruction, which aids in clarifying the severity of the problem ([American Urological Association, 2010](#)). The tool gives a numerical score to the severity of each symptom of urinary retention. The total numerical score is used to determine appropriate treatment options.

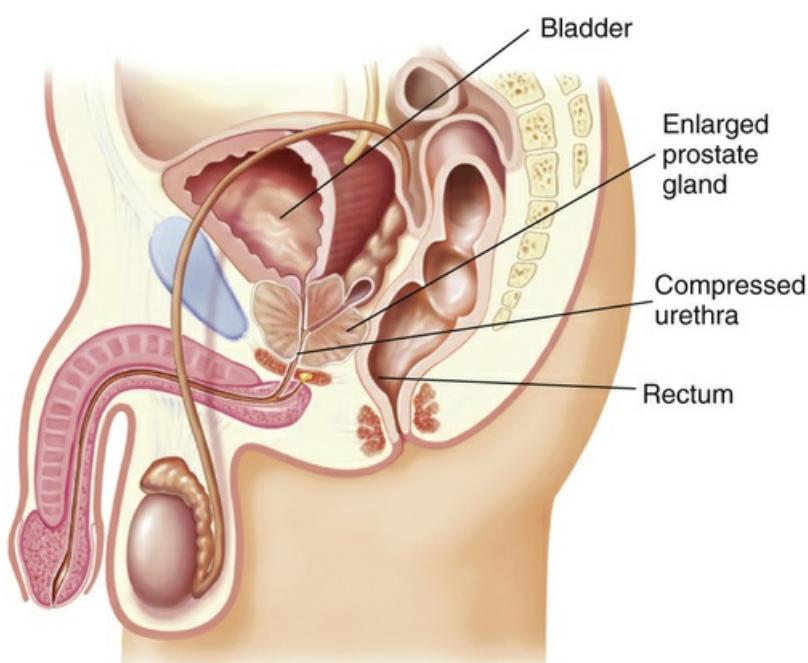

FIGURE 39-5 Benign prostatic hyperplasia. (From Lewis SL, Heitkemper MM, Dirksen SR et al: *Medical-surgical nursing: Assessment and management of clinical problems*, ed. 9, St. Louis, 2014, Mosby.)

Diagnosis

A digital rectal examination will reveal an enlarged prostate. The gold standard test for bladder outlet obstruction is increased bladder pressure relative to urinary flow. Pressure flow studies can be performed ([urodynamics](#)). An ultrasound after urination or catheterization to determine residual urine volume is also a helpful diagnostic aid. A transrectal ultrasound differentiates BPH from prostate cancer, and a serum creatinine level can rule out renal insufficiency.

Treatment

If the patient cannot void, an immediate catheterization will relieve the emergency problem, and follow-up care concerning the cause and severity of the prostate enlargement will then be completed.

Drug therapy.

Drug therapy includes:

- **Alpha-adrenergic blockers**, which promote relaxation of smooth muscle and reduce blood

pressure. Side effects of doxazosin (Cardura), terazosin (Hytrin), tamsulosin (Flomax), and alfuzosin (Uroxatral) include dizziness and orthostatic hypotension. These drugs offer prompt relief but may not reduce the prostate size. Silodosin (Rapaflo) also induces smooth muscle relaxation by selective action in the prostate, bladder base, prostatic capsule, and prostatic urethra. Because of reduced side effects, sometimes prazosin (Minipress) is prescribed off-label. However, it is not always efficacious (Deters, 2014).

- **5-Alpha-reductase inhibitors (ARIs)** are steroids and may take several months to work. Antiandrogen agents such as finasteride (Proscar) and dutasteride (Avodart) can decrease prostate size by reduced dihydrotestosterone (DHT) production. Side effects include decreased libido and increased breast size (**gynecomastia**). Finasteride has been approved for use to prevent prostate cancer in select patients when combined with doxazosin. Dutasteride is used alone or in combination with tamsulosin to reduce the conversion of testosterone to DHT, thus reducing symptoms (Deters, 2014).
- **PDE-5 enzyme inhibitors** are agents that inhibit the enzyme PDE-5, thus producing an increased vasodilation and inducing smooth muscle relaxation. Tadalafil (Cialis) requires sexual stimulation to activate the effect.
- Combination products recently have been emerging and have been shown to provide an improvement in symptoms and compliance. The most well-known of these is a combination of dutasteride and tamsulosin (Jalyn). This combination is indicated for BPH with an enlarged prostate.

Safety Alert

5-Alpha Reductase Inhibitors and Cancer

A warning has been issued by the Food and Drug Administration (FDA) that individuals taking 5-ARIs may be at an increased risk for developing high-grade prostate cancer (Drugs.com, 2014).

Herbal therapy.

Plant extracts such as saw palmetto (*Serenoa repens*) have been thought to relieve symptoms, although research has not proven their effectiveness and side effects may include an increase in blood pressure and gastrointestinal disturbances. Plant extracts should not be taken if the patient is receiving hormone replacement therapy. Research in the treatment of BPH is ongoing (Erlich, 2013).

Complementary and Alternative Therapy

Simple Lifestyle Changes for Benign Prostatic Hyperplasia

Urinating immediately when the urge occurs and going to the bathroom at every opportunity can relieve minor symptoms of BPH (Erlich, 2013).

Surgery.

Indications for surgical intervention include incontinence, hematuria, urinary retention, bladder stones, and urinary tract infections. Minimally invasive techniques such as balloon dilation, transurethral needle ablation, laser resection, and transurethral microwave thermotherapy are newer techniques that may help relieve symptoms. They are more effective than medications but less effective than surgery.

The most effective way to reduce symptoms is through surgery. This includes transurethral resection of the prostate (TURP), transurethral incision of the prostate (TUIP), laser photoselective vaporization of the prostate (PVP), and open prostatectomy. Review the surgical options that were presented by the health care provider to ensure that the patient has a clear understanding of treatment options (Table 39-3).

Table 39-3

Surgical Interventions for Male Urogenital Problems

TREATMENT	COMMENTS
Minimally Invasive Treatment (Outpatient Surgery)	
Transurethral microwave thermotherapy (TUMT)	Heats and coagulates prostate tissue via a transurethral probe. A urinary catheter may be left in place for 1 wk after treatment to facilitate passing of necrotic tissue and prevent urinary retention. Antibiotics, analgesics, and bladder antispasmodics are prescribed after the procedure.
Transurethral needle ablation (TUNA)	Places radiofrequency needles directly into the prostate to coagulate specific tissue areas. Hematuria may occur for 1 wk after this procedure.
High-intensity focused ultrasound (HIFU)	High-intensity, low-frequency ultrasound waves destroy prostate tissue. Has been found effective in treatment of BPH, but continued research concerning after effects are ongoing.
Surgery	
Open prostatectomy	Involves an external abdominal incision that allows complete visualization of prostate tissue. There is risk for infection and erectile dysfunction, postoperative pain, and a longer recovery period.
Suprapubic prostatectomy	Enters via the bladder.
Retropubic prostatectomy	Does not enter the bladder.
Perineal prostatectomy	The removal of the prostate via an incision in the perineum; has high risk for postoperative wound contamination, incontinence, and impotence.
Transurethral resection of the prostate (TURP)	TURP is the gold standard of treatment for BPH and is performed under spinal anesthesia. A resectoscope is inserted into the urethra to excise and cauterize obstructive prostate tissue. A large three-way catheter is inserted to provide hemostasis and allow urinary drainage. May be performed as outpatient surgery at many facilities.
Transurethral incision of the prostate (TUIP)	The TUIP incises the prostate. May be performed as outpatient surgery at many facilities.
Laser prostatectomy	A modified TURP; uses a laser beam to destroy prostate tissue. Minimal postoperative bleeding occurs, but a catheter may be required for 1 wk postoperatively to prevent urinary retention from edema.
Transurethral electrovaporization of the prostate (TUVP)	Electrosurgical vaporization and desiccation destroy prostate tissue. Complications include hematuria and retrograde ejaculation.
Transurethral photoselective vaporization of prostate (PVP)	Uses a green light laser beam to coagulate prostate tissue.
Urethral stent	A metallic stent is placed in the urethra to hold the urethra open. This is usually a temporary measure, because displacement is common.
Laparoscopic radical prostatectomy	Provides better visualization and less postoperative complications and has a shorter hospital stay.

Serum PSA is a protein-specific antigen that is produced by the prostate tissue and is elevated in BPH, cancer of the prostate, and prostatitis and after prostate biopsy. Interpretation of PSA levels should take into consideration any diagnostic procedures involving the prostate gland. An elevated PSA is therefore not **always** indicative of cancer. The value of routine PSA screening is currently under evaluation.

Think Critically

A patient has been experiencing increasing difficulty in emptying his bladder; he is diagnosed with BPH. His provider has recommended prostate surgery, but he is reluctant to have surgery. What other options are available to this patient that might prevent further organ damage?

Nursing Management

Preoperative care.

Urinary drainage is accomplished by insertion of a catheter using sterile technique. If the obstruction is severe, a urologist may insert a special rigid catheter. A high fluid intake is encouraged, and antibiotics are routinely prescribed. You should interview the patient to assess the understanding of the procedure to be performed and the impact on his lifestyle, self-image, and sexual function.

Preoperative teaching includes deep-breathing exercises; range-of-motion leg exercises; the general preoperative and postoperative routine; and explanation of care for the incision, catheters, irrigation system, and drains (see [Chapters 4 and 5](#)).

Postoperative care.

The postoperative nursing care of the patient varies according to the type of prostate surgery performed ([Figure 39-6](#)). The general principles of postoperative nursing care that apply to all patients having major surgery are necessary for the patient undergoing a prostatectomy. Potential postoperative complications are bleeding, urinary incontinence, and bladder spasms. Because hemorrhage always is a danger, vital signs are taken per agency protocol, then every 4 hours. The patient is monitored for pallor and rising pulse, which, along with blood pressure changes, may indicate excessive bleeding and shock. A high-fiber diet and a stool softener may be prescribed to prevent straining, which increases intra-abdominal pressure and can cause further bleeding.

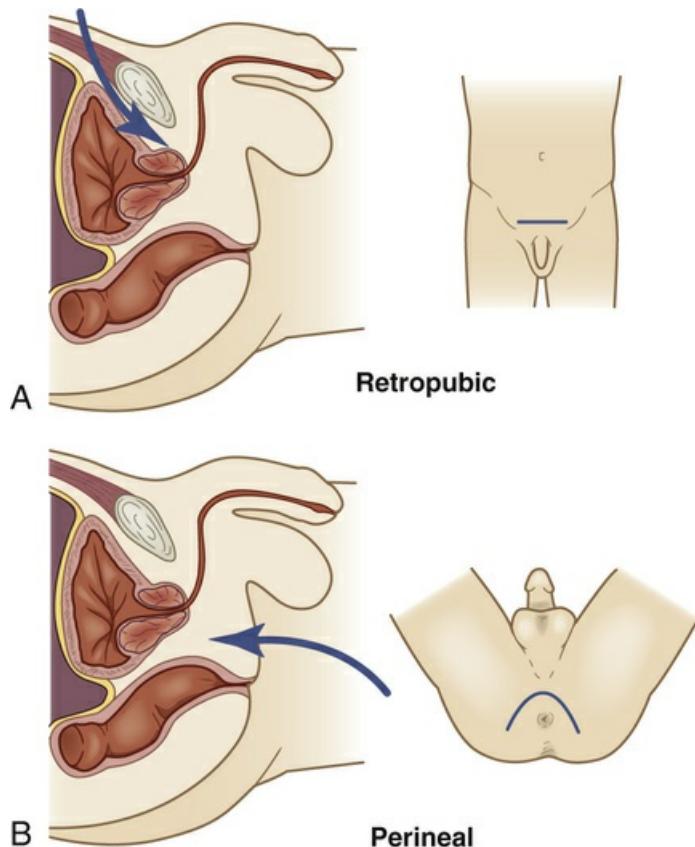

FIGURE 39-6 Two approaches to perform a prostatectomy. **A**, The retropubic approach involves a midline abdominal incision. **B**, The perineal approach involves an incision between the scrotum and anus. (From Lewis SL, Heitkemper MM, Dirksen SR, Bucher L: *Medical-surgical nursing: Assessment and management of clinical problems*, ed. 9, St. Louis, 2014, Mosby.)

Patients with suprapubic prostatectomy and transurethral resection of the prostate (TURP) will return from surgery with a three-way urethral catheter connected to continuous bladder irrigation with sterile normal saline (Figure 39-7). Blood-tinged urine is normal for the first few days after the surgery. To decrease clot formation, the bladder irrigation flow rate is adjusted to keep the urine diluted to a reddish pink, clearing to a pink tinge within 48 hours. Some pieces of tissue and small clots may be seen in the drainage. Additional intermittent irrigation with 20 to 30 mL of normal saline may be needed to clear the catheter of obstruction ([Nursing Care Plan 39-1](#)). Hemorrhage is a possible complication and occurs mostly in the first 24 hours. Strict sterile technique must be used when irrigating the bladder, and the catheter should be connected to a closed drainage system to prevent infection.

Clinical Cues

When caring for a bladder irrigation system:

- Use sterile normal saline unless otherwise ordered.
- Monitor rate of irrigation.
- Monitor and record intake and output.
- Record the amount of irrigation fluid instilled and the amount returned. The difference equals the urine output.
- Check drainage tubes for kinks and clots.
- Observe for signs of bladder spasms and medicate promptly as needed.

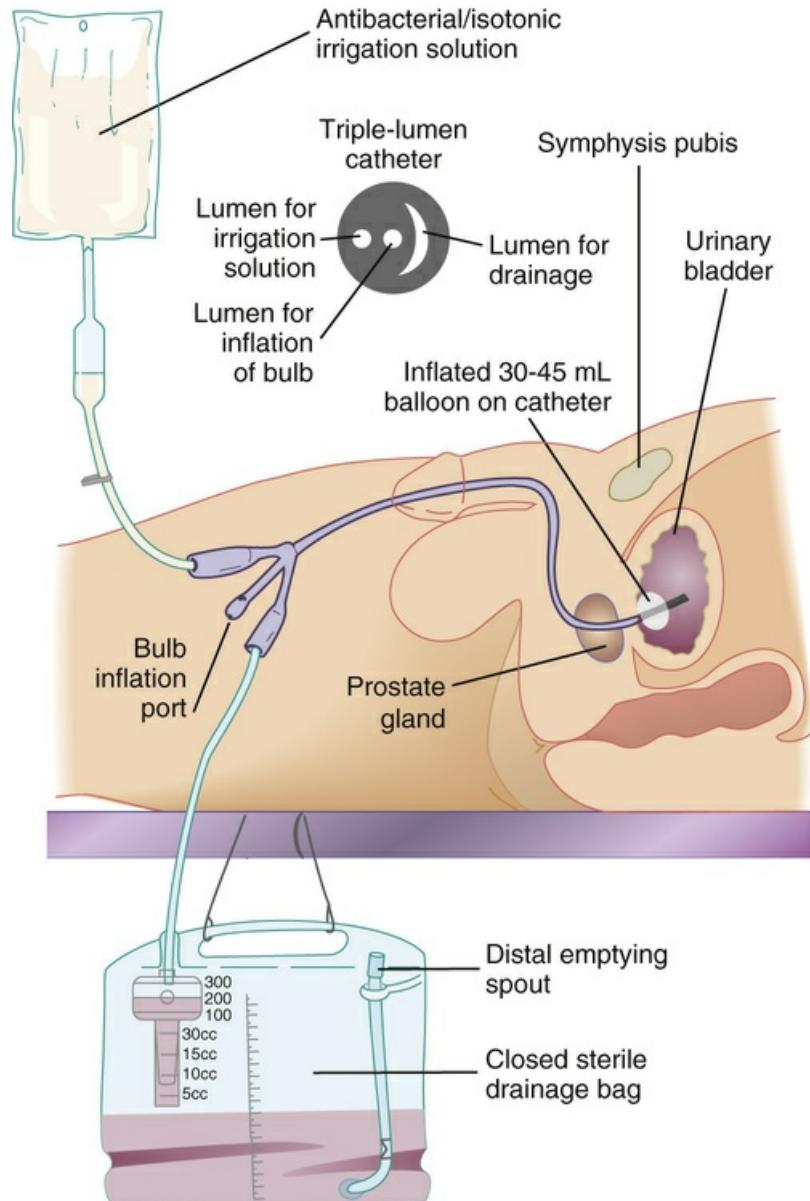

FIGURE 39-7 Continuous bladder irrigation system. (From Black JM, Hawks JH: *Medical-surgical nursing: Clinical management for positive outcomes*, ed. 8, Philadelphia, 2009, Saunders.)

* Nursing Care Plan 39-1

Care of a Patient After Prostatectomy

Scenario

A 65-year-old man is admitted to the postoperative unit after a prostatectomy. His vital signs are stable, and a bladder irrigation system is set up at the bedside. The patient is awake and oriented, and the provider's orders include diet as tolerated.

Problem Statement/Nursing Diagnosis

Potential fluid volume deficit/Risk for deficient fluid volume secondary to postoperative hemorrhage and limited fluid intake.

Supporting Assessment Data

Objective: Transurethral prostatectomy.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient evidences normal fluid volume and stable vital signs.	Monitor vital signs.	A change in vital signs can indicate fluid deficit.	Vital signs stable.
	Monitor intake and output.	Encouraging oral fluids as tolerated and recording amount and type of output enable identification of fluid volume status.	Intake >3500 mL; output >3200 mL. Taking sufficient oral fluids.
Patient evidences clear to pink urinary drainage with no clots.	Perform closed bladder irrigation as prescribed.	Irrigation removes accumulating clots that can obstruct urine outflow and precipitate further hemorrhage.	Irrigation outflow pink with few clots.
	Administer IV fluids as prescribed.	IV therapy can help maintain fluid balance.	IV infusion at 150 mL/hr.

IV, Intravenous.

Problem Statement/Nursing Diagnosis

Insufficient knowledge/Deficient knowledge related to lack of knowledge regarding self-care after discharge.

Supporting Assessment Data

Subjective: "No, I've never had to do any wound care before. What do I have to do?"

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will list signs of infection; explain need for increased fluid intake; demonstrate care of wounds, dressings, and catheter; and follow medication regimen.	Instruct to report signs of infection: fever, chills, malaise, increased pain, purulent drainage, excessive swelling.	Finding infection early means early treatment.	Able to provide accurate feedback of all instructions.
	Instruct to avoid heavy lifting, driving, and sexual activity until permitted by urologist.	Heavy lifting or sexual activity may cause disruption of tissue and bleeding.	States he understands and will comply with restrictions.
	Instruct to report new onset of burning on urination or cloudy urine.	Burning on urination or cloudy urine may indicate bladder infection.	No burning on urination; no cloudy urine.
	Explain what each medication is for and when and how to take it.	Helps with compliance with medication regimen.	States understands when and how to take the medications.
	Provide written information about signs and symptoms of urethral stricture or infection and instruct to report these.	Written instructions can be reviewed at home and help to get quick attention for problems.	Given written instructions regarding complications and what to report to surgeon.

Problem Statement/Nursing Diagnosis

Anxiety/Sexual dysfunction, fear of related to inability to achieve erection.

Supporting Assessment Data

Subjective data: "Do you think my wife will leave me if I can no longer have an erection to meet her sexual needs?"

Objective data: Prostatectomy 6/25.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will discuss concerns before discharge.	Encourage verbalization of problems and concerns.	Verbalization of concerns helps with identifying solutions.	Verbalizes concern about the possibility of not being able to obtain an erection.
	Provide information on alternative ways to achieve erection.	Gives the patient useful information in case of need.	Provided with information about the alternate ways to achieve erection.
Patient will discuss concerns with his spouse before discharge.	Counsel in other ways to achieve intimacy. Include spouse or significant other in discussions.	Addressing individual needs of patient encourages learning and retention.	Agrees to include spouse in discussions regarding his sexual concerns.
	Assist to make plan to meet sexual needs.	Provides tools to cope with sexual problems.	—

Critical Thinking Questions

- What are the priority nursing interventions if the nurse notices that the urinary outflow is less than the irrigation input after bladder irrigation?
- Why is it important to attend to complaints of pain from bladder spasms as soon as possible? What medication is generally used for this type of pain?

Persistent bleeding turning the urine darker than cherry red or bright red, or viscous drainage with many clots, should be reported immediately to the surgeon. Traction may be applied to the catheter to supply pressure (**tamponade**) to prevent excessive bleeding. The surgeon does this by pulling against the balloon and then taping the catheter to the thigh or abdomen. This pressure may cause the patient to have a sensation of a continuous need to void. Check frequently to see that the catheter and tubing are not kinked and that outflow is appropriate. Irrigation is continued for 2 to 3 days. The patient may have some urinary frequency and burning after catheter use is discontinued. Some blood in the urine may occur for several more days.

The patient who has had a suprapubic prostatectomy will have a suprapubic catheter in addition

to a urethral catheter. Each catheter is attached to a separate sterile drainage system. After the urethral catheter is removed (sometime after the third day), the suprapubic catheter is clamped, and the patient attempts to void. Residual urine is measured afterward by unclamping the suprapubic catheter. When there is no more than 60 mL of residual urine after voiding, the suprapubic catheter is removed. Dribbling of urine often occurs after prostatectomy because of decreased sphincter tone but usually stops within about 6 months. Patients who experience incontinence are taught perineal muscle strengthening (Kegel) exercises for this problem and are given instruction in bladder training (see [Chapters 33](#) and [34](#)). Teaching begins 24 to 48 hours after surgery. Kegel exercises and coping strategies should be taught to enable early return to a normal lifestyle.

When the urethral or suprapubic catheter is removed, the patient must be carefully monitored for ability to void. Intake and output are tracked closely. Any difficulty in voiding within 6 hours after removal must be reported to the surgeon promptly, because a distended bladder may cause bleeding.

Monitor the incisional dressings and changes them as often as necessary to keep the patient dry and comfortable. Urine is very irritating to the skin, and any area that is exposed to urine drainage is thoroughly cleansed before a new dressing is applied.

Prophylactic antimicrobials and analgesics are administered in the early postoperative period. Bladder spasms often are a problem after TURP or suprapubic prostatectomy. Before giving medication, check to see that the tubing is not kinked and the catheter is draining well, because obstruction can cause bladder spasm. Abdominal distention may be a sign of catheter obstruction as well. A patient who has had a radical procedure may have a patient-controlled analgesia pump to control pain.

Clinical Cues

Belladonna and opium (B&O) rectal suppositories are effective for bladder spasms if they are given when the spasms first begin. Relaxation techniques and an anticholinergic drug, such as oxybutynin (Ditropan), may be used to help relieve bladder spasms.

Discharge teaching includes care of the catheter, management of incontinence, maintaining hydration, preventing constipation, observing for signs of infection, and management of anxiety related to impaired sexual function and self-image (see [Patient Teaching](#) on p. 939). Retrograde ejaculation (semen discharged into the bladder) may cause the urine to appear cloudy. Frequent planned urination and avoidance of irritating foods such as citrus, caffeine-containing products, and alcohol should be initiated. The patient should be taught to monitor output and contact the health care provider if unable to void. BPH can recur, so annual digital rectal examinations should be continued (see [Nursing Care Plan 39-1](#)).

Inflammations and Infections of the Male Reproductive Tract

Many of the inflammations and infections affecting the male reproductive system are similar to those of the female reproductive system in cause and effect. For example, urethritis in the men and women can be caused by common pyogenic and colonic bacteria and by *Neisseria gonorrhoeae*. Men also can be infected with *Trichomonas vaginalis* or *Chlamydia*, which are transmitted by sexual contact. The sexual partners may continue to reinfect each other until both are treated simultaneously.

Nonspecific genitourinary infections in men—including nongonococcal urethritis (NGU)—may be caused by various organisms, but these infections present substantially the same clinical picture. Among the symptoms of nonspecific urethritis are mucopurulent discharge from the urethra, painful urination of varying degrees of severity, and the occasional appearance of blood in the urine. A microscopic examination of a smear from urethral secretions may not show any specific organisms, but there may be an excessive number of white cells.

Epididymitis

Epididymitis is an inflammation of the epididymis and may result from an infection of the prostate or urinary tract infection. A patient with epididymitis experiences groin pain and swelling and pain in the scrotum. In men younger than 35 years, the major cause of epididymitis is *Chlamydia*.

trachomatis, a sexually transmitted organism. Symptoms include scrotal pain, swelling, induration of the epididymis, and eventual edema of the scrotal wall. The adjacent testicle may become involved. The urine may contain pus (pyuria), and chills and fever may follow. Antibiotics, ice packs, analgesics, sitz baths, and elevation of the scrotum are the prescribed treatment protocol. A local anesthetic may be injected into the spermatic cord to manage pain.

Orchitis

Orchitis is inflammation of the testicle and may affect one or both testes. It may be caused by local or systemic infection (viral or bacterial) or by trauma. Bilateral orchitis is serious and often causes sterility. **Mumps orchitis** occurs in about 20% of adult men who contract mumps. Gamma globulin usually is given to decrease the possibility or severity of mumps orchitis. The symptoms and treatment parallel those of epididymitis.

Prostatitis

Prostatitis is an inflammation of the prostate that occurs from an infectious agent or other causes. The National Institutes of Health (NIH) uses the following classification system:

- **Type I: Acute bacterial prostatitis** with recovery of bacteria from fluid and signs of illness such as fever
- **Type II: Chronic bacterial prostatitis** with recovery of bacteria from fluid and no signs of systemic illness
- **Type III: Nonbacterial prostatitis/chronic pelvic pain syndrome** with recovery of leukocytes; microscopic purulence of prostate fluid is present but few or no bacteria are recovered
- **Type IV: Asymptomatic inflammatory prostatitis (prostatedynia)** with no bacteria or leukocytes in prostate fluid but persistent symptoms of prostate discomfort, including poor urinary flow, frequency, and dysuria ([Merck Manual, 2014](#))

Symptoms include recurrent urinary infection, pelvic pain, and sexual dysfunction and are often mistaken for BPH. Because blood PSA levels are often elevated in prostatitis, misdiagnosis of prostate cancer can occur. Prostate massage, useful for diagnosis, presents a risk for bacteremia. The various types of prostatitis can be diagnosed with a segmented culture of the initial stream urine, midstream urine, prostate fluid before and after massage, and postmassage urine specimen. Treatment includes bed rest, analgesia, bladder sedatives, sitz baths, and stool softeners to prevent straining. Antibiotics may be prescribed according to culture and sensitivity laboratory findings.

Antibiotics diffuse poorly into the prostatic fluid, so chronic prostatitis is commonly treated with alpha-adrenergic blockers (tamsulosin); fluoroquinolones may be prescribed. The patient is taught to recognize symptoms of urinary tract infection and to reduce retention of prostatic fluid by ejaculation. The patient should be taught to avoid foods that increase prostatic secretions, such as alcohol, chocolate, tea, and spices. Follow-up care to detect reinfection is essential.

Cancer of the Male Reproductive Tract

Penile Cancer

Cancer of the penis is rare, occurring mostly in men with human papillomavirus infections or who were not circumcised.

Cultural Considerations

Incidence and Mortality Rate of Penile Cancer

Penile cancer is very rare in the United States. Testicular cancer is more common in whites; prostate cancer occurs most frequently, and has a high mortality rate, among African American men.

A nontender nodule may appear on the penis, and biopsy will show a squamous cell-type carcinoma. Laser resection of the lesion is the treatment of choice unless the cancer has spread. Radical resection of the penis followed by radiation and chemotherapy may be required. The shaft of the resected penis can respond to sexual stimulation and enable orgasm and ejaculation. After a

total removal of the penis (penectomy) the patient may experience orgasm via stimulation of the scrotum and perineal area.

Testicular Cancer

Testicular cancer occurs most commonly in men ages 15 to 40 years and is the leading cause of cancer death in men 25 to 35 years of age. Studies have identified a gene mutation that may predispose a man to develop a type  of familial testicular cancer ([American Cancer Society, 2015](#)). The 5-year survival rate for testicular cancer is greater than 95% ([American Cancer Society, 2015](#)).

Men most at risk for testicular cancer are those who have had an undescended or partially descended testicle. Men who were exposed to diethylstilbestrol (DES) in utero also may be at high risk for testicular cancer, but evidence-based research is lacking. All males between ages 15 and 40 years should practice testicular self-examination on a monthly basis. Cancer symptoms appear slowly and involve painless enlargement of the testes, backache, and weight loss.

Health Promotion

Testicular Self-Examination

- Testicular self-examination should be performed monthly.
- Perform after bathing when scrotal skin is relaxed.
- Roll each testicle between thumb and fingers.
- Report lumps to health care provider.

If a mass is found and thought to be malignant, diagnostic tests for tumor marker proteins such as elevated levels of AFP, beta-HCG, alkaline phosphatase, and lactate dehydrogenase are obtained to confirm diagnosis. Computed tomography (CT) scans and/or ultrasound should be performed to detect sites of testicular mass. Testicular cancer spreads rapidly via lymph and blood vessels. A microscopic tissue analysis is performed after surgical removal of the mass for definitive diagnosis.

There are three stages for classifying the malignancy of testicular cancer. In **stage I**, the tumor is confined to the affected testis. In **stage II**, malignant cells have spread to the regional lymph nodes, usually on the same side as the affected testis. In **stage III**, there is metastasis to other organs, such as the lungs and liver.

If the testicular tumor is limited to the scrotal sac and there is no metastasis, a laparoscopic surgical removal of the testis ([orchietomy](#)) may be all that is necessary to cure the patient of his disease. A gel prosthesis can be implanted. Care is taken to preserve the nerves associated with ejaculation. The nursing care focuses on teaching and providing psychological support. Ice bags and scrotal support provide comfort, and the importance of follow-up care is stressed. Removal of only one testis will not affect the patient's ability to produce the male hormone testosterone or render him impotent, because the other testis can carry on adequate testicular function.

Further treatment for stage II testicular cancer may include radiation. Chemotherapy is reserved for advanced stages of cancer and results in a high percentage of complete remission. See [Chapter 8](#) for a detailed discussion of radiation and chemotherapy in the care of cancer patients.

Some men view an orchietomy as a loss of manhood. You can be instrumental in assisting the patient to accept the procedure. Time for questions and discussion of concerns should be provided for the patient and his sexual partner. Sperm banking before surgery is an option for patients who may face chemotherapy. Continued follow-up care is essential.

Prostate Cancer

Carcinoma of the prostate is the second most common cause of cancer deaths in men (after lung cancer). The American Cancer Society predicted approximately 220,800 new cases for 2015 in the United States, with 27,540 men dying of prostate cancer ([American Cancer Society, 2015](#)).

Carcinoma of the prostate is usually a slow-growing cancer that is dependent on the hormone androgen. Some studies have identified an association of the prostate cancer antigen gene (*PCA3*),

which can be measured via urinary assay as a significant risk factor. Studies are in progress to determine the effect of chemotherapy on prevention of prostate cancer (ACS, 2014). Both finasteride and dutasteride have been found to decrease the risk of prostate cancer by 25%. However, further studies have found that finasteride has no effect on long-term survival, and neither of these drugs are approved for cancer prevention use (ACS, 2014).

Clinical symptoms and screening.

If prostate cancer is detected early, the possibility of cure is high. Early detection by digital rectal examination can reveal a hardened lobe of prostate early in the course of the disease. Routine PSA screening of young healthy men is not recommended by the American Cancer Society; the United States Preventative Task Force has recommended against prostate screening (USPSTF, 2012), and the National Comprehensive Cancer Network recommends only risk-stratified screening (NCCN, 2014). Men with prostate cancer often exhibit some sexual dysfunction.

Think Critically

What sort of psychological care would the patient undergoing a prostatic biopsy need from the nurse? What might be some of the patient's concerns?

An elevated PSA (about 4 ng/mL) may indicate prostate pathology but is not diagnostic for prostate cancer. The **PSA velocity** is a trend in PSA levels over time that may indicate a need for further tests to diagnose prostate cancer. A transrectal ultrasound may be performed, and bones may be scanned to detect metastasis. A ProstaScint scan combined with CT or magnetic resonance imaging (MRI) scans can detect prostate cancer cells when the PSA levels are low. A urine test to detect prostate cancer, Progensa (PCA-3) assay, is closely related to biopsy outcomes. Transrectal, transurethral, and transperineal prostate biopsy and tissue analyses determine the severity or extent of prostate cancer.

Treatment and nursing care.

Because prostate cancer is relatively slow growing, conservative treatment may involve monitoring and follow-up care. Annual digital rectal examinations are performed, and PSA levels are monitored in high-risk patients. When surgical therapy is indicated, a laparoscopic radical prostatectomy is considered the most effective treatment for long-term survival before metastasis occurs. Other treatment options are listed in Table 39-4. In 2011 a monoclonal antibody, denosumab, received FDA approval for treatment of bone loss (osteoporosis) in men who have had androgen deprivation therapy for prostate cancer (NCI, 2013).

Table 39-4
Treatment Options for Prostate Cancer

TREATMENT	COMMENTS
Radical prostatectomy	The prostate gland, seminal vesicles, and portions of the neck of the bladder are removed. ED and incontinence are long-term complications. A laparoscopic approach provides fewer complications and shorter hospital stay. Robotic prostatectomy reduces risk of incontinence and impotence.
Cryosurgery	A freezing technique destroys prostate tissue. Complications include urethral damage, ED, and incontinence.
Radiation therapy	May be prescribed when the patient is not a candidate for surgery or may be offered in combination with surgery and hormone therapy.
External beam radiation	Most popular form of radiation therapy, given weekly on an outpatient basis for 2 mo. Side effects can include skin irritation, GI cramping and bleeding, ED, and bone marrow suppression. Cure rates for patients with localized cancer are comparable to radical prostatectomy.
Brachytherapy	The implantation of radioactive seeds into the prostate gland. It may be offered in combination with external beam irradiation.
Hormone therapy	Designed to reduce androgens. Leuproreotide (Lupron, Viadur), goserelin (Zoladex), and triptorelin (Trelstar) are common drugs used; produces a chemical castration.
Chemotherapy	Used for hormone-resistant cancer or late-stage cancer. The prostate has limited response to chemotherapy.
Bisphosphonates	Reduce bone complications in advanced stages of prostate cancer. Drugs may include zoledronic acid (Zometa), risedronate (Actonel), etidronate (Didronel), or alendronate (Fosamax).

ED, Erectile dysfunction; GI, gastrointestinal.

A multidisciplinary approach integrates surgery, radiation, and androgen restriction. After surgery, PSA levels are monitored; a decrease may indicate treatment success. In the early stages, radiation therapy may be the treatment of choice. Gamma teletherapy (external) and brachytherapy (internal) are used for cancer of the prostate and provide greater preservation of sexual ability.

Chapter 8 presents a detailed discussion concerning care of patients receiving radiation and chemotherapy. Hormonal therapy is designed to suppress androgen stimulation of the prostate by decreasing plasma testosterone. Removal of the testes may be performed to cause prostate atrophy.

An LH-releasing hormone (LHRH) agonist such as leuprolide or goserelin or androgen agents such as flutamide (Eulexin) suppress androgen and may be used in combination with radiation therapy. Provide a sensitive, caring approach to the patient and family to help them cope with the diagnosis and make informed choices. Preoperative care involves restoration of urinary drainage, prevention of urinary tract infection, and understanding the options for treatment and their effect on sexual function. Complications of surgery may include bleeding, catheter obstruction, and sexual dysfunction. Impotence or retrograde ejaculation may occur. Options to enable erections and improve sexual function via prosthetic devices or medication should be discussed with the patient. The nursing care of a patient with a prostatectomy includes reducing anxiety, relieving discomfort, maintaining fluid balance, monitoring for bleeding or infection, catheter care, and teaching the patient self-care and the need for continued follow-up care.

Older Adult Care Points

For older adults undergoing chemotherapy or radiation therapy:

- Monitor for infections.
- Promote assisted ambulation.
- Institute fall precautions.
- Encourage use of an incentive spirometer.
- Minimize pain.
- Reorient to environment as needed.

Community Care

Nurses in the community can be instrumental in teaching and promoting testicular self-examination in men between ages 15 and 40 years. Educating all men older than 40 years about prostate cancer screening benefits and drawbacks will allow them to make a personal decision regarding PSA testing.

Patient Teaching

Discharge Instructions for a Patient After a Prostatectomy

The patient is instructed regarding the following points:

- Drink 12 to 14 glasses of water during the day to keep the urine flowing freely.
- Do not lift any object weighing more than 8 lb.
- For 2 to 3 weeks after surgery (depending on provider's instructions), avoid strenuous activities.
- If blood is noticed in the urine, lie down and rest; drink more fluids and call the surgeon if the bleeding continues.
- Depending on the type of employment, it may be possible to return to work within 2 to 4 weeks. Consult the surgeon.
- Keep the catheter clean; cleanse the catheter and around the meatus daily with soap and water and rinse thoroughly.
- Report any cloudiness or foul smell in the urine.
- Report signs of infection such as fever, chills, or purulent wound drainage.
- After catheter removal, dribbling of urine may occur for up to 6 months. The problem usually will resolve. Perineal strengthening exercises help.
- After healing is complete, report any changes in the force or size of the urine stream to the surgeon.
- Report for annual checkups to detect recurrence of tissue growth or the development of prostate cancer.

Nurses should be sufficiently knowledgeable about BPH and prostate cancer to direct patients toward treatment options and reliable information.

Nurses in long-term care facilities must be watchful for urinary obstruction in older adult male residents. Alert men should be questioned regularly about problems with urination; men with cognitive impairment who do not have a normal urinary stream should be placed on intake and output recording to detect any problems with urinary obstruction. Palpation just above the symphysis pubis may reveal a distended bladder.

All nurses can be instrumental in teaching perineal muscle (Kegel) exercises to decrease the incidence of incontinence. Incontinence is one of the prime causes of loss of self-esteem in older adults and can be corrected in many cases. Correcting incontinence also greatly decreases the nursing care time that needs to be spent with the patient, thereby cutting health care costs.

Home care nurses supervise or assist with dressing changes for patients after radical surgery, monitor side effects and complications in patients undergoing radiation, teach self-care, and provide psychosocial support for patients with prostate cancer and sexual dysfunction. Collaboration with the provider, social worker, and community agencies can provide avenues of help for these patients.

Nurses in the community can assist patients who are experiencing ED by including assessment for this problem when working with male patients. Knowledge about treatment options, a matter-of-fact optimistic attitude, and a comfortable manner when speaking about this topic can provide hope and guidance. Sometimes ED is brought to light when speaking with the spouse of an older patient. Many times a satisfying sexual life can be reinstated for these couples, providing added fulfillment and joy in the later years.

Get Ready for the NCLEX® Examination!

Key Points

- Anxiety, depression, various medications, and certain diseases can contribute to ED.
- Complications of treatment for ED can include priapism, which requires prompt intervention.
- Testicular cancer occurs most commonly in men ages 15 to 40 years, and the 5-year survival rate is 95%.
- Nurses can be instrumental in teaching and promoting use of monthly testicular self-examination and monitoring for prostate cancer by digital rectal examination and PSA testing.
- Serum PSA levels become elevated when prostate disease is present (such as BPH or prostatitis) and therefore may not be a reliable marker indicating cancer.
- The medical treatment of BPH involves medications that relax the bladder and urethra (alpha blockers) and reduce prostate tissue through reduced DHT production (5-ARIs).
- Indications for surgical intervention for BPH include urinary retention, gross hematuria, bladder stones, and urinary tract infections.
- Nursing care is planned based on the patient's age, educational level, degree of comfort in discussing reproductive problems, and culture.
- Patient education concerning disorders of the reproductive tract should include information about the effects on sexual activity.
- Older adults who have consistently participated in intercourse throughout adult life have the best chance of maintaining this capability into old age.
- Nurses in long-term care facilities must watch for signs of urinary obstruction in older men.

Additional Learning Resources

Review Questions for the NCLEX® Examination

1. A patient is discharged after having a vasectomy. Which statement by the patient would indicate a need for further teaching?

1. "I don't want any more children."
2. "Now I can go home and have sex without fear of impregnating my wife."
3. "There is a possibility that this procedure can be reversed in the future."
4. "I should use ice packs to the scrotum after surgery to reduce swelling."

NCLEX Client Need: Physiological Integrity: Reduction of Risk Potential

2. A 22-year-old man complains of sudden acute scrotal pain. Initial examination reveals absence of the cremasteric reflex. Doppler ultrasound reveals a diminished blood flow. This condition would most likely be:

1. varicocele.
2. testicular torsion.
3. hydrocele.
4. priapism.

NCLEX Client Need: Health Promotion and Maintenance

3. A 25-year-old African American man was hospitalized for a prolonged penile erection unrelated to sexual desire or activity. A likely cause would be:

1. diabetes mellitus.
2. sickle cell disease.
3. hemophilia.
4. urinary infection.

NCLEX Client Need: Health Promotion and Maintenance

4. A post-prostatectomy patient expresses concerns regarding his ability to have intimate relations with his wife. The nurse identifies a possible sexual dysfunction. Priority nursing interventions would be geared toward which of the following nursing goals?

1. Identify signs and symptoms of infection.
2. Facilitate verbalization of personal concerns with his partner.
3. Demonstrate good aseptic wound care.
4. Facilitate development of alternative coping strategies.

NCLEX Client Need: Physiological Integrity: Physiological Adaptation

5. A 65-year-old man complains of difficulty urinating, described as decreased caliber of the urine stream. He also has accompanying hesitancy, dribbling, and urgency. A digital rectal examination reveals an enlarged prostate. Which nursing intervention(s) would be appropriate? (*Select all that*

apply.)

1. Teach to decrease caffeine and artificial sweeteners.
2. Teach to limit spicy foods and alcohol intake.
3. Apply a condom catheter.
4. Restrict fluid intake.
5. Plan a timed voiding schedule.

NCLEX Client Need: Physiological Integrity: Basic Care and Comfort

6. A 30-year-old white male presents to the clinic for an annual examination. While there he states, "I have a hard lump on my testicle. I just noticed it recently and I think it's because I took up bike riding. I will have the doctor check it the next time I come in if it's still there." What should the nurse tell him?

1. "That's probably a good plan. Most testicular lumps are not cancer and you can always come back sooner if it does not go away."
2. "The doctor should look at it now. Most testicular lumps are cancerous and we can begin treatment right away."
3. "The doctor should check that lump today. Most testicular lumps are benign, but we do not want to take a risk."
4. "Yes. I think the doctor is running late anyway, and you should make an appointment with the doctor because that is an add-on problem, and this is a prevention visit."

NCLEX Client Need: Physiological Integrity: Reduction of Risk Potential

7. A nurse is taking care of a 40-year-old Hispanic man who had a bilateral orchiectomy. Clinical interviews with the patient confirm mounting concerns regarding his "manhood." The nurse would effectively approach the patient's disturbance in body image by:

1. establishing eye contact.
2. demonstrating sensitivity to nonverbal cues.
3. asking specific questions.

4. involving nonessential members of the family.

NCLEX Client Need: Psychosocial Integrity

8. A 40-year-old man comes into the clinic and asks for a prostate examination and a PSA test. He states, "I know that prostate cancer is the most common cancer in men. I want to start getting screened now and then annually. Screening is the best prevention." What should the nurse tell him?

1. "Screening for prostate cancer can begin at age 45 years; depending on the results, a screening prevention plan is devised based on risk."
2. "Oh you do not need to worry now. Prostate screening begins at age 50 years and then continues annually."
3. "Prostate screening is done at the same time as your colon cancer screening and begins by age 50 years."
4. "We only check PSA levels now. Examinations have been found to be unreliable."

NCLEX Client Need: Physiological Integrity: Reduction of Risk Potential

9. A patient who had TURP complains of increasing bladder spasms. Which is an appropriate initial nursing action?

1. Medicate with a B&O suppository.
2. Check the urinary catheter tubing for kinks and obstruction.
3. Teach relaxation exercises.
4. Encourage use of patient-controlled analgesia.

NCLEX Client Need: Health Promotion and Maintenance

10. A patient states, "The doctor says I have a hydrocele." How should the nurse explain a hydrocele? (*Select all that apply.*)

1. "A fluid collection within the scrotum that can be drained."
2. "Sometimes caused by an infection of the testis that causes inflammation."
3. "An inflammation of the testes and scrotum from an illness such

as mumps."

4. "Possibly from an injury with inflammation."

NCLEX Client Need: Health Promotion and Maintenance

Critical Thinking Questions

Scenario A

Your brother, who is 20 years old, tells you of a friend who has just learned that he has testicular cancer and is scheduled for surgery tomorrow. Your brother is concerned about the effect the surgery will have on his friend's "manhood." He also says that, if ever he has that kind of cancer, he "doesn't want to know about it, and certainly wouldn't allow surgery."

1. What information could you give your brother about testicular cancer and self-examination of the testes?
2. How could you explain that removal of a testis does not render a man less masculine?

Scenario B

Mr. Watts, age 67 years, has been admitted to the hospital to undergo TURP. He is assigned to your care on his second postoperative day. Mr. Watts seems disoriented and restless, and when you begin to give him his bath, he tells you that his bladder is full and he needs to urinate. You check the catheter and find that it apparently is not draining as it should.

1. What would you tell Mr. Watts about his need to void?
2. What would you do about the catheter, which seems to be obstructed?
3. What observations should you make while caring for this patient?
4. What special precautions should be taken for his safety?

CHAPTER 40

Care of Patients With Sexually Transmitted Infections

Objectives

Theory

1. Differentiate the signs and symptoms of common sexually transmitted infections (STIs).
2. Present the danger of contracting human papillomavirus (HPV) and preventive measures.
3. Explain the procedure for the various tests for STIs.
4. Describe the treatment of common STIs, their prevention, and the resources available to those who need information about STIs.
5. Compare the symptoms of gonorrhea in male and female patients.
6. Distinguish the ways in which human immunodeficiency virus (HIV) is transmitted.
7. Contrast the three stages of syphilis and discuss prevention, treatment, and complications.
8. Illustrate the nurse's role in preventing, identifying, reporting, and treating common STIs.

Clinical Practice

9. Devise a teaching plan for a patient who has experienced a first incidence of genital herpes.
10. Instruct a female patient on ways to prevent contracting or transmitting HIV.
11. Teach a female patient and a male patient ways to prevent STIs.

KEY TERMS

agglutination (ă-GLŪ-tĕ-NĀ-shūn, p. 951)

bacterial vaginosis (băk-TĒ-rē-ăl vă-jī-NŌ-sīs, p. 944)

chancre (SHÄNG-kĕr, p. 950)

gram negative (grām 'NE-gē-tiv p. 951)

gram positive (grām 'PÄ-zə-tiv, p. 951)

oophoritis (oof-ō-RĪ-tīs, p. 944)

pelvic inflammatory disease (PID) (PĚL-vīk īn-FLĂ-mă-tō-rē dī-ZĒZ, p. 944)

peritonitis (pér-i-tō-NĪ-tīs, p. 944)

salpingitis (săl-pīn-GĪ-tīs, p. 944)

sexually transmitted infection (STI) (SEK-sh(ə-)wēl-lē TRAN(t)s-'mit-tēd, in-'FEK-shēn, p. 943)

The term **sexually transmitted infection (STI)** refers to those particular infections spread by intimate physical contact. Modes of transmission include sexual intercourse and contact with the genitals (sexual organs), rectum, or mouth. STIs can also be transmitted via blood contact and can

be transmitted to a fetus via the placenta or to a newborn during the birth process.

The incidence of STIs continues to rise throughout the world. Although all sexually active people must be considered potentially at risk, people with multiple sexual partners are at very high risk for contracting an STI. The largest population groups affected by STIs are adolescents and young adults ([Centers for Disease Control and Prevention, 2013](#)). Teens are engaging in sexual practices at an earlier age and have an opportunity for multiple partners. They are often unaware of signs and symptoms of STIs and are reluctant or unable to access confidential health care. Inflamed tissue and open lesions associated with STIs increase the risk of developing human immunodeficiency virus (HIV) infection, which can result in acquired immunodeficiency syndrome (AIDS). AIDS is an STI for which there is currently no cure (see [Chapter 11](#)). The risks of STIs do not disappear with age. More than 10% of HIV cases occur in patients older than 50 years ([Wold, 2011](#)). Safe sex practices are essential at all ages.

Think Critically

What safe sex practices can help prevent the spread of STIs?

STIs have a major impact on reproduction and general health. Because STIs are communicable, these infections are of concern both to the patient and to the general public health. One of the goals of [@Healthy People 2020](#) is to increase efforts to “promote responsible sexual behaviors, strengthen community capacity and increase access to quality services to prevent STIs and their complications.” Another *Healthy People 2020* objective is to “prevent HIV infection and its related illness and death.” The progress in reaching these national objectives is monitored by the U.S. Department of Health and Human Services. An interesting point regarding progress toward these objectives is that the “CDCs Division of STD Prevention launched a Facebook page for clinicians, health departments, and partners to promote STD awareness and prevention. [Interested parties can] visit and ‘like’ the DSTDP Facebook page and join the conversation!” ([CDC, 2013](#))

Common Infections of the Female Reproductive Tract

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) refers to any inflammation in the pelvic cavity. If the infection is located in the fallopian tubes, it is called **salpingitis**. Infection of the ovary is called **oophoritis**; involvement of the pelvic peritoneum is called pelvic **peritonitis**. The organisms causing the infection are usually introduced from the outside, traveling through the uterus to infect pelvic organs. Therefore PID is much more common in sexually active women, particularly women with multiple sexual partners. Most of these infections are caused by two sexually transmitted organisms, *Neisseria gonorrhoeae* and *Chlamydia trachomatis*, and the most common complication is infertility from fallopian tube damage. However, PID can also be the result of an infection after pelvic surgery or childbirth and is not **always** an STI.

Symptoms of acute PID include severe abdominal and pelvic pain and fever, commonly accompanied by a foul-smelling purulent vaginal discharge, and the woman appears acutely ill. Chronic PID usually causes backache, a feeling of pelvic heaviness, and disturbances in menstruation. However, mild cases may produce no symptoms but still cause significant reproductive damage. Acute PID usually is treated with intravenous (IV) antimicrobials, symptom relief, and patient support and teaching. See [Chapter 38](#) for other common inflammations and infections of the female reproductive tract.

Candidiasis

Candidiasis (moniliasis) is a yeast infection, and although it is not considered a sexually transmitted infection, recurrent infections increase the risk for STIs in sexually active women. Candidiasis is caused by a change in the vaginal pH, which allows the yeastlike fungus *Candida albicans* to grow. The pH of the vagina can be altered by diabetes mellitus, oral contraceptives, some systemic antibiotic use, or the frequent douches sometimes practiced by sexually active women. Symptoms of candidiasis include itching; burning on urination; and a white, cheeselike discharge. Treatment includes vaginal miconazole or clotrimazole for 3 to 7 days or oral fluconazole in a single dose.

Bacterial Vaginosis

Bacterial vaginosis occurs when normal lactobacillus in the vagina is replaced by *Mycoplasma hominis* or anaerobic bacteria. Bacterial vaginosis is associated with minor vaginal tissue trauma, often caused by frequent sexual activity or douching. Symptoms include a grayish-white discharge that has a fishy odor. Although not considered an STI, this condition can increase the risk for STIs and does have serious consequences if it occurs during pregnancy. Treatment includes metronidazole or clindamycin (see [Chapter 38](#) for other common inflammations or infections of the female reproductive tract).

Risk Factors for Transmission of Sexually Transmitted Infections

Although men and women are equally susceptible to STIs, **women are diagnosed with STIs at a much higher rate than men.** Biologically, young, sexually active women have a large proportion of columnar epithelium lining the cervix and a vaginal pH that can be altered by frequent douching. An alteration of vaginal pH can place the woman at higher risk for an STI. During and after the sexual act, male secretions and semen are in contact with female mucous membranes for a period of time longer than female secretions are in contact with male mucous membranes. Therefore women have an increased risk for STI.

Cultural Considerations

Media Effects on Sexually Transmitted Infections

Custom and culture can also affect the development of STIs. STI rates increase in societies in which the media (television, magazines, movies, and Internet chat rooms) focus on sexuality and premarital sexual experiences of people with varying behaviors and values, including greater sexual freedom.

The mucus plug in the cervix of women (that protects the upper genital tract) becomes more permeable around the menstrual period, which can result in an increased risk during this time for infections in the upper genital tract, such as PID.

Contraceptive choice may influence a woman's increased risk of STIs, because the use of oral contraceptives alters the cervical secretions, resulting in a more alkaline environment in the vagina and thus a more favorable setting for growth of organisms that cause STIs. The use of long-acting oral contraceptives may reduce the use of condoms, thus increasing the risk of exposure to STIs in both partners.

Cultural Considerations

Contraception Choices

In societies or cultures in which women are passive, they may not insist on condom protection before intercourse. The condom offers protection from STIs, but the man often decides whether or not it is to be used.

Women may not seek medical care as quickly as men for symptoms of an STI. Commonly a vaginal discharge is considered a normal variance, and health care may not be sought until the infection spreads and symptoms of PID occur. In men, urinary tract infections associated with sexual activity may be the first sign of an STI. Men may seek earlier health care intervention because the signs and symptoms are obvious and distressing. STIs can have long-term effects in the form of sterility, complicated pregnancy, or neonatal infection. Health care screening services and easy access to health care are important in preventing the spread of STIs.

Prevention of Human Papillomavirus

The Advisory Committee on Immunization Practices of the Centers for Disease Control and Prevention (CDC) has recommended routine HPV vaccinations for all girls and boys 11 to 26 years old. Gardasil® provides protection against types 6 and 11, which cause genital warts, and against 16 and 18, the cancer-causing HPV strains. Cervarix, another HPV vaccine, provides protection against types 16 and 18 only. Both types of vaccine are highly efficacious against cervical, vaginal, vulvar, and anal cancers; are well-tolerated; and are considered safe. HPV vaccine can be given to girls and boys as young as 9 years of age and to women up to 45 years of age. Three doses are required (the

second dose is given 2 months after the first, and the third dose is given 6 months later).

Lesions of Sexually Transmitted Infections

In men, the lesions related to STIs may appear under the prepuce; on the head or body of the penis; or on the scrotum, perianal area, rectum, anus, or inner thighs. In women, lesions of STIs can appear on the vulva, vagina, cervix, perianal area, or inner thighs. Lesions around the mouth can occur in cases of oral sexual practices. Lesions can also be found far from the genital area. For example, lesions of syphilis include a classic rash on the palms of the hands and soles of the feet. Lesions of *Neisseria gonorrhoeae* may spread and cause pustules on the extremities as part of an "arthritis-dermatitis" syndrome. Examples of common organisms involved in STIs are listed in Box 40-1.

Box 40-1

Causes of Sexually Transmitted Infections

Bacteria

- *Neisseria gonorrhoeae*
- *Chlamydia trachomatis*
- *Treponema pallidum* (syphilis)
- *Haemophilus ducreyi* (chancroid)
- *Mycoplasma hominis*

Viruses

- Human herpesvirus 2 (herpes simplex virus type 2)
- Hepatitis B virus
- Human immunodeficiency virus (HIV)
- Human papillomavirus (HPV)

Yeasts and Fungi

- *Candida albicans*
- *Candida glabrata*
- *Candida tropicalis*

Parasite

- *Trichomonas vaginalis* (trichomoniasis)

Data from www.cdc.gov/std/trichomoniasis/default.htm.

Reporting Sexually Transmitted Infections

STIs must be reported to the local public health agency in accordance with state and local statutory requirements. The CDC and local health authorities establish these regulations and provide regular updates and reporting forms to health care providers for monitored infections. Syphilis, gonorrhea, chlamydia, chancroid, lymphogranuloma venereum, hepatitis B, PID, HIV infection, and AIDS are reportable diseases in all parts of the United States, according to the public health guidelines from

the CDC. The requirements for reporting other STIs differ by state, and clinicians must be familiar with state and local reporting requirements. This tracking information is used to determine community resource needs and is evaluated in terms of the national goals of *Healthy People 2020*[®].

Transmission of Sexually Transmitted Infections

STIs are primarily passed through some type of intimate contact, either genital to genital, mouth to genital, or genital to rectum. They occur in both heterosexual and homosexual relationships. Some infections, such as HIV or hepatitis B or C, also may be passed through blood contact, by the sharing of contaminated needles, or—though rarely—through transfusion with contaminated blood. Accidental transmission to medical personnel may occur via needle or sharps injuries or by direct exposure to open wounds or body fluids.

Blood-borne infections may be transmitted to a fetus before birth. Newborns are at risk for contracting any STI that may reside in the vagina at the time of birth. Depending on the organism, such exposure can lead to a variety of serious problems for the infant, including pneumonia and blindness.

Think Critically

What are the four major modes of transmission for STIs?

In many states screening for some STIs—particularly for syphilis—is required for a marriage license. However, it is expensive to screen for all STIs. The greatest hope for controlling STIs is public awareness and willingness to take responsibility for prevention and for treatment, should infection occur.

Common Diagnostic Tests

Table 40-1 lists common STIs and contains information about modes of transmission, diagnosis, symptoms, treatments, and nursing responsibilities.

Table 40-1
Common Sexually Transmitted Infections

INFECTION	MODES OF TRANSMISSION	SYMPTOMS	MEDICAL DIAGNOSIS	MEDICAL TREATMENT	NURSING INTERVENTIONS
<i>Chlamydia trachomatis</i>	Direct sexual contact. May be transmitted to the newborn during vaginal delivery. Second-most common STI in the United States.	<i>Male:</i> Often asymptomatic. Dysuria; frequency of urination; watery, mucuslike discharge. Causes about half the cases of epididymitis and nongonococcal urethritis. <i>Female:</i> Approximately 75% have no symptoms. Yellow vaginal discharge, urinary frequency, dysuria. May have unusual odor after intercourse. Can result in PID, ectopic pregnancy, and sterility. <i>Neonate:</i> Exposure can cause eye infections and pneumonia.	By cervical culture, DNA probe, enzyme immunoassay, ELISA, or nucleic acid amplification. <i>Screening protocol:</i> Test women ages 15–25 yr via low vaginal swab (SOLVS) or first void urine (SVU). Test men seen in genitourinary clinic via urine sample. TMA, SDA, or PCR test; test for gonorrhea as well.	Azithromycin 1 g orally in a single dose OR Doxycycline 100 mg orally twice a day for 7 days Alternative: Erythromycin base 500 g orally four times a day for 7 days. OR Erythromycin ethylsuccinate 800 mg orally four times a day for 7 days. OR Levofloxacin 500 mg orally once daily for 7 days OR Ofloxacin 300 mg orally twice a day for 7 days	<i>Education:</i> Encourage patients to seek attention for any unusual vaginal or penile discharge. Partner(s) must be treated concurrently. Encourage condom use for prevention of future infection, with abstinence until course of treatment completed. Remind that patient must complete antibiotics to ensure effective treatment and prevent development of PID. CDC recommends screening all pregnant women and sexually active young women.
Human papillomavirus (HPV) Condylomata acuminata (venereal warts) caused by HPV	Spread during sexual contact. Highly contagious. Can be transmitted to newborn during vaginal delivery. Most common STI in the United States.	Warts are flat or raised, rough, cauliflower-like growths on the vulva, penis, perianal area, vaginal or rectal walls, or cervix. The flat variety is more likely to lead to tissue changes that contribute to cervical or penile cancer. <i>Neonate:</i> Laryngeal papillomas.	Biopsy, colposcopy, anoscopy, Pap smear.	Laser therapy, surgical removal, cryotherapy. Topical podophyllin, TCA, imiquimod, and podofilox are alternative treatments for external warts. Topical TCA or interferon is used for difficult cases. Some lesions can cause cancer.	<i>Education:</i> Teach about mode of infection and use of condoms to prevent spread. Recommend regular Pap smears because of risk of cervical cancer. Two vaccines are available and are recommended for all girls and boys ages 9–26 yr. May be given to women until age 45 yr. Should remain supine for 15 min after vaccination; fainting may occur.

Genital herpes	<p>Caused by herpes simplex virus (HSV) types 1 and 2. Highly contagious, spread by direct contact; not limited to sexual contact. Self-inoculation also possible, for example, from lip ulcer (fever blister) to genitals. Invades nerve cells located near the site of infection. Lies dormant; flare-ups erratic and unpredictable. Some patients have frequent recurrence, others rarely or none. Neonate may be infected during delivery if mother has active disease (more common if initial episode occurs during pregnancy).</p>	<p>Primary: Fever, headache, malaise, myalgia, burning genital pain, dysuria (female), painful intercourse. Vesicles in genital area that ulcerate, crust over, and resolve spontaneously in about 2 wk.</p> <p>Secondary: Burning genital pain, possible numbness and tingling 24 hr before lesions appear, vesicles.</p> <p>Male: Lesions may appear on glans penis, shaft of penis, prepuce, scrotal sac, inner thighs.</p> <p>Female: Vulva, vaginal surface, buttocks, cervix. Cervical lesions may be superficial with diffuse inflammation or a single, large, necrotic ulcer.</p> <p>Primary infection during pregnancy associated with high risk of premature labor and spontaneous abortion.</p> <p>Neonate: Local infections of eyes, skin, or mucous membranes to severe disseminated infection that can be lethal may occur.</p>	<p>Lesions usually easily identified by experienced clinician. Can be confirmed by viral cultures of fluid from vesicles.</p>	<p>No known cure. Treatment with acyclovir, valacyclovir, or famciclovir may reduce symptoms and accelerate healing. For individuals with frequent recurrence, continuous treatment may reduce frequency. Viral shedding may continue after lesions are healed.</p> <p>Contact Precautions are necessary.</p> <p>Education: Encourage use of condoms with spermicide to help prevent spread, avoidance of sex if lesions present; scrupulous hand hygiene. If patient becomes pregnant while disease is active, infant will be delivered by cesarean section to protect it from exposure.</p>
Gonorrhea (GC)	<p>Easily transmitted by direct sexual contact. Transmitted to the newborn during vaginal delivery if mother has active disease. Autoinoculation via fingers to eye possible. Occasionally becomes blood-borne.</p>	<p>Incubation: 2-6 days after exposure. May be asymptomatic.</p> <p>Male: Dysuria with frequency; scant to copious purulent discharge from penis, unilateral testicular pain. If untreated may develop urethral stricture and epididymitis; can cause sterility.</p> <p>Female: Vaginal discharge, burning on urination. Untreated, results in PID. May involve rectum, eyes, oropharynx.</p> <p>Neonate: If exposed at birth to mother's vaginal secretions, is at risk for ophthalmia neonatorum, which can cause blindness,</p>	<p>Confirmed by presence of the causative organism, <i>Neisseria gonorrhoeae</i>, in vaginal or urethral smear, rectal or pharyngeal culture. Nucleic acid amplification test using urine sample is accurate.</p>	<p>Single intramuscular dose of ceftriaxone 250 mg plus a single dose of azithromycin 1 g orally.* Alternative (if ceftriaxone is not available): Cefixime 400 mg orally plus azithromycin 1 g orally.* If ceftriaxone cannot be given because of severe allergy. Dual treatment with single doses of oral gemifloxacin 320 mg plus oral azithromycin 2 g OR Single doses of intramuscular</p> <p>Standard Contact Precautions and frequent hand hygiene.</p> <p>Education: Teach about prevention, treatment, and importance of completing treatment; naming all contacts for treatment; and having follow-up cultures to ensure that treatment has been effective. Encourage safer sex practices to prevent reinfection. Be sure patient understands how to take prescribed medication. Teach CDC recommendations for sexually active patients to be screened for GC infection.</p>

		and other infections within 2-5 days after birth. <i>Children:</i> Infection in children over 1 yr of age is likely the result of sexual abuse.	gentamicin 240 mg plus oral azithromycin 2 g Hospitalize if PID or severe illness occurs.* Empirical treatment for chlamydia is recommended by CDC.		
Hepatitis B	Caused by hepatitis B virus (HBV). Transmission via sexual contact, blood contact, and to the fetus via the placenta in an infected mother.	May have anorexia, malaise, vomiting, abdominal pain, dark urine, jaundice, skin rashes, arthralgias, arthritis. Acute infection may be asymptomatic. Infection may be persistent and result in a chronic carrier state and may develop chronic active hepatitis, cirrhosis, hepatocellular carcinoma, hepatic failure, and death. Infants born infected are at high risk for chronic hepatitis B infection.	Serologic testing for HBV infection gives definitive diagnosis.	No specific therapy is available. HBIG is given prophylactically after known exposure. Hepatitis B vaccine (Hep B) is recommended for people at risk for exposure, including health care workers. Hep B vaccine is currently given as part of normal childhood immunizations with a three-dose regimen beginning at birth. Postexposure interval before vaccination administration should not exceed 7 days for needle-stick exposure and 14 days for sexual exposure.	
HIV, AIDS, ARC	HIV is transmitted by intimate contact with body secretions of an infected person or exposure to infected blood or by perinatal transmission from mother to newborn.	Initially, flu-like symptoms several weeks after HIV exposure. Antibodies appear in blood a few months to 1 yr later. A latent period follows with gradual reduction in CD4 cells. CD4 cell decline results in reduced immune function, resulting in opportunistic infections, such as Kaposi sarcoma, <i>Pneumocystis jiroveci</i> (formerly <i>Pneumocystis carinii</i>) pneumonia, and oral candidiasis. CD4 count below 200/mm ³ is diagnostic of AIDS.	Diagnosis of HIV infection based on reactive enzyme immunoassay (EIA) confirmed by a more specific assay (e.g., Western blot or immunofluorescent assay). The ELISA and HIV-RNA tests are recommended by the CDC (Swan, 2009). AIDS and ARC may be diagnosed based on laboratory results and/or specific diagnostic criteria. The FDA has approved a rapid test for HIV screening that provides results in less than 1 hr. A positive rapid HIV test requires further testing for confirmation.*	Currently there is no cure. Drug regimens interrupt reproduction of viruses. There are five major classes of antiretroviral drugs that are tailored to individual patient needs. Raltegravir is the first HIV integrase inhibitor and is used for initial antiretroviral therapy (Lennox, 2009). Postexposure prophylaxis (PEP) treatment should start within 72 hr of exposure (Kurtyka, 2010).	
Syphilis		Direct body contact; organism (<i>Treponema pallidum</i> , a spirochete) requires warm, wet environment to survive; can be destroyed with plain soap and water. Can penetrate intact mucous membrane. Placental transmission to fetus in about 50% of women with active disease during pregnancy.	Syphilis has three stages. Primary (after 3-4 wk incubation period): Chancres (hard, painless sore) on the mucous membrane of the mouth or genitals, often unnoticed in women. Chancres teeming with spirochetes, very contagious at this stage. Spirochetes enter bloodstream 3-7 days after infection and begin to multiply rapidly (bacteremia). Symptoms disappear within 3-8 wk. Secondary (6 wk later): Symptoms vary. May have generalized skin rash. Serology test is positive.	Screening: VDRL and RPR tests, performed on blood or spinal fluid if neurosyphilis is suspected. May be negative in primary, but always positive in secondary and tertiary phases. Confirmation: Dark-field microscopy of scrapings from chancre. FTA-Abs blood test. Tests for other STIs should also be done. Single-dose Benzathine penicillin G 2.4 million units* Alternatively: In the case of penicillin allergy: Doxycycline 100 mg orally twice daily for 14 days OR Tetracycline 500 mg four times daily for 14 days OR Ceftriaxone 1-2 g daily either IM or IV for 10-14 days* Other regimens have documented treatment failures*	<i>Education:</i> Caution patients not to ingest alcohol for 24 hr before VDRL or RPR (may cause false-positive result). Remember that chancre is highly infectious (gloved contact only). Encourage naming of contacts so everyone can be treated. Encourage condom use to prevent reinfection. Explain importance of follow-up (usually 3- and 6-mo VDRL) to ensure treatment has been effective. Follow-up usually at 1, 2, 3, 6, 9, and 12 mo for HIV-positive individuals.

		Symptoms may disappear as the disease enters latent period. <i>Tertiary</i> (late: 1-20 yr after infection): Spirochetes have had access to all body tissues. "Gumma," a soft encapsulated tumor, appears on any organ, causing symptoms (including neurologic). Congenital. Stillbirth, CNS damage.		
Trichomoniasis	Sexually transmitted.	Pruritus; frothy gray-green vaginal discharge; dysuria.	Laboratory observation of protozoa; ulceration on cervix or vaginal wall.	Metronidazole (Flagyl), single 2-g dose for patient and partner. OR Tinidazole 2g orally in a single dose Alternative regimen: Metronidazole 500 mg orally twice a day for 7 days*

*2015 Centers for Disease Control and Prevention Treatment Guidelines.

AIDS, Acquired immunodeficiency syndrome; ARC, AIDS-related complex; CD4, T helper cell; CDC, Centers for Disease Control and Prevention; CNS, central nervous system; DNA, deoxyribonucleic acid; ELISA, enzyme-linked immunosorbent assay; FDA, Food and Drug Administration; FTA-Abs, fluorescent treponemal antibody absorption; HBIG, hepatitis B immune globulin; HBsAg, hepatitis B surface antigen; HIV, human immunodeficiency virus; IM, intramuscular; Pap, Papanicolaou; PID, pelvic inflammatory disease; RNA, ribonucleic acid; RPR, rapid plasma reagins; STI, sexually transmitted infection; TCA, trichloroacetic acid; VDRL, Venereal Disease Research Laboratory.

Syphilis figure courtesy U.S. Public Health Service, Washington, DC.

A variety of tests are used to detect STIs. Noninvasive diagnostic techniques have been developed that use urine samples. **Smears** and **cultures** may be taken directly from the site (e.g., vaginal, cervical, or urethral swabs). In some instances, organisms also can be cultured from the blood. **Biopsies** are microscopic tissue examinations performed on a sample taken from the affected area and are usually done to differentiate between benign and malignant tissues, but can also provide a differential diagnosis in diseases that have specific cellular changes or organisms present.

Numerous types of blood tests can help detect STIs. They look for specific antibodies formed by the presence of certain microorganisms, or for the effects of antigens (substances in the bloodstream that stimulate the production of antibodies). Such effects include the tendency for **agglutination**—the clumping together of cells in a variety of characteristic patterns.

Staining procedures differentiate organisms by using dyes that have been found to stain some bacteria in specific ways. An example of this would be a Gram stain, in which bacteria are first stained with crystal violet, then treated with a strong iodine solution, decolorized with ethanol or ethanol acetone, and then counterstained with contrasting dye. Those retaining the initial stain are considered **gram positive**; those losing the stain but accepting the counterstain are considered **gram negative**. Current development of noninvasive testing and screening procedures using urine samples will increase public acceptance of mass screening. See [Chapter 6](#) for further discussion on testing for infectious agents.

❖Nursing Management

Identifying microorganisms is a complex procedure. When collecting or assisting in the collection of specimens, there are several specific responsibilities to ensure that the samples will allow accurate studies to be performed. These include:

- Ensure that appropriate laboratory request slips have been prepared according to the health care provider's specific orders. If antimicrobials have been started, note this on the laboratory slip.
- Check the laboratory manual for any specific restrictions or preparations for the tests ordered.
- Urethral swabs should not be done within 1 hour of the last void, because organisms will have been flushed away.
- Female patients should not douche before vaginal cultures or smears.

- Some tests will give a false-positive reading if the patient is on specific medications or has other types of infection present. Check the patient's history.
- Antimicrobials may cause cultures to be negative even though the drug or the dose may not be sufficient to cure the infection. Document the medication history.
- Stool present in the rectum can prevent good rectal swabs from being obtained.
- Cultures and smears usually are obtained with a **sterile** swab and sent to the laboratory.
- Prepare the patient. (See information on preparing the patient for a pelvic examination in [Chapter 38](#).)
- Explain what tests have been ordered and any specific home preparation. Answer all questions.
- Provide appropriate draping and privacy, and remain with the patient during the procedure.
- Provide emotional support as needed.
- Make sure that specimens are appropriately labeled and delivered to the laboratory with the corresponding laboratory slips.

Assessment (Data Collection)

Screening for potential STIs or risk for acquiring such an infection should be part of any patient history data collection. However, it often is difficult to get accurate information. Patients may not disclose symptoms such as inflammation, rash, or discharge if they fear it is related to sexual activity. Adolescents may fear parental disapproval, rejection, or disciplinary action if they admit to being sexually active, and so may hide symptoms. Fear of finding a serious disorder such as HIV also may make the patient reluctant to cooperate with data collection.

Communication

Gathering Information

When someone is diagnosed with an STI, the public health department is responsible for collecting the names of sexual partners so that they can be contacted and treated. Many people do not wish to give out this information. Professionals who deal with these issues regularly, such as public health nurses, often have special training in obtaining an appropriate history.

Obtaining a history on a patient seeking treatment for an STI requires tact and sensitivity. Such a history involves very intimate questions and may involve a variety of cultural and personal issues. You must maintain an open and nonjudgmental attitude.

Focused Assessment

Data Collection for Sexually Transmitted Infections

The following questions are asked when assessing a patient with or at risk for an STI:

- Are you currently sexually active?
- At what age did you become sexually active?
- Do you currently have more than one sexual partner?
- Have you had other partners in the past?
- If yes to either of the last two questions: Do you understand the risks associated with having multiple sexual partners?
- If a sexually active female: Are you having regular gynecologic examinations with Papanicolaou (Pap) smears? If yes, when was your last examination?
- If a sexually active female: Are you currently pregnant or trying to become pregnant?

- Are you checked at least annually for STIs even if you do not have symptoms?
- If currently in non-monogamous relationships: Are you using condoms to help prevent STIs?
- Have you ever had an STI? If yes, ask for specific information (what, when, how treated; was follow-up done?).
- Do you have symptoms or reasons to believe you might have an STI now? If yes, ask for specific information (symptoms, duration; partner[s] symptomatic?).

Think Critically

What factors make it difficult to take an accurate history or provide education for a patient with an STI?

Physical examination for STIs involves exposure of the most private parts of the anatomy. Such an examination is usually performed by both a health care provider and a nurse, particularly when there are gender differences between the medical personnel and the patient. Provide appropriate draping and to give the patient privacy when he or she is undressing for the examination.

Patients may request that a family member be allowed to remain with them, and they have this right. You should escort such individuals into the room and have them sit or stand by the patient in a manner that allows them to provide support. Make sure that any required equipment, supplies, specimen containers, and laboratory slips are ready in the examination room.

Nursing Diagnosis

Problem statements for patients with an STI may include:

- Insufficient knowledge regarding modes of transmission, signs and symptoms, and treatment of STI
 - Pain due to inflammation
 - Anxiety due to intimate examination and personal information required
 - Fear of being HIV positive
 - Absence of compliance due to repeated infection with STIs and refusal to use condoms
- Specific NANDA-I diagnoses can be chosen from the NANDA-I list (see inside back cover).

Planning

Expected outcomes for the patient with an STI may include:

- Patient will verbalize knowledge of self-care to prevent recurrence or other STI.
- Patient will be free of pain after treatment.
- Patient will cope adequately with history taking and physical examination.
- Patient will have decreased fear of HIV diagnosis after examination and treatment.
- Patient will comply with safer sex practices.
- Patient will comply with treatment requirements.

In addition to managing the treatment protocol and any pain related to an STI, patient education and emotional support are primary aspects of planning for patients with or at risk for STIs. Education in this area commonly is hampered by the patient's reluctance to discuss sexual issues. This may result from cultural views or more personal feelings. Patients of all ages may wish to protect themselves or their partners from possible condemnation or embarrassment through disclosure of sensitive information. Maintain a nonjudgmental attitude and give assurance that information will be kept confidential within the health care system.

When planning education, consider the patient's existing knowledge and ability to understand information provided. Select appropriate teaching aids, such as pictures, pamphlets, and three-dimensional models, to assist in the education of the patient.

Emotional support is another important aspect of care for patients with an STI. Allow time in the teaching plan for listening to the patient's concerns and for answering questions. Be prepared with information on support groups, counseling services, and informational programs that may be of

assistance. In the case of serious infections, such as HIV, support programs and professional counseling are of particular importance to the patient.

■ Implementation

Symptom Relief

STIs cause a variety of symptoms, some of which may cause mild discomfort or significant pain. Review Chapter 7 on pain management techniques and Table 40-1 for specific nursing interventions. Nursing Care Plan 40-1 gives specific nursing interventions for a patient with chlamydia.

✳ Nursing Care Plan 40-1

Care of a Patient With Chlamydia

Scenario

A 21-year-old woman is admitted to the clinic and diagnosed with a chlamydia infection.

Problem Statement/Nursing Diagnosis

Insufficient knowledge/*Deficient knowledge related to new diagnosis of chlamydia infection.*

Supporting Assessment Data

Subjective: "What is chlamydia?"

Objective: Positive test for chlamydia.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will verbalize understanding of disease prevention, transmission, and treatment protocols.	Assess readiness to learn about chlamydia.	Readiness to learn is essential for successful learning to occur.	Patient asking questions about her diagnosis.
	Determine knowledge base concerning chlamydia.	Learning plan should build on existing knowledge.	Patient discussing her understanding.
	Identify barriers to learning.	Language barriers, cultural beliefs, and embarrassment can alter learning effectiveness.	Patient speaks fluent English and is willing to discuss illness.
	Teach the medication regimen.	Compliance with medication regimen is essential for successful treatment.	Patient verbalizes understanding of when and how to take medication.
	Review safer sex practices.	Safer sex practices can prevent exchange of body fluids and minimize risk of STI transmission.	Patient demonstrates understanding of safer sex practices.
	Schedule follow-up appointments.	Follow-up testing is an essential part of confirming successful treatment of chlamydia.	Patient promises to return for follow-up care.

Problem Statement/Nursing Diagnosis

Altered tissue integrity/*Impaired tissue integrity related to testing positive for chlamydia.*

Supporting Assessment Data

Subjective: "I've had a small amount of vaginal discharge."

Objective: Chlamydia test positive.

Goals/Expected Outcomes	Nursing Interventions	Selected Rationale	Evaluation
Patient will show signs of successful treatment of chlamydia as evidenced by absence of symptoms and completion of medication regimen.	Assess for signs and symptoms of chlamydia such as vaginal discharge and dysuria.	Absence of symptoms may indicate successful treatment.	Patient does not evidence continued signs of the disease.
	Assess for risk factors for reactivation of disease.	Minimizing risk factors can prevent reinfection.	Patient states she is now in a monogamous relationship.
	Encourage woman to identify partners to enable treatment.	Treating sexual partners can minimize risk for reinfection and spread of infection.	Patient has contacted other partners, who have come in for examination.
	Teach safer sex practices and risk for recurrence.	Use of safer sex practices can minimize reinfection.	Patient evidences understanding of safer sex practices.

Critical Thinking Question

1. What are the long-term problems associated with untreated chlamydia?

Prevention of Spread

The spread of STIs is a major health concern in the United States. People often become sexually

active at a young age, and it is not uncommon for individuals to have a variety of sexual partners over the years. Strategies for prevention and control of STIs are given in **Box 40-2**.

Health Promotion

Preventing Sexually Transmitted Infections

Although the only absolute prevention is abstinence, certain behaviors significantly reduce the risk of contracting an STI. These behaviors include using condoms with a spermicide containing nonoxynol-9, which acts as a barrier and has viricidal and bactericidal action; limiting sexual contacts, preferably to one partner; and avoiding sexual contact if a partner is known to be infected or if lesions are observed in the genital, perianal, or oral regions. If the patient or the sexual partner is an IV drug user, education regarding not sharing needles is important.

Box 40-2

Prevention of Sexually Transmitted Infections

The prevention and control of STIs are based on the following major strategies:

- Early education of adolescents concerning abstinence and safer sex practices.
- Education and counseling of people at risk on ways to prevent STI through changes in sexual and lifestyle behaviors.
- Identification of asymptotically infected people and of symptomatic people unlikely to seek diagnostic and treatment services.
- Effective diagnosis and treatment of infected people.
- Evaluation, treatment, and counseling of sex partners of people who are infected with an STI.
- Pre-exposure vaccination of patients at risk for vaccine-preventable STIs such as hepatitis B and HPV.
- Follow-up of patients at risk or under treatment to ensure compliance.

HPV, Human papillomavirus; *STIs*, sexually transmitted infections.

Adapted from www.cdc.gov/std/hpv/default.htm.

Evaluation

Initially, each patient teaching contact should be evaluated for effectiveness by reviewing information discussed to determine whether learning has occurred. Over time, evaluate whether the patient is following the recommendations. Follow-up cultures that are negative are a good indicator that treatments were followed as prescribed. During the follow-up interview, inquire about use of safer sex practices and evaluate retention of information previously taught.

Community Care

Most communities have clinics, often through the public health system, that provide screening and treatment for STIs. These may be low cost or no cost, and they provide a valuable service by assisting the community to control the spread of STIs.

Patient education is an important service provided by community clinics. The health department and organizations such as Planned Parenthood are just two of the community agencies that routinely provide pamphlets, posters, and classes on preventing and treating STIs. Confidential screening and education on safer sexual practices are important services provided by these clinics. Public service announcements, such as the television spots on HIV/AIDS awareness, are another source of public education. In many areas, information and education are made available through schools and colleges and are directed both at students and their families and at the general community.

Get Ready for the NCLEX® Examination!

Key Points

- STIs are primarily passed through intimate contact with body fluids. Needle sticks or blood transfusions with contaminated blood can also spread STIs. An STI can also be transmitted to a newborn during the birth process.
- One objective of *Healthy People 2020* is to “prevent HIV infection and its related illness and death.”
- STIs can be caused by bacteria, viruses, or protozoa.
- Contraceptive choice influences a woman’s risk for STIs.
- A properly used condom offers protection from the transmission of STIs.
- STIs can cause sterility, complicate pregnancy, or cause neonatal infection.
- Many STIs are reportable to the public health department.
- Awareness of symptoms of STIs can aid in early diagnosis, treatment, and education of patients.
- Nursing responsibilities include helping to identify, screen, and educate patients at risk for STIs.
- PID is an inflammation of the pelvic cavity commonly caused by STIs that can cause sterility.
- Candidiasis is a yeast infection caused by a change in vaginal pH that can be the result of frequent douching, use of oral contraceptives, or systemic antibiotic therapy.
- Bacterial vaginosis occurs when normal lactobacillus in the vagina is replaced by pathogenic organisms, and it increases the risk for STIs.
- Education concerning safer sex practices can prevent STIs.

Additional Learning Resources

- STI information, www.cdc.gov/std; www.womenshealth.gov

Review Questions for the NCLEX® Examination

1. Changes in the vaginal pH predispose women to develop various forms of infections. Which product decreases vaginal resistance to infections?

1. Vaginal douche
2. Tampons
3. Latex condoms
4. Spermicidal agents

NCLEX Client Need: Physiological Integrity: Reduction of Risk Potential

2. A mother brings her 12-year-old daughter in for an annual checkup. The nurse recommends administration of one of the HPV vaccines. The mother replies, “My daughter does not need the vaccine because she is not sexually active.” What is the best response?

1. “Perhaps you can bring her back when she becomes sexually

active."

2. "Regardless of your daughter's sexual activity now, studies have shown that the earlier the vaccine is given, the more effective it is. When she does become sexually active, the vaccine will be protecting her."
3. "If you wait until your daughter is sexually active it will be too late. How will you know?"
4. "It's your choice."

NCLEX Client Need: Health Promotion and Maintenance

3. The nurse talks with the parents of a 9-year-old girl regarding the HPV vaccinations. The information session must include which statement(s)? (*Select all that apply.*)

1. "The vaccine is a one-dose immunization."
2. "The vaccine prevents genital warts."
3. "The vaccine prevents some precancerous lesions of the cervix."
4. "The vaccine protects against some other full-blown HPV infections."
5. "The vaccine eliminates the need for routine cervical cancer screening."

NCLEX Client Need: Health Promotion and Maintenance

4. An important nursing responsibility is the reporting of certain sexually transmitted infections to the CDC and local health authorities. Which infection(s) should the nurse prepare to report? (*Select all that apply.*)

1. Gonorrhea
2. Syphilis
3. Bacterial vaginosis
4. Candidiasis
5. Chlamydia

NCLEX Client Need: Safe and Effective Care Environment

5. Which statement is true regarding the Venereal Disease Research Laboratory (VDRL) test?

1. VDRL tests are used for screening and diagnosis.
2. False-negative reactions are associated with malaria, leprosy, and viral pneumonia.
3. The VDRL values increase quantitatively after completion of therapy.
4. False-negative reactions are associated with alcohol consumption.

NCLEX Client Need: Physiological Integrity: Risk Reduction Potential

6. A nurse is assessing a patient for clinical signs and symptoms of syphilis. What are the classic manifestations of syphilis? (*Select all that apply.*)

1. An open ulcer on the genitals
2. A red rash on the palms of the hands
3. A cough and fever
4. A red rash on the soles of the feet

NCLEX Client Need: Physiological Integrity: Basic Care

7. Which sexually transmitted infections can put a neonate at risk? (*Select all that apply.*)

1. Syphilis
2. Herpes simplex virus
3. HPV
4. Chlamydia

NCLEX Client Need: Physiological Integrity: Reduction of Risk Potential

8. A nurse is taking the clinical history of an adolescent with a tentative diagnosis of gonococcal urethritis. Initial assessment confirms a patient problem of fear. A likely etiology for the diagnosis would be:

1. potential death.
2. parental disapproval.
3. disfigurement.
4. loss of reproductive function.

NCLEX Client Need: Health Promotion and Maintenance

9. A nurse is teaching a patient about her diagnosis of genital herpes. Which statement made by the patient indicates that further teaching is necessary?

1. "Once my lesions are healed I am no longer communicable."
2. "Primary lesions will resolve in about 2 weeks."
3. "This infection can spread to other parts of my body."
4. "A cesarean section may be necessary if the infection is active during pregnancy."

NCLEX Client Need: Physiological Integrity: Basic Comfort

10. While inserting an indwelling urinary catheter, the nurse finds raised, rough, cauliflower-like growths on the vulva and vaginal walls. A likely causative agent would be:

1. herpes simplex virus.
2. human papillomavirus.
3. *Treponema pallidum*.
4. *Neisseria gonorrhoeae*.

NCLEX Client Need: Physiological Integrity: Basic Care

Critical Thinking Questions

Scenario A

A friend confides that she has a rash in her genital area that occurred after she began having sex with her latest boyfriend. She is afraid she may have syphilis or genital herpes and does not know what to do.

1. What would you say to convince her that she needs to see an experienced clinician for diagnosis and treatment?

2. Where can she go if she does not want to see her regular health care provider?

Scenario B

A patient confides in you that he has three girlfriends, all of whom are taking oral contraceptives, so he sees no reason to use condoms.

1. What could you tell him about the importance of using condoms and his risky behavior?

UNIT XIV

Integumentary System

OUTLINE

Chapter 41 The Integumentary System

Chapter 42 Care of Patients With Integumentary Disorders and Burns

CHAPTER 41

The Integumentary System

Objectives

Theory

1. Describe the structure and functions of the skin.
2. Compare and contrast the various causes of integumentary disorders.
3. Analyze important factors in the prevention of skin disease.
4. Plan specific measures to prevent skin tears.
5. Interpret laboratory and diagnostic test results for skin disorders.
6. State nursing responsibilities in the diagnosis of skin disorders.
7. Write outcome objectives for a patient with a problem of altered skin integrity.

Clinical Practice

8. Teach three patients to perform a self-assessment of the skin.
9. Analyze the changes that have occurred with aging that affect the skin barrier for one of your older adult patients.
10. Perform a focused integumentary assessment on a patient.
11. Provide skin care for an older adult with dry skin.
12. Implement a teaching plan appropriate for adolescents and young adults for the prevention of skin cancer.

Anatomy and Physiology of the Integumentary System

Structure of the Skin, Hair, and Nails

- The skin consists of two layers of tissue, the epidermis and the dermis (Figure 41-1).

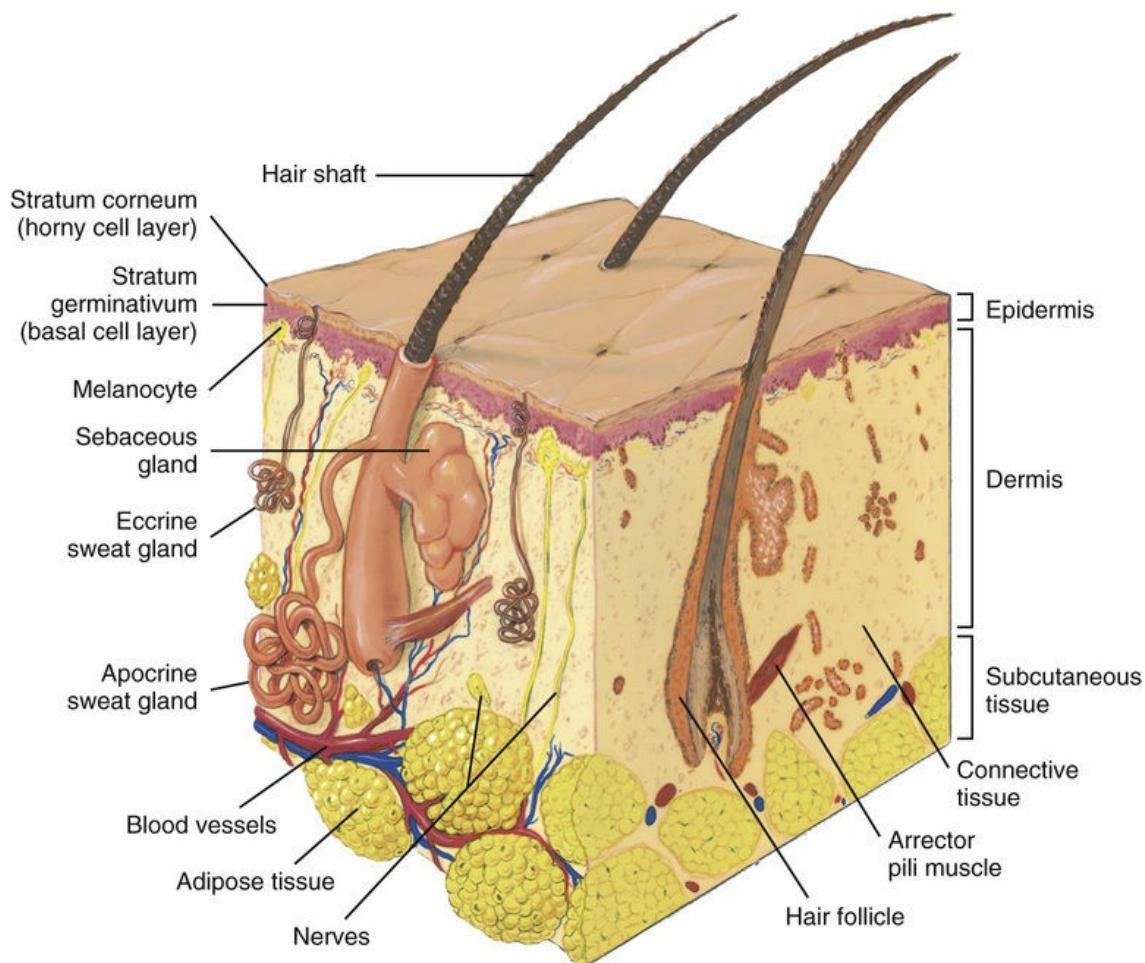

FIGURE 41-1 Structure of the skin. (From Lewis SL, Heitkemper MM, Dirksen SR, et al: *Medical-surgical nursing: Assessment and management of clinical problems*, ed. 9, St. Louis, 2014, Mosby.)

- The skin is attached to underlying structures by subcutaneous tissue.
- The epidermis consists of squamous epithelium and contains no blood vessels; cells receive nutrients by diffusion from vessels in the underlying tissue.
- Cell growth occurs from the bottom of the epidermis and pushes cells above to the surface, where they eventually die and slough off or are washed off. This layer is called the *stratum corneum*.
- The bottom layer of the epidermis contains melanocytes that contribute color to the skin.
- The dermis, also called the *corium*, is thicker than the epidermis and consists of dense connective tissue.
- The dermis contains both elastic and collagenous fibers that give it strength and elasticity.
- The dermis contains blood vessels and nerves as well as the base of hair follicles, glands, and nails that are derived from the epidermis.
- A hair consists of a shaft and a root made up of dead keratinized epithelial cells.
- The hair root is below the surface of the epidermis and is enclosed in a hair follicle that is embedded in the dermis.

- Fibroblasts that produce new cells to heal the skin are contained in the dermis.
- Glands contained in the skin are *sebaceous* (sweat producing) or *ceruminous* (wax producing).
- Nails are dead stratum corneum with a very hard type of keratin (Seeley et al, 2011).

Functions of the Skin and Its Structures

- The skin acts as a protective covering over the entire surface of the body.
- The keratin in the skin makes it waterproof, preventing water loss from the underlying tissues and too much water absorption during swimming and bathing.
- Skin provides a barrier to bacteria and other invading organisms.
- Skin protects underlying tissues from thermal, chemical, and mechanical injury.
- The skin helps regulate body temperature by dilating and constricting blood vessels and by activating or inactivating sweat glands.
- When the skin is exposed to ultraviolet (UV) light, molecules in the cells convert the rays to vitamin D.
- Melanin pigment absorbs light and acts to protect tissue from UV light.
- The nerve receptors in the dermis transmit feelings of heat, cold, pain, touch, and pressure.
- Hair follicles contained in the skin produce hair.
- Sebaceous glands secrete sebum that functions to keep hair and skin soft and pliable. Sebum also inhibits bacterial growth on the surface of the skin and, because of its oily nature, helps prevent water loss from the skin.
- Sweat glands act to excrete water and salt when the body temperature increases; sweat evaporates, producing a cooling effect.
- Sweat glands in the axillae and external genitalia secrete fatty acids and proteins as well as water and salts. They become active at puberty and are stimulated by the nervous system in response to sexual arousal, emotional stress, and pain.
- Hair color is produced by melanocytes in the skin and depends on the type of melanin produced.
- The shape of the hair shaft determines whether hair is straight or curly.
- Hair assists the body to retain heat.
- Nails cover the distal ends of the fingers and toes.
- Each nail has a free edge, a nail body, and a nail root that is covered by skin.
- The cuticle of each nail is a fold of stratum corneum.

Aging-Related Changes in the Skin and Its Structures

- The number of elastic fibers decreases, and adipose tissue diminishes in the dermis and subcutaneous layers, causing skin to wrinkle and sag.
- Loss of collagen fibers in the dermis makes the skin increasingly fragile and slower to heal.
- The skin becomes thinner and more transparent.
- Reduced sebaceous gland activity causes dry skin that may itch.
- Thinned skin and decreased sebaceous gland activity reduce temperature control and lead to an intolerance of cold and a susceptibility to heat exhaustion.
- A reduction in melanocyte activity increases the risk of sunburn and skin cancer.
- The number of hair follicles decreases and the growth rate of hair declines; the hair thins.
- A decrease in the numbers of melanocytes at the hair follicle causes gradual loss of hair color.
- Nail growth decreases, longitudinal ridges appear, and the nails thicken; nails become more susceptible to fungal infections.
- Some areas of melanocytes increase in production, producing brown “age spots” or “liver spots,” properly named **senile lentigines** (Figure 41-2).

FIGURE 41-2 Senile lentigines (age spots or liver spots).

The Integumentary System

The skin is the first line of defense against invasion by pathogenic bacteria living in the environment. When an area of the skin is destroyed by disease or trauma, its protective functions are immediately impaired. This impairment makes the body susceptible to infection. If very large areas of skin are destroyed, as in an extensive burn, fluid and electrolyte balance is disturbed. Protein and body heat are lost from burned areas. Skin diseases are common; they are often difficult to diagnose and cure and tend to recur. The physical effects of skin diseases are not often serious. However, when the disorder renders the patient unattractive, there is a psychological impact that threatens self-image and damages self-esteem. The skin also reflects systemic diseases.

Disorders of the Integumentary System

Causes

More than 3000 disorders of the skin have been officially named, and many more are not included in any official nomenclature. Most of the recognized and named skin disorders arise from some pathology in the skin itself. The remainder are manifestations of systemic disease. Skin disorders may occur from immunologic and inflammatory disorders, proliferative and neoplastic disorders, metabolic and endocrine disorders, and nutritional problems. Physical, chemical, and microbiologic factors also can damage the skin.

Many patients with dermatologic disease are not hospitalized and are seen only in providers' offices and outpatient clinics. Others do not seek medical attention but treat their skin disorder themselves with home remedies and over-the-counter drugs. In some cases self-care measures are successful, but they also have the potential for aggravating the condition or only temporarily relieving more severe symptoms. This can lead to delay in treatment and allows the disease to progress to a chronic and sometimes untreatable state.

Prevention

Hygiene.

The ritual of the daily bath is almost an obsession with the average American. Traditionally, plenty of soap, hot water, and friction were considered a necessity for cleanliness; however, many facilities have adopted disposable cleansing cloths to replace the individual bathing basin. In a recent study, [Marshall and colleagues \(2012\)](#) cultured bath and kitchen basins and cleaning sponges and found *Staphylococcus aureus*, *Klebsiella* spp., *Escherichia coli*, and *Pseudomonas aeruginosa* flourishing. Soap and water continues to have a place in hygiene, but beyond infection control, astute nurses assess for and consider skin type. Blondes and redheads with a fair complexion usually have very delicate skin that requires special care to prevent drying and irritation. If the skin appears dry and scaly, frequent bathing with soap and hot water only aggravates the condition. Oils and creams are available that cleanse the skin quite effectively and help replace the natural oils at the same time. On the other hand, people with dark hair usually have skin that is oilier and less susceptible to excessive drying and irritation. People with oily skin will need to clean the skin frequently with a liberal amount of soap and water and will need to apply fewer or no additional oils to the skin.

Think Critically

You assist an older adult with a bath and notice that she has very dry skin. What interventions would you use?

Clinical Cues

Remember to dry areas where two skin surfaces touch, such as the axilla and under the breasts.

Diet.

Even borderline deficiencies of vitamins and minerals will cause the skin to take on a sallow and

dull appearance. Severe nutritional deficiencies lead to skin breakdown and the development of sores and ulcers. Dehydration causes loss of skin turgor and predisposes to pressure ulcers. People can be so concerned about their physical appearance that they refuse to eat properly for fear of gaining weight; however a well-balanced diet will enhance appearance.

Age.

Young people are not the only ones who should be concerned with the care of their skin. As we grow older, our skin undergoes certain changes that easily lead to irritation and breakdown if proper care is not given. The oil and sweat glands become less active, and the skin has a tendency to become dry and scaly. It also loses some of its tone, becoming less elastic and more fragile. Frequent cleansing of the skin becomes unnecessary as the skin ages, and alcohol and other drying agents must be used sparingly, if at all. Assist older patients to establish a regular routine of massaging oil, cream, or oily lotion into the skin.

Older Adult Care Points

Older adults who have dry skin do not need a full bath every day; cleansing of the axillae and genital-rectal area between bathing days should be sufficient. Older adults should use a mild lotion-based soap or body wash for bathing. After showering or bathing, a lotion or cream that helps seal in moisture should be applied while the skin is still damp. Moisturizing lotion or cream should be reapplied at bedtime.

Environment.
